The amputation should be performed proximal to the lower third of the tibia, since the preponderance of tendinous structures distal to this area predisposes to poor circulation and an unstable, painful stump (Fig. 20-49). A long posterior flap technique is normally used. The skin and soft tissue are cut perpendicular to the axis of the leg over the anterior 180 degrees of the calf circumference. The incision is extended distally to create a long posterior flap of suitable length to close the defect. The posterior incision is beveled to reduce the bulk of muscle in order to provide a better stump. The soleus muscle should be completely excised, because no contribution to the blood supply of the skin passes through it. Equally short anterior and posterior flaps may be made if there is compromised circulation or if recent distal scars preclude the usual incisions. The tibia is usually transected 5 cm above the distal level of the skin flap, and the fibula is transected slightly above the tibial level. The tibia may be beveled approximately 45 degrees to prevent a sharp edge of bone from eroding into the thin anterior skin flap. The nerves are pulled gently down, transected, and then allowed to retract, and the vessels are ligated above the level of the end of the tibia. The fascia and skin are closed with interrupted absorbable sutures. If desired, closed suction drainage may be used, removing the drain on the second postoperative day.

An *IPOP* may be used, in which case the patient is encouraged to stand and bear weight on the first postoperative day, with activity rapidly increased thereafter. A permanent prosthesis usually can be applied at the time of the second cast change, i.e., at 3 weeks, when the stump is sufficiently mature (Fig. 20-50). In a series of cases, the use of IPOPs at this level has shown promise in reducing the incidence of phantom limb symptoms.

Above-Knee (AK) Amputation

Indications for an AK amputation include extension of skin gangrene above a level that would permit *BK* amputation and rigor of the calf muscles. Peripheral gangrene coupled with contracture of the knee or hip constitutes a relative indication, since there is no advantage to a BK amputation.

The AK amputation has the highest healing rates, 90 percent or more, in patients with peripheral vascular disease. The rate of reamputation is lower, which is an important consideration in elderly and debilitated patients. The higher mortality rate of AK amputations is related to the fact that they are more frequently performed in elderly and debilitated patients.

Anterior and posterior skin flaps are fashioned of equal length in a “fish- mouth” configuration (Fig. 20-51). The vascular bundles are divided individually at the level of proposed transection of the femur. Gentle traction is applied to the sciatic nerve before it is transected so that it retracts proximally to the stump of the femur. The periosteum of the femur is scraped with a periosteal elevator, and the femur is transected at a point well proximal to the soft-tissue resection. The edge of the bone is beveled and rasped to provide a smooth radius. Rehabilitation toward ambulation usually requires more time than with BK amputations.

Hip Disarticulation

The indications for hip disarticulation usually include extensive lower- extremity ischemia with proximal gangrenous change, tumors, and extensive traumatic injuries. Flaps are fashioned so that they will come together anteriorly, and the posterior flap is constructed such that it forms a unit of skin, fascia, and muscle to swing forward so that the patient may

sit comfortably in the socket of the prosthesis. The femoral vessels are ligated anteriorly, and, after the posterior dissection is completed, the femur is disarticulated. The sciatic nerve is cut high and tied to prevent bleeding from vasa nervorum. The undersurface of the gluteal muscle is tapered to facilitate approximation of the tissue to the lower abdominal wall. When hip disarticulation is performed in patients with peripheral vascular disease, the results are dismal. These patients typically have had a succession of failed lower amputations, often complicated by peripheral bypass graft sepsis.

Upper-Extremity Amputations

Upper-extremity amputations usually are performed for trauma. Malignant disease is the second most common indication. Peripheral vascular disease, particularly thromboangiitis obliterans, is a rare indication. In all circumstances, the treatment is directed at conserving as much viable tissue as possible and, with more distal amputations, maintaining the function of the hand as a grasping organ (Fig. 20-52). The latter requires preservation of intrinsic muscle-tendon systems of the hand and the longer and more powerful flexors and extensors originating in the arm. The technique used for amputations in the upper extremity is directed at producing minimal scar tissue, and the procedure is planned so that the scar is in an area as far removed as possible from bones, tendons, nerves, and points of external contact. Above the level of the metacarpals, opposing tendons should be fixed to one another in order to preserve muscle length and tone.

Digital Amputation

When part or all of the distal phalanx requires amputation, an attempt should be made to create a longer volar flap and a shorter dorsal flap, so that the scar may be positioned dorsad, away from pressure. Neither bone nor viable soft tissue should be sacrificed to produce an ideal flap. If the amputation removes less than one-half of the nail, it is preferable to retain the nail bed, but if more than one-half of the nail is removed, the entire root should be excised. When it is necessary to disarticulate at the distal interphalangeal joint, the cartilage should be removed from the head of the middle phalanx, and the flexor digitorum profundus tendon should be withdrawn, transected, and allowed to retract.

Amputations of fingers distal to the *PIP* joint should leave pinching and finer movements. Amputations through the middle phalanx result in little alteration of extension when only the more distal portion of the dorsal expansion of the extensor digitorum communis tendon is cut. By contrast, the flexor digitorum superficialis tendon has a long insertion on either side of the phalanx, and if a significant portion of this insertion cannot be left intact, disarticulation may be necessary. Whenever possible, amputation through the proximal phalanx is preferable to disarticulation at the metacarpophalangeal joint, since the stump, however short, has function. In the case of the index finger, a stump less of than one and a half phalanges usually gets in the way, and amputation through the metacarpal should be considered. Stumps that stick out when a fist is made should be avoided. The fifth ray is important for gripping, and even a short but mobile stump is advantageous.

When one or more fingers must be removed in entirety, attention should be directed to the hand as a working unit. When the long and ring fingers are both removed, the adjoining fingers may continue to function perfectly, or they may deviate toward each other, and deviation weakens flexion. If only the long or ring finger is removed, it is best also to remove the head of its metacarpal to allow the adjoining metacarpals to approximate each other. This tends to prevent adjoining fingers from rotating and crossing toward each other. As a secondary procedure, the index (in the case of amputation of the long finger) or the little finger (in the case of amputation of the ring finger) may be moved over by resecting the metacarpal of the missing finger through the proximal third of its shaft and shifting the adjoining finger onto the stump.

When the middle finger and either the index or little finger are removed together, the heads of the metacarpals should be cut in an oblique fashion to produce a smooth contour. When the index finger has been disarticulated, the metacarpal should be partially excised to improve the final appearance of the hand and to prevent its interference with function. In the case of the little finger, it is preferable not to resect the whole metacarpal, because the extensor and flexor carpi ulnaris tendons are attached to the base.

The thumb is the most important of the digits, and every bit possible should be saved, since even the smallest stump is preferable to a prosthesis. When only the thumb and small finger remain, a rotation osteotomy of the metacarpal of the thumb can be performed to permit approximation and grasping.

Forearm Amputation

To avoid excessive scarring and immobility of skin, skin flaps should not be dissected extensively from the fascia. The wound should run across, and not between the ends of the radius and ulna. The long flexor and extensor muscles and tendons are dissected and tapered so that they adhere to underlying tissue. After the bones have been transected, a margin of periosteum should be removed to prevent spur formation, and the fascia should be closed over the end so that muscle length is maintained.

With longer stumps, the actions of pronation and supination should be preserved, and the tendinous muscles and bones are therefore treated atraumatically to prevent fibrosis. If only a short stump can be achieved, this is superior to an above-elbow amputation. The formation of a functioning stump through the upper forearm can be successful if there is a short segment of radius or ulna that might be preserved distal to the tuberosity.

Upper Arm Amputation

Every attempt should be made to preserve as long a stump as possible, because the longer the stump, the greater the applicability of subsequent kineplastic procedures for functional prosthesis. If a high amputation is necessary, it is preferable to preserve the head of the humerus; this maintains the width of the shoulders and serves as a support for a prosthesis.

After anterior and posterior flaps are developed, the muscles are transected so that there is sufficient length of biceps and brachialis tendons and triceps muscle for these tendons to be joined over the end of the bone to avoid retraction.

When the stump is mature it can be fitted with a prosthesis with a terminal device operated by a shoulder cable and with an elbow that can be fixed at varying degrees of flexion. The type of elbow joint used depends on the type of function required by the patient. The most functional terminal devices are hooks that may be voluntarily opened. In the case of the adult unilateral amputee, the prosthesis usually functions only as an aid for the contralateral hand.

Extremity Replantation

The first report on the reattachment of a fully amputated hand, with return of useful function, was in 1963. In the ensuing years, refinements in microvascular techniques resulted in an increasing success rate. A summary of the experiences from China, Switzerland, and the United States in 1981 noted that one-third of the patients had excellent functional recovery, one-third had good results, and one-third had fair-to-poor results.

No shoulder replantation achieved excellent or good functional results. Good function resulted with replantation above the elbow in 0 to 40 percent of cases. Replantation at the proximal forearm was associated with excellent to good functional results in 0 to 70 percent. Much better results have been reported when replantation was carried out at the distal forearm, with success rates ranging from 50 to 83 percent. At the wrist, success rates are around 80 percent; at the palm, 25 to 70 percent; at the thumb, 32 to 90 percent; the fingers proximal to the *PIP* joint, about 70 percent; and distal to the PIP joint, almost 100 percent.

Guillotine injuries are associated with a higher degree of success after replantation than compression or crush injuries, with the worst results occurring in avulsion injuries. Reasonable success rates are achieved if the duration of anoxia is less than 20 h; the success rate drops sharply when anoxic periods are longer than 20 h.

The essential structures of the dismembered extremity must be intact and the severed limb reasonably well preserved if replantation is attempted. Following thorough debridement, the bones are repaired before the circulation is reestablished. A main vein is anastomosed before the arterial repair. The muscles, tendon, and nerves are then repaired and skin coverage is provided. Decompressive fasciotomy is frequently indicated.

CHAPTER 21 - Venous and Lymphatic Disease

Richard M. Green
Kenneth Ouriel

VENOUS DISEASE

Venous Anatomy and Physiology

Lower extremity veins can be divided into three types: superficial, deep, and perforating veins (Fig. 21-1). The systemic veins contain approximately two-thirds of the circulating blood volume under relatively low pressure, and venous flow from the lower extremities must overcome gravity and intraabdominal pressure to return blood to the right ventricle. The initial force produced by the left ventricle is reduced through the capillary bed to a pressure of about 15 mmHg in the venules. The calf muscles provide an additional pump function as they compress deep veins within an unyielding fascial compartment. Proximal flow is assured by the presence of the delicate but strong venous valves, which prevent reflux.

The superficial venous system is composed of the greater and lesser saphenous veins (GSV and LSV) and lies above the investing fascia. The GSV begins in the dorsum of the foot and ascends cephalad anterior to the medial malleolus. It runs along the medial aspect of the leg, crossing the knee joint 8 to 10 cm dorsal to the medial edge of the patella. The saphenous nerve accompanies the vein from the foot to the upper thigh, where it penetrates the fascia and enters the subsartorial canal along the superficial femoral artery. The GSV pierces Scarpa's fascia in the midthigh and enters the fossa ovalis in the groin, 4 cm lateral and inferior to the pubic tubercle. The LSV begins laterally from the dorsal venous arch, courses posterior to the lateral malleolus, and enters the popliteal vein between the medial and lateral heads of the gastrocnemius muscle. The sural nerve lies lateral to the GSV.

The deep veins are primarily responsible for lower extremity venous return. These veins follow the course of the major arteries and share their names. In the lower leg the veins are paired and join at the knee to form the popliteal vein, which continues through the adductor hiatus to become the superficial femoral vein. The latter is joined by the deep femoral vein in the upper thigh to become the common femoral vein, which becomes the external iliac vein as it enters the pelvis beneath the inguinal ligament. Numbers of valves increase with distance from the heart, though the vena cava and common iliac veins are valveless. Each valve is based within a dilated sinus of the vein, which keeps the valve cusps away from the walls and promotes rapid closure when flow ceases. Valves are the focal point of most of the pathology of venous thrombosis because their sinuses are where the initial thrombus forms, and the loss of valvular function after recanalization of a thrombus produces venous insufficiency (Fig. 21-2). Autopsies suggest that it is more common for thrombi to originate in the veins of the soleus and then propagate proximally, but there is evidence that primary thrombosis of the femoral and iliac venous tributaries occurs as well. There also are a number of venous sinuses within the substance of the soleus muscle, which empty into the posterior tibial vein, and in the gastrocnemius muscle, which empty into the popliteal vein. These sinuses are critical to the function of the calf muscle pump.

The perforating or communicating veins connect the superficial venous system with the deep and direct flow internally from the superficial veins in all areas of the lower extremity except the foot, where the opposite occurs. The perforating veins are so named because they penetrate the fascia of the lower leg to connect the superficial and deep systems. The perforators adjacent to the medial malleolus often are responsible for the development of stasis ulcers at that level when they become incompetent. Boyd's perforator connects the GSV to the deep veins 10 cm below the knee. Cockett's perforators connect the posterior arch vein with the posterior tibial vein and often become varicose. The Hunterian perforator connects the GSV to the superficial femoral vein; its incompetence accounts for many thigh varicosities when the saphenofemoral junction is competent.

When a person is in the supine position, lower extremity venous return is primarily dependent on the respiratory cycle. Intraabdominal pressure increases as the diaphragm descends during inspiration and the external pressure on the external iliac veins decreases venous return. Valve closure prevents significant reflux during inspiration. The converse occurs during expiration. Venous return is increased as intraabdominal pressure is decreased with upward movement of the diaphragm. When a person is in the upright position, venous flow is dependent on the contractile force of the heart, static filling pressure, and gravity. The expiratory enhancement of venous flow is insufficient, and the calf muscle pump is necessary to overcome the hydrostatic forces. A single contraction of the calf muscles can empty 60 percent of the blood pooled in the tibial veins and muscular sinuses. The standing venous pressure in the foot veins is 80 to 90 mmHg while standing and falls to 40 mmHg during ambulation (see Fig. 21-22).

Deep Vein Thrombosis

Etiology of Deep Vein Thrombosis

Three factors are primarily responsible for the development of a thrombus within a vein: abnormalities of blood flow, abnormalities of blood, and injury to the vessel wall. The occurrence of this process in a nontraumatized vein was recognized by Rudolf Virchow, who introduced the term thrombosis in 1856.

Stasis

Although stasis alone is not sufficient, it is the most important factor in the development of *deep vein thrombosis (DVT)*. The main event in the formation of a venous thrombus is the generation of thrombin in areas of stasis. This leads to platelet aggregation and fibrin formation. When contrast medium is injected into the veins of the lower extremities of a bedridden patient, it may remain in venous valve sinuses for as long as an hour, confirming the pooling effect in the soleal veins. Primary and secondary vortices are produced beyond the valve cusps, the favored location for the formation of a thrombus, and trap red cells to form the early nidus for thrombus formation. Early thrombi attach to normal endothelium and consist of loosely packed red cells within a fibrin network accompanied by a variable number of leukocytes. The propagation of the thrombus depends on the relative balance between activated coagulation and fibrinolysis. More commonly, in about 60 percent of patients the thrombus propagates without interrupting flow and develops a long floating "tail" that is more susceptible to breaking loose from its tenuous anchor within the valvular sinus. It is the latter sequence of events that is the most dangerous aspect of the disorder, because major pulmonary embolism can and does occur without premonitory signs or symptoms at its point of origin. This process can begin under general anesthesia in the operating room but usually requires other contributing factors such as shock, infection, trauma, or congestive heart failure. Aging, obesity, pregnancy, and malignant disease also are important risk factors.

Endothelial Damage

The role of endothelial injury is questionable. It appears that it is neither a necessary nor a sufficient condition for thrombosis. With the exceptions of hip arthroplasty and central venous catheters, there is little evidence that gross or microscopic venous injury has a role in venous thrombogenesis. Routine histologic examination of veins containing thrombus usually fails to show an inflammatory response consistent with vessel wall injury. It is possible that hypoxic or biochemical injury has a role, but definitive evidence is lacking.

Hypercoagulability

Abnormalities of the blood include aberrations of the clotting and fibrinolytic systems. Stasis and injury alone are not sufficient to cause thrombosis experimentally in the absence of low levels of activated coagulation factors. Patients who present at an early age with spontaneous venous thrombosis, who have a strong family history of *DVT*, or who develop recurrent venous thromboembolisms are usually considered "prothrombotic" or "hypercoagulable." These conditions are listed in Table 21-1.

Activated protein C resistance (APC-R) is a common hereditary condition that results in decreased efficacy of the natural anticoagulant protein C. It is transmitted as an autosomal dominant trait, and 90 percent of the cases are because of a mutation in factor V (factor V Leiden mutation). The syndrome was initially described in young patients with venous thrombosis but may also have a role in hypercoagulability after arterial reconstruction.

Antithrombin III deficiency often is associated with unexplained arterial thrombosis. It is found more often in patients with serum albumin levels less than 3.0 g/dL. Patients with antithrombin III deficiency present as a resistance to heparin. Typically, heparin is given and no increase in the *partial thromboplastin time (PTT)* is noted. In this setting, immediate anticoagulation can be achieved by providing substrate (fresh frozen plasma) in addition to heparin and then conversion to coumarin derivatives.

The antiphospholipid syndrome (APS) is another hypercoagulable state with recurrent thrombotic events and antibodies directed against phospholipids. There are primary (no associated autoimmune disease) and secondary forms. APS occurs in younger patients rather than in atherosclerotic populations, and very few of these patients smoke. Antiphospholipid antibodies, which include anticardiolipin, are being recognized with increasing frequency in association with a variety of thrombotic disorders. Their association with unexplained juvenile *DVT* indicates that screening for antiphospholipid antibodies should be included in the workup of any unexplained thrombosis. One-third of patients with systemic lupus erythematosus have antiphospholipid antibodies. Women with APS often have a history of spontaneous abortions. The diagnosis is suggested in a patient with an appropriate history and a spurious elevation of the *PTT*. Patients on estrogen therapy for postmenopausal replacement, birth control, or chemotherapy are at increased risk for venous thrombosis.

The association between venous thrombosis and cancer was first suggested by Armand Trousseau in 1856 and often has been confirmed in postmortem studies. In a series reported by Aderka and associates, 34 percent of otherwise healthy patients with idiopathic *DVT* were found to have malignant disease diagnosed an average of 24 months later. Increased likelihood of cancer in these patients was associated with age over 65 years, anemia, and eosinophilia. The earliest-onset malignancies were found within 1 year and usually occurred in the pelvic organs and breast.

Patients presenting with a thrombotic episode at a young age or those with previous events should be screened for hypercoagulability. Routine screening should include measurements of prothrombin time, activated partial thromboplastin time, hematocrit level, white blood cell count, sedimentation rate, and platelet count. Measurements of homocysteine levels, antiphospholipid antibodies, protein C and protein S, antithrombin III, activated protein C resistance, platelet aggregation, and mutant factor V should be done in very high-risk patients. Screening is difficult once anticoagulation has begun. For instance, coumarin derivatives interfere with measurements of proteins C and S and the functional assay for activated protein C resistance, heparin reduces circulating levels of antithrombin III, and antiplatelet drugs may produce false negatives when testing for heparin-induced thrombocytopenia.

Sequence of Pathology

The venous lumen is most often recanalized after an episode of *DVT*. This process is a result of spontaneous lysis and involves a complex series of cellular and humoral processes. Organization of the thrombus begins at the attachment zone as endothelial cells activate thrombus-bound plasminogen. This results in enlarging pockets within the thrombus and eventual fragmentation. The clot itself undergoes softening and contraction during this process, with the potential to restore the venous lumen. Serial studies using duplex ultrasonography show that the process of recanalization begins by day 7 in roughly 50 percent of thromboses and is uniformly observed by 90 days.

Recurrent thrombotic events compete with recanalization early in the course of a *DVT*. This encompasses those patients with propagation of clot in previously uninvolved areas, thromboses in another extremity, and rethrombosis of a partially recanalized segment. The incidence of these recurrences is reduced tenfold when patients are given adequate anticoagulation therapy for a 3-month period.

Clinical Manifestations

The site of venous obstruction determines the level at which swelling is observed clinically (Fig. 21-3). Calf vein thrombosis is localized to one or more of the three major named veins below the knee. Calf tenderness is frequently present, but because the thrombi are rarely completely obstructive and the veins are paired, swelling is not a universal finding. Femoral vein thrombosis usually is associated with swelling of the foot and calf. Iliofemoral venous thrombosis represents the most extensive form of DVT and usually is associated with tenderness in the groin and swelling of the entire leg. Major venous thrombosis involving the deep venous system of the thigh and pelvis produces a characteristic presentation of pain and extensive pitting edema. The extremity may have bluish discoloration (phlegmasia cerulea dolens) or blanching (phlegmasia alba dolens, or “milk leg”). The latter usually occurs in association with pregnancy. Other mechanical factors that can affect the left iliac vein include compression from the right iliac artery, an overdistended bladder, and congenital webs within the vein. These factors are responsible for the observed 4:1 preponderance of left versus right iliac vein involvement.

Phlegmasia cerulea dolens occurs when the venous thrombosis progresses and impedes most of the venous return from the extremity. There is danger of limb loss from cessation of arterial flow. Fortunately, this occurrence is rare. Loss of sensory and motor function and venous gangrene are likely unless an aggressive approach is implemented to remove the thrombus and restore blood flow. This condition almost always occurs with advanced malignant disease.

Diagnosis

Only 40 percent of patients with venous thrombosis have any clinical signs of the disorder. Homans's test is performed by dorsiflexing the foot. It is considered positive for DVT if the patient complains of calf pain. False-positive clinical signs occur in more than 30 percent of patients studied. Venous duplex ultrasonography has relegated other noninvasive tests, such as radioactive-labeled fibrinogen scans and all types of plethysmography, to historical interest. In some centers duplex scans have replaced contrast venography as the best diagnostic test for DVT. Accuracy rates above 90 percent have been consistently reported for venous duplex exams. Indications for duplex venous scans include patients with pulmonary emboli, patients with extremity pain or swelling, and patients at increased risk for developing a DVT. The latter group includes those with trauma, joint replacement, other major surgeries, prolonged immobilization, and known hypercoagulability states.

There are three essential phases to the venous duplex scan: (1) thrombus visualization, (2) vein compressibility, and (3) venous flow analysis. Accuracy is dependent on the examiner's skill. Thrombus may be difficult to visualize in its acute form, and the addition of color flow imaging facilitates the identification of nonoccluding clots. Thrombus echogenicity increases with age of clot. Venous compressibility is determined by placing the probe directly over the vein and applying gentle pressure while observing under B-mode imaging (Fig. 21-4). Veins filled with thrombus do not collapse with this maneuver. Venous flow assessment evaluates the respiratory phasicity and response to external extremity compression. Persistent lack of a flow signal indicates total obstruction. A negative scan performed by a well-trained ultrasonographer is sufficient to rule out a DVT of the lower extremity.

The role of venography has been diminished by the advances in ultrasound technology. Nonetheless, the injection of contrast material for direct visualization of the venous system of the extremity remains the most accurate method of confirming the diagnosis of venous thrombosis and the extent of involvement. The main indication for its use in the diagnosis of an acute DVT is a nondefinitive duplex scan. Injection usually is made into the foot while the superficial veins are occluded by tourniquet, and a supplemental injection into the femoral veins may be required to visualize the iliofemoral system (Fig. 21-5). Potential false-positive examinations may result from external compression of a vein or washout of the contrast material from venous flow from collateral veins.

Prophylaxis

Because the first manifestation of a DVT may be a fatal pulmonary embolus, some form of prophylaxis is indicated in high-risk patients. Patients older than 70 years of age, those with previous thromboembolism, malignant disease, paralysis, multiple trauma, or lower extremity joint surgical procedures have a very high risk for DVT. Prophylactic measures are directed toward altering blood coagulability or eliminating or reducing venous stasis.

Efforts to reduce stasis include elastic compression stockings, intermittent external leg compression, leg elevation, and early ambulation. Intermittent pneumatic leg compression is the most effective measure. It reduces stasis and increases fibrinolytic activity with virtually no side effects. The pneumatic boots can be applied in the operating room to minimize the risk of venous thrombosis beginning under general anesthesia and are of proven efficacy in patients undergoing total knee replacement, radical prostatectomy, or operations where adjuvant anticoagulation therapy is contraindicated.

Pharmacologic prophylaxis includes low-dosage unfractionated heparin (UFH), adjusted-dose heparin, low-molecular-weight heparin (LMWH), warfarin (international normalized ratio 2.0–3.0), and dextran 70. Prophylactic low-dosage subcutaneous UFH that does not alter the clotting profile has been extensively tested and is safe and effective in moderate-risk patients. A 5000-unit dose is given subcutaneously 2 h preoperatively and then every 12 h postoperatively for 6 days. This provides protection for most high-risk groups with the exception of those undergoing orthopaedic or urologic procedures. Higher-risk patients require adjusted-dose UFH with the activated partial thromboplastin time (APTT) held in the upper normal range. Both regimens are associated with an increased incidence of wound hematomas. The studies comparing the prophylactic use of LMWH and UFH have concluded that there is little difference between the two drugs. LMWH is ten times more costly than UFH, however.

There are good data to support the use of preoperative oral anticoagulant therapy with coumarin derivatives in high-risk patients. When given the night before operation, warfarin anticoagulation is achieved within 3 to 4 days. The “two-step” or minidose warfarin regimen is designed to circumvent the delay in anticoagulation. Warfarin is started at a dose of 1 mg 14 days before operation to prolong the prothrombin time (PT) by 2 or 3 seconds. This procedure increases the risk of hemorrhage, and because of the added difficulties of laboratory control of prothrombin time, there has not been widespread acceptance of this approach. A national task force on prophylaxis for patients undergoing hip surgery recommends warfarin or adjusted-dose heparin to prolong the APTT to the upper normal range. The administration of dextran, which produces a variety of effects on platelets and clotting factors, has been demonstrated to reduce the incidence of detectable thrombi. It too can produce hemorrhagic problems, allergic reactions and, in older patients, congestive heart failure. Recommendations for prophylaxis are listed in Table 21-2.

Medical Treatment

The approach to management of the patient with DVT is based on three objectives: minimizing the risk of pulmonary embolism, limiting further thrombosis, and facilitating resolution of existing thrombi to avoid the postthrombotic syndrome. The traditional treatment places the patient at bed rest with the foot of the bed elevated 8 to 10 inches. Intravenous UFH is administered, and oral warfarin is started when the patient's APTT is in a satisfactory range. As the pain, swelling, and tenderness resolve over a 5 to 7 day period, ambulation is permitted with elastic stocking support. Standing still and sitting should be prohibited to avoid increased venous pressure and stasis. Patients with large thrombus loads are candidates for fibrinolytic agents in an attempt to preserve venous valvular competence. The practice of mandatory bed rest and hospitalization has been challenged by the encouraging results of outpatient treatment of DVT with LMWH.

Anticoagulation

The foundation of therapy for DVT is adequate anticoagulation, initially with heparin and then with coumarin derivatives for prolonged protection against recurrent thrombosis. Unless there are specific contraindications, heparin should be administered in an initial dose of 100 to 150 units/kg intravenously. Heparin is an acid mucopolysaccharide that neutralizes thrombin, inhibits thromboplastin, and reduces the platelet release reaction. It may be administered by continuous or intermittent intravenous doses regulated by whole blood clotting time or APTT. Recurrent episodes of thromboembolism are 15 times more common in patients with inadequate anticoagulation treatment within the first 24 hours. Bleeding complications can be minimized by doses of heparin that prolong the laboratory clotting determinations by about twice the normal time. Continuous intravenous infusion regulated by an infusion pump minimizes the total dose required for control and is associated with a lower incidence of complications and no loss of effectiveness.

Thrombocytopenia is the most common complication of heparin therapy and is estimated to occur in 1 to 5 percent of patients receiving the drug. Unlike other drug-induced thrombocytopenias, heparin-induced thrombocytopenia often is associated with thromboembolic complications from antibody-mediated platelet activation. The paradox of thrombosis occurring in a patient receiving heparin was first described in 1958 by Weismann and Tobin. Towne and associates described the “white clot” syndrome, a peripheral vascular complication of heparin therapy in 1979. Heparin-induced thrombocytopenia (HIT) represents the prodrome to the thrombotic syndrome (HITTS) that occurs in 1 in 2000 patients who receive more than 20,000 IU of UFH per day for more than 5 days, 1 in 5 patients with HIT, and 1 in 3 patients who have heparin-dependent antiplatelet antibodies. Patients who develop HITTS have a mortality rate ranging from 25 to 37 percent resulting from diffuse uncontrolled clotting with limb ischemia and organ infarction. There are no known factors that predict risk. Development of thrombocytopenia from heparin is independent of sex, age, blood type, amount of heparin given, type of heparin, and route of administration. HIT has been documented after minimal heparin dosages such as those received with I.V. flushes and heparin-coated indwelling catheters.

Two forms of HIT exist. Type I, the most frequent, is mild (platelet counts $>100,000/\text{mm}^3$), reverses despite continuation of heparin, is due to a direct pro-aggregant effect of heparin, and is not associated with thromboses. In contrast, Type II HIT is severe (platelet counts $<100,000/\text{mm}^3$), resulting from antibodies binding to a platelet-heparin complex that leads to platelet activation and aggregation and is often associated with arterial or venous thromboses. The thrombocytopenia typically occurs after 5 days of heparin therapy but can occur earlier in patients who have a prior exposure to heparin. Type II HIT requires the immediate withdrawal of all heparin.

The most important advantage of the LMWHs over UFH is their superior pharmacokinetic properties, allowing their use without laboratory monitoring. LMWH preparations have been compared with UFH for the acute treatment of DVT in 13 well-designed trials. Pooled results from these studies show that LMWHs administered subcutaneously are as effective and safe as UFH but have the advantage of the potential for home treatment and do not require laboratory monitoring. These advantages may offset the increased cost of LMWH.

Oral administration of anticoagulants is begun shortly after initiation of heparin therapy. There is a risk in giving coumarin derivatives to a patient who is not already anticoagulated with heparin. The coumarin derivatives block the synthesis of the vitamin K-dependent clotting factors and inhibit vitamin K carboxylation of proteins C and S. These latter proteins are naturally occurring anticoagulants that function by inhibiting activated factors V and VIII. A vitamin K antagonist potentially can create a hypercoagulable state before achieving its anticoagulant effect because the half-lives of proteins C and S are shorter than the half-lives of the other clotting factors. Heparin should be continued for the 4 to 5 days required to achieve full anticoagulation with coumarin derivatives.

Data from prospective studies indicate that the level of anticoagulation with coumarin derivatives are effective at an international normalized ratio of 2.0 to 3.0. Higher levels are not more effective and are associated with a higher incidence of bleeding complications. Administration of fresh frozen plasma usually can normalize the prothrombin time and control hemorrhagic complications. Coumarin derivatives cross the placenta and should not be used during pregnancy. After an episode of acute DVT, anticoagulation therapy should be maintained for a minimum of 3 months; some investigators favor 6 months for treatment of thrombi in the larger veins. Many drugs interact with coumarin derivatives (e.g., barbiturates), and it is essential that a routine for regular monitoring of prothrombin time be established after the patient leaves the hospital.

Thrombolysis

Anticoagulant therapy is designed to prevent recurrent thromboembolism. Ideally, a treatment would be available with the potential to eliminate the thrombus and maintain valvular function. A number of trials have been performed comparing thrombolysis with standard anticoagulant therapy. Complete clearing of thrombus was noted in 45 percent of patients treated with thrombolytic agents, compared to 4 percent of those treated with heparin. This seems to translate into a long-term improvement in venous function. Popliteal valve incompetence was documented in 77 percent of those patients who did not have clearing, compared to a 9 percent incidence in those with complete lysis. These agents have no advantage over heparin in the treatment of recurrent venous thrombosis or thrombosis that has existed for more than 72 h, and they are contraindicated in postoperative or posttraumatic patients.

There are more bleeding complications with thrombolytic treatment, and this approach is reserved for those patients with clot in the common femoral and iliac venous systems. In a prospective study of 29 patients with thrombosis involving the popliteal veins, with or without involvement of calf veins, Kakkar compared hemodynamic and clinical results in patients receiving 5-day treatment with heparin or streptokinase, followed by a 6-month course of a coumarin derivative. Overall, at 2-year follow-up they found more than half of the limbs to have evidence of the postthrombotic syndrome. Clinically, 14 percent of patients had no symptoms, 20 percent had severe symptoms, and the remainder demonstrated mild to moderate changes. No difference was seen between patients receiving heparin or streptokinase. These studies were done with systemic infusion of lytic agents. Studies evaluating the use of catheter-directed thrombolysis have had encouraging results in selected areas and are discussed in detail in the section Subclavian Vein Thrombosis.

Surgical Approaches

Operative Thrombectomy

There are very few indications for operative thrombectomy because catheter-directed thrombolysis is so effective in treating iliofemoral venous thrombosis. The procedure is reserved for limb salvage in the presence of phlegmasia cerulea dolens and impending venous gangrene and in patients with a contraindication to thrombolysis. The direct surgical approach to remove thrombi from the deep veins of the leg uses the common femoral vein and is facilitated by the use of a Fogarty venous balloon catheter and an elastic wrap for milking the extremity (Fig. 21-6). Results are improved when the extent of thrombus is documented preoperatively, when completion phlebography is performed to assure complete clot removal, when a small arteriovenous fistula is constructed to maintain high blood flows in the iliac vein, and when anticoagulation therapy is given over prolonged periods. Early results in 57 patients treated in this fashion reported by Einarsson and associates showed patency of the iliofemoral segment by venography in 61 percent, and 75 percent had a good clinical result. Measurement by venous function, however, using plethysmography and foot volumetry, showed normal results in only 29 percent.

The use of arteriovenous fistulas after iliofemoral thrombectomy or reconstruction of the venous system is controversial. Most of the experience has been accumulated in Europe, where it is believed to reduce the incidence of early rethrombosis. The two most commonly used sites are the femoral triangle and the ankle. After surgery on the iliofemoral system, an H-shaped fistula can be established easily by anastomosing a branch of the saphenous vein end-to-side to the proximal portion of the superficial femoral artery. At the ankle, the posterior tibial artery may be anastomosed to the posterior tibial vein or the greater saphenous vein. Two problems have led to the reluctance of some surgeons to adopt this procedure: the fear of damaging functioning valves distal to the fistula and the requirement for a second operation to close the fistula. Fistulas usually are closed 3 to 4 months postoperatively, and problems with incompetent valves distal to the fistula have not been reported. Two steps during primary venous reconstruction simplify operative closure of the fistula later. The fistula is made distal to the venous reconstruction, avoiding damage to this area at reoperation, and a ligature is wrapped around the fistula and left in the subcutaneous tissue, where it can be found under local anesthesia. Obliteration of the fistula percutaneously by a detachable balloon has been described.

Vena Caval Interruption

Vena caval interruption also is indicated when there is a contraindication to or failure of anticoagulation therapy (Table 21-3). Early operations in which one or both common femoral veins were ligated were associated with high recurrence rates and a high incidence of sequelae because of stasis in the lower extremity. Control of the inferior vena cava for ligation required a laparotomy and added the adverse effect of a sudden reduction in cardiac output under general anesthesia. This effect, coupled with stasis sequelae and recurrent embolism through dilated collateral veins, led to efforts to compartmentalize the vena cava by means of sutures, staples, and external clips in order to provide filtration without occlusion (Fig. 21-7).

Because these procedures required general anesthesia and laparotomy, the next logical step was to devise a transvenous approach that could be performed under local anesthesia. The Mobin-Uddin "umbrella" unit was inserted from the jugular vein and positioned under fluoroscopic control below the renal veins. The incidence of vena cava occlusion was 70 percent, and fatal embolism sporadically occurred with device migration.

The Greenfield cone-shaped filter was developed to maintain patency after trapping emboli. This is possible because of the geometry of the cone, which collects emboli in its apex and retains perimeter flow. Preservation of flow avoids stasis and facilitates lysis of the embolus (Fig. 21-8). It can be inserted percutaneously from either the jugular vein or the femoral vein. The rate of recurrent embolism with this device has been 4 percent over 12 years of follow-up. Its long-term patency rate in excess of 95 percent allows it to be placed above the renal veins when necessary for embolism control, such as when there is a thrombus within the renal veins or the vena cava. There are a number of proprietary devices available for percutaneous insertion that are equally successful in preventing pulmonary embolism.

Superficial Thrombophlebitis

The term thrombophlebitis should be restricted to a disorder of the superficial veins characterized by a local inflammatory process that usually is aseptic (Fig. 21-9). Patients present with a painful swelling and erythema along the course of a superficial vein. The cause of thrombophlebitis in the upper limb usually is acidic fluid infusion or prolonged cannulation. In the lower extremity it is often associated with varicose veins and may coexist with *DVT*. Its association with the injection of contrast material can be minimized by washout of the contrast material with heparinized saline. The diagnosis usually is obvious. Duplex scans are very accurate in confirming the diagnosis and should be performed especially when swelling is present to rule out a concomitant deep venous problem.

Symptoms usually last for 2 to 3 weeks. Nonsteroidal anti-inflammatory agents provide significant pain relief. Patients should not be kept at bed rest. Activity should be encouraged with the extremity in external elastic support. If the thrombus extends into the saphenofemoral junction, the patient should have the saphenous vein disconnected from the common femoral vein or undergo full anticoagulation therapy.

Thrombophlebitis Migrans

Thrombophlebitis migrans, a condition of recurrent episodes of superficial thrombophlebitis, can be associated with visceral malignancy, Buerger's disease, the hypercoagulable states, systemic collagen vascular disease, and blood dyscrasias. Involvement of the deep veins and the visceral veins also has been described. The presence of this condition should alert the clinician to search for an underlying condition.

Subclavian Vein Thrombosis

Subclavian venous thrombosis (SVT) may be associated with an anatomic abnormality at the thoracic outlet, may be related to the placement of a central venous catheter, or may occur in a hypercoagulable patient. If left untreated, 25 to 74 percent of affected patients will have some limitations in activity, as many as 12 percent will have a pulmonary embolus, and 1 percent will die. Those cases related to a thoracic outlet abnormality make up 0.5 percent to 1.5 percent of all venous thromboses and often are associated with strenuous activities. These cases are referred to as the Paget-Schroetter syndrome or "effort thrombosis." Catheter-induced thrombosis is an increasingly common event because of the more frequent use of central veins for access, nutrition, chemotherapy, and monitoring. Screening venography in patients with central venous catheters demonstrates that 33 to 60 percent have thrombus in the axillosubclavian segments. Clinically evident SVT develops in 3 percent of these patients.

Patients with SVT present with a bluish, swollen arm and a pattern of upper extremity venous hypertension. Collateral veins usually are visible around the shoulder and chest wall. Patients typically describe an aching pain that is exacerbated by exercise. The color duplex scan has virtually replaced contrast venography in the diagnosis of lower extremity venous thrombosis, but the opposite is true in the upper extremity. Venography has a greater diagnostic accuracy when performed with the catheter in the basilic vein. A typical SVT is shown in Fig. 21-10.

Data support a role for conventional anticoagulation in all patients with SVT for prophylaxis against pulmonary embolism and for reduction of residual symptoms. Aggressive surgical therapy focused on clot removal is no longer recommended. Instead, physically active patients with SVT diagnosed in the acute phase should undergo catheter-directed thrombolysis. Current protocols recommend urokinase delivered via a catheter placed through the thrombus. This approach is successful in more than 50 percent of patients and ideally identifies the anatomic cause of the thrombosis (Fig. 21-11). Although the timing of correction is debated, most surgeons agree that extrinsic and extrinsic venous lesions should be aggressively treated. This means eliminating the compression at the costoclavicular space by a transaxillary first rib resection or a medial claviclectomy. The former is used when a direct approach to the vein is not required; the latter is used when the vein requires repair.

Inferior Vena Caval Thrombosis

Thrombosis of the inferior vena cava can result from tumor invasion or propagating thrombus from the iliac veins. Tumors of the vena cava are rare and are usually malignant and have a poor prognosis. They may be primary, such as a leiomyosarcoma, or secondary, such as a hypernephroma and a retroperitoneal sarcoma. Symptoms and signs depend on the segment of vena cava affected by the tumor and the degree of obstruction of adjacent organs. Involvement of the suprahepatic cava may cause the Budd-Chiari syndrome. The diagnosis can be made with a variety of imaging modalities, including magnetic resonance imaging (MRI), computed tomography (CT), ultrasonography, and contrast cavography.

The most common cause of vena cava obstruction is iatrogenic, resulting from ligation, plication, or insertion of partially occluding caval devices. Any caval filtration device can become totally occluded by a trapped massive thrombus, causing sudden reduction in venous return and cardiac output. In a patient with known prior pulmonary embolism, it is a grave error to ascribe the resulting hypotension to recurrent pulmonary embolism and treat the patient with vasopressor agents. In this situation, the cause of the hypotension may be functional hypovolemia that can readily be confirmed by measurement of central venous pressure. Thrombosis of the renal vein can result from extension of vena caval thrombosis, but it is most likely to occur in association with the nephrotic syndrome. It can be a source of thromboembolism and has been treated successfully by suprarenal placement of the Greenfield filter.

Visceral Venous Thrombosis

Mesenteric venous thrombosis is an uncommon but often fatal cause of intestinal ischemia. Patients present with nonspecific abdominal complaints. Pain out of proportion to abdominal findings is a common occurrence. Unlike arterial ischemia, progression is slow. Delay in diagnosis is frequent. Laboratory findings are not usually helpful. Abdominal CT scanning is the best diagnostic tool for demonstrating thrombus in the superior mesenteric vein. Color duplex scans also are accurate, especially if performed early in the course of the disease. The event may be spontaneous and idiopathic or associated with hypercoagulability, pancreatitis, trauma, cirrhosis, splenomegaly, or infection. Polycythemia is the most common associated condition. The goal of treatment is to prevent intestinal necrosis, or, if bowel necrosis has already occurred, to resect the nonviable areas. Anticoagulation therapy with heparin is the mainstay of medical management. Patients with local or diffuse peritonitis should undergo abdominal exploration.

Portal vein thrombosis can occur in the neonate, usually secondary to propagating septic thrombophlebitis of the umbilical vein. Collateral development leads to the occurrence of esophageal varices. In the adult, thrombosis of the portal, hepatic, splenic, or superior mesenteric vein can occur spontaneously but usually is associated with hepatic cirrhosis or a hypercoagulable state.

Hepatic vein thrombosis (Budd-Chiari syndrome) usually produces massive hepatomegaly, ascites, and liver failure. It can occur in association with a congenital web, endophlebitis, or polycythemia vera. Some success has been reported using a direct approach to the congenital webs, but the usual treatment is a side-to-side portacaval shunt to allow decompression of the liver.

The development of pelvic sepsis after abortion, tubal infection, or puerperal sepsis can lead to septic thrombophlebitis of the pelvic veins and septic thromboembolism. Ligation of the ovarian vein and vena cava has been the traditional treatment, but the emphasis should be on drainage or excision of the abscesses and appropriate antibiotic therapy. It also is appropriate to use the Greenfield filter in this situation because it is inert stainless steel and avoids the development of an intraluminal abscess that can occur after ligation of the vena cava, as demonstrated experimentally by Peyton and associates in 1983.

Pulmonary Thromboembolism

Pulmonary embolism is the third leading cause of death from cardiovascular events, second only to myocardial infarction and stroke. Estimates of the mortality in the United States alone range from 50,000 to 200,000 per annum. It may be the most common form of preventable hospital death. It is estimated that 5 of every 1,000 adults undergoing major surgery will die from massive pulmonary embolism.

Virchow first recognized the association between the venous thrombosis and pulmonary embolus after performing autopsies in 76 patients with antemortem thrombi obstructing their pulmonary arteries. It also became obvious in the early reports by pathologists that pulmonary embolism could be well tolerated by some patients who then died of other causes. The full spectrum of the disorder ranges from asymptomatic minor embolism to sudden death from massive embolism. Autopsy studies consistently demonstrated a 10 to 15 percent incidence of fatal pulmonary embolism until the 1970s. With aggressive prophylaxis, the incidence has been reduced to 6 percent.

Clinical Manifestations

The signs and symptoms of an embolic episode depend primarily on the magnitude of embolus and, to a lesser extent, on the cardiopulmonary status of the patient. Less than 33 percent of patients with documented pulmonary embolism show clinical signs of venous thrombosis. The diagnosis is unsuspected in the majority of patients who die of pulmonary embolism. The vast majority of patients suddenly develop chest pain or dyspnea. Other early symptoms may include tachypnea, diaphoresis, and marked anxiety. Hemoptysis is an uncommon sign, and when present it usually occurs late in the course of the disease and represents pulmonary infarction. Objectively, the patient with major embolism usually shows tachycardia, an increased pulmonary second sound, cyanosis, prominent jugular veins, and varying degrees of collapse. Less commonly, there may be wheezing, a pleural friction rub, splinting of the chest wall, rales, low-grade fever, ventricular gallop, and wide splitting of the pulmonic second sound. The incidence of these findings found in the Urokinase Pulmonary Embolism Trial is shown in Table [21-4](#).

The differential diagnosis includes esophageal perforation, pneumonia, septic shock, and myocardial infarction. Because all these entities are life-threatening, it is mandatory that an orderly approach be formulated to confirm or reject the working diagnosis. Laboratory studies in general are not very helpful in the differential diagnosis, although a white blood cell count of less than 15,000/mm³ might be suggestive when a pulmonary infiltrate is present to help rule out pneumonitis.

Diagnostic Studies

Electrocardiography

The primary value of the electrocardiogram (ECG) is to rule out a myocardial infarction. In the presence of a pulmonary embolus, the ECG may have signs of right ventricular overload such as the S1, Q3, T3 pattern. This only occurs in 16 percent of patients with documented pulmonary embolism. More commonly, the ECG has nonspecific ST and T wave changes that are nondiagnostic.

Chest Radiography

The primary value of the chest radiograph is to exclude other diagnostic possibilities, such as pneumonia, pneumothorax, esophageal perforation, or congestive heart failure. Although central vascular enlargement, asymmetry of the vascular markings with segmental or lobar ischemia (Westermark's sign), or pleural effusion may suggest pulmonary embolism, they are rarely sufficient to establish a diagnosis. The chest radiograph is critical in the interpretation of a lung scan, because any radiographic density or evidence of chronic lung disease makes a perfusion defect less likely to represent a pulmonary embolism. Pulmonary infarction as a consequence of embolism is a rare finding. A wedge-shaped density usually is seen on the chest radiograph (Fig. [21-12](#)).

Arterial Blood Gases

Hypoxemia with PaO₂ of less than 60 mmHg is highly suggestive of pulmonary embolism, especially when the chest radiograph does not show any other pulmonary pathology. The low PaO₂ is believed to be a result of shunting by overperfusion of nonembolized lung and a widened alveolar-arterial oxygen gradient from reduced cardiac output. The reduction in arterial P_{CO2} that follows major embolism is the most discriminating finding because hypoxemia is present in several disorders likely to be misdiagnosed as massive embolism (e.g., septic shock). If hypoxemia and hypocapnia are not present, the diagnosis of major embolism in the severely ill patient is unlikely, and an alternative diagnosis should be sought.

Central Venous Pressure

Low *central venous pressure (CVP)* virtually excludes pulmonary embolism as the primary cause of the hypotension because massive embolism almost always is accompanied by right ventricular overload and elevated right atrial pressures. Elevated right ventricular filling pressures may be transient, however, as hemodynamic accommodation occurs, and in subacute or chronic embolism the central venous pressure may be normal.

Lung Scan

The most commonly used diagnostic test is the perfusion lung scan. A normal scan rules out a major pulmonary embolus, but an abnormal scan does not ensure the diagnosis. In a nonhypotensive patient with a normal chest radiograph, the lung scan is a valuable screening test that has increasing validity as the size of the perfusion defect approaches lobar distribution (Fig. [21-13](#)). Smaller peripheral perfusion defects are more difficult to interpret because pneumonitis, atelectasis, or other ventilation abnormalities alter pulmonary perfusion. When the ventilation/ perfusion lung scan is interpreted as high probability, the diagnostic accuracy as compared to pulmonary angiography is 96 percent.

Pulmonary Arteriography

Selective pulmonary arteriography is the most accurate method of confirming the presence of pulmonary emboli and should be performed for any equivocal ventilation/perfusion scan. The procedure is invasive, requiring passage of a cardiac catheter into the pulmonary artery for injection of a bolus of contrast medium. A series of radiographs that outline areas of decreased perfusion and usually show filling defects or the rounded trailing edge of impacted emboli (Fig. [21-14](#)) is obtained. Straight cutoffs of the smaller pulmonary arteries are more difficult to interpret, particularly if there is associated chronic lung disease that obliterates pulmonary vessels. The procedure can be performed with low risk, although pulmonary hypertensive and cardiac patients are at highest risk for this type of study, which usually carries a 0.3 to 0.5 percent mortality rate. Avoidance of injection of contrast medium into the main pulmonary artery minimizes the complications and mortality rates. Additional useful information is obtained before contrast injection by measurement of pulmonary arterial pressures. A normal pulmonary angiogram excludes the diagnosis of pulmonary embolism in acutely ill patients.

Pathophysiology

It is estimated that 85 to 90 percent of all pulmonary emboli originate from the veins of the lower extremity, and the remainder arise from the right side of the heart or other veins. Once the embolus has lodged and interrupted pulmonary blood flow, the ratio of regional ventilation to perfusion increases, and the lung responds by bronchoconstriction to reduce wasted ventilation. This response is mediated by a local reduction in CO₂ output because it can be prevented by ventilation with increased concentration of CO₂. The bronchoconstriction is exacerbated by the release of serotonin from platelets adherent to the embolus. The ability of heparin to inhibit the release of serotonin adds further justification to the early use of this drug. Other vasoactive agents, such as histamine and prostaglandins, may have a role, but the net effect is a reduction in size of peripheral airways, reduced lung volume, and reduced static pulmonary compliance. The hypoxemia that characterizes major embolism is thought to be due to a ventilation-perfusion imbalance secondary to the ventilation changes described above, although the findings in some patients resemble true arteriovenous shunting. Although there may be some improvement in PaO₂ after supplemental oxygen is administered, the effects usually are minimal. The pulmonary vascular and cardiac effects of embolism are a direct consequence of the degree of occlusion of the pulmonary vascular bed. The loss of more than 30 percent of the vascular tree is required to begin to elevate mean *pulmonary artery (PA)* pressure, and usually more than 50 percent occlusion is required to reduce systemic pressure.

Treatment

Anticoagulation

The hemodynamic variables previously described provide a means of classification of patients that uses four grades of severity and is a useful guide to therapy and prognosis (Table 21-5). The minor degrees of embolism usually can be managed with anticoagulants alone with a satisfactory outcome. Continuous-infusion heparin is the initial treatment, in a dosage designed to prolong the partial thromboplastin time to at least twice normal (approximately 150 units/ kg). Most clinicians also begin oral anticoagulation therapy to allow several days' overlap of the drugs as prothrombin time is extended into the therapeutic range. Adequate anticoagulation stops the progression of thrombosis and is associated with a recurrence rate of less than 5 percent.

Fibrinolytic Therapy

Emboli typically undergo dissolution as a result of the active fibrinolytic mechanism in the pulmonary circulation. Activation of plasminogen to plasmin, which is found in high concentration in the pulmonary circulation, promotes this fibrinolytic effect. Fibrinolytic agents have been administered to increase the rate of lysis after pulmonary embolism. Tissue plasminogen activator (t-PA) works more rapidly than urokinase, but both are costly and are associated with a high incidence of bleeding complications. Indications for fibrinolytic treatment include any critically ill patient with a pulmonary embolus. Bleeding complications can be reduced by taking a careful neurologic history to eliminate patients with any brain pathology, minimizing venous and arterial punctures, stopping heparin administration, and identifying any other potential causes of bleeding.

The advantage of thrombolytic therapy may well be to improve the ultimate resolution of major thromboembolism, as demonstrated by Sharma and associates. Their follow-up studies in patients treated with urokinase or streptokinase showed a better restoration of pulmonary-capillary blood volume and diffusing capacity at 2 weeks than in patients treated with heparin and anticoagulants alone. The reason for the continued improvement at 1 year was not clear but was believed to be related to more complete early resolution of the

embolic condition, allowing more effective natural lytic processes, or to more complete clearance of peripheral venous thrombi, preventing silent recurrent embolism. Therefore, the patient who is not in shock and who has no clear contraindication should be treated with a fibrinolytic agent.

Vena Caval Interruption

In some patients, anticoagulants cannot be used because of associated problems (e.g., peptic ulcer disease), and management must be directed toward a mechanical means of protection against recurrent embolism as outlined earlier (see Table 21-3). Other patients, in whom anticoagulation appears to be adequate, sustain recurrent embolism and become candidates for surgical intervention. The third indication is when there has been a complication of anticoagulant therapy, forcing it to be discontinued and leaving the patient with untreated *DVT*. Another indication for a vena caval filter is protection against recurrent embolism in a patient who has sustained massive pulmonary embolism requiring open or catheter embolectomy. In these patients, in spite of a satisfactory embolectomy of the pulmonary circulation, the original focus of venous thrombosis remains untreated and recurrent embolism is likely.

There are two additional relative indications for a vena caval filter in a patient with active or recent *DVT*. One is the high- risk patient over 40 years of age who is obese and has a serious associated medical illness (e.g., heart disease), malignant disease, or a history of previous embolism and who undergoes a major abdominal or vascular procedure. The final relative indication is the patient in whom 40 to 50 percent of the vascular bed has been occluded (major) and who would most likely not be able to tolerate additional emboli, particularly if there is associated cardiac or pulmonary disease.

Pulmonary Embolectomy

The direct surgical approach to pulmonary embolism can be traced back to Trendelenburg (1908), who demonstrated the feasibility of pulmonary embolectomy experimentally but had no successes clinically. It remained for his pupil Kirschner (1924) to confirm the possibility of embolectomy by a successful clinical outcome. Because this procedure was attempted without circulatory support using a direct approach to the pulmonary artery at thoracotomy, the number of survivors was very small, and the first successful case in the United States was not reported until 1958 by Steenburg. The first successful open embolectomy during cardiopulmonary bypass was reported by Sharp in 1962. Since then, partial bypass support has also been used for the patient in shock. Local anesthesia is used, and the femoral artery and vein are cannulated for venoarterial bypass. The equipment is fully portable (Fig. 21-15), and patients can be supported during pulmonary arteriography and then transported to the operating room, where they can tolerate general anesthesia and sternotomy much better while being maintained on partial cardiopulmonary bypass.

Emergency pulmonary embolectomy rarely is indicated but should be considered in any patient with an acute pulmonary embolism who appears preterminal. These patients rarely survive the trip to the angiography suite and operating room, but when they do, the operation is probably not necessary if fibrinolytic therapy is available. Documentation of the diagnosis of massive pulmonary embolism by pulmonary arteriography is mandatory because the clinical diagnosis often is incorrect. The initial approach to patients who have transient collapse or persistent systemic hypotension should include full heparinization and administration of inotropic drugs, if necessary, to support the circulation while the diagnosis is confirmed. Isoproterenol (4 mg in 1000 mL of 5% dextrose in water) is useful initially because of its bronchodilating and vasodilating effects and its positive inotropic cardiac effect. It may provoke arrhythmias, however, necessitating the use of dopamine. In the patient who responds to heparin and does not require vasopressors for systemic pressure or urine output, careful monitoring is essential to determine whether anticoagulation and fibrinolysis will control the disorder. Open pulmonary embolectomy carries a mortality rate in the range of 50 percent, however, and uncontrollable pulmonary hemorrhage may follow open restoration of pulmonary perfusion.

An alternative approach using local anesthesia has been suggested by Greenfield and associates for transvenous removal of pulmonary emboli. A cup device attached to a steerable catheter is inserted in the jugular or the femoral vein, and the cup is positioned under fluoroscopy adjacent to the embolus seen on arteriography (Fig. 21-16). The position is verified by injection of contrast medium through the catheter. Then syringe suction is applied to aspirate the embolus into the cup, where it is held by suction vacuum as the catheter and captured embolus are withdrawn. Clinical experience with the technique in 32 patients demonstrated that emboli could be extracted in 29 of them (91 percent) with an overall survival rate of 76 percent. Emboli could not be removed when they had been impacted for more than 72 h or if the patient suffered cardiac arrest at the time of angiography, in which case open embolectomy was required. Placement of a Greenfield vena caval filter after removal of sufficient emboli to produce near- normal hemodynamics protected the patients from recurrent embolism.

Pulmonary Hypertension and Thromboembolism

Pulmonary emboli may accumulate gradually over a prolonged period if they fail to undergo lysis and obliterate the pulmonary vascular bed. The clinical picture in this case is one of chronic cor pulmonale because significant pulmonary hypertension results from changes in the pulmonary vascular bed. The presentation may be subtle with only dyspnea or syncope on exertion, but there is a loud P₂ and right-sided strain on the electrocardiogram. The sequence also may occur unaccompanied by significant respiratory symptoms, and this may explain the cause in some of the patients considered to have primary pulmonary hypertension. When the diagnosis is made, there is limited life expectancy, but the patient may benefit from a vena caval filter to prevent additional embolism even if the disorder is primary pulmonary hypertension, as reported by Greenfield and associates. The rationale for this is that they ultimately develop right heart failure, predisposing to pulmonary embolism that is lethal even if small. When acute cardiopulmonary decompensation occurs in these patients after embolism, they are not good candidates for embolectomy because of fixation of the older thrombi to the pulmonary arterial wall. They should be classified separately (chronic) and managed by long-term anticoagulation therapy, or in some cases should be considered for open pulmonary thromboendarterectomy or heart-lung transplantation.

Recurrent thromboembolic pulmonary hypertension produces exertional dyspnea and signs of right heart strain with cor pulmonale. With further progression of right heart overload, tricuspid insufficiency may develop. This disorder may be difficult to distinguish from primary pulmonary hypertension, although the latter is more likely to be found in women under 20 years of age without a history of *DVT*. Severe pulmonary hypertension is a serious problem and usually limits the life expectancy to less than 2 years from diagnosis.

Open thrombectomy for chronic occlusion was first performed by Allison and associates in 1958 and remains a possibility for improving pulmonary blood flow. For a patient to be eligible for this procedure, the occlusion must involve the proximal portion of the pulmonary arterial tree, and the distal bed must be patent. The physiologic basis for continued distal patency after proximal occlusion is bronchial arterial collateral flow. The procedure also has a significant mortality, but this has been decreasing with greater experience and identification of risk factors. Daily and associates performed pulmonary thromboendarterectomy on 127 patients under deep hypothermic circulatory arrest with a mortality rate of 12.6 percent. For the majority of patients with severe pulmonary hypertension, however, the outlook is poor unless they receive maximum protection from recurrent embolism, which in the authors' experience has required anticoagulation therapy and vena caval filter placement.

Fig. 21-17 presents an algorithm for the management of pulmonary embolism.

Varicose Veins

Varicose veins are the most common vascular disorder affecting human beings. A definition of a varicose vein that lays the groundwork for a unified theory of causation was given by Carl Arnoldi, who described them as “any dilated, elongated, or tortuous vein, irrespective of size.”

Etiology

There are four factors that affect the development and progression of varicose veins: heredity, female sex hormones, gravitational hydrostatic force, and hydrodynamic muscular compartment forces. A familial tendency toward the development of varicosities may be the most important predisposing factor. Female sex hormones also have a profound effect on the lower extremity superficial veins. Varicose veins are common occurrences in pregnancy, usually appearing in the first trimester (70 to 80 percent) when the corpus luteum is secreting progesterone. Progesterone is known to inhibit smooth muscle contractility and increase venous distensibility. These effects are maximal on the first day of the menstrual cycle, when the effects of progesterone are amplified by estrogen. Hydrostatic forces produce venous dilatation from the weight of the blood column transmitted through incompetent valves. The other force is exerted by the contracting muscles on adjacent veins via the perforating system. These forces regularly exceed 150 mmHg.

Clinical Manifestations

The usual distribution of varices is below the knee in branches of the greater saphenous system (Fig. 21-18). The symptoms associated with varicose veins are nonspecific aching and heaviness of the legs that can be attributed to the congestion and pooling of blood in the enlarged superficial venous system. These symptoms worsen as the day progresses, requiring the patient to rest with leg elevation to obtain relief. Calf-length elastic stocking support in the range of 20 to 30 mmHg may provide symptomatic relief for those whose vocations require long periods of standing or sitting. Although mild edema may occur from varicosities alone, it usually reflects additional incompetence of the deep or perforating venous system and other medical conditions, such as cardiac or renal failure. Associated night cramping of the legs may be helped by the administration of quinine sulfate, which reduces muscular irritability.

Diagnosis

The Trendelenburg test is useful in distinguishing between primary varicose veins and the more serious condition of varicosities secondary to underlying deep venous disease. In the Trendelenburg test the limb is elevated to evacuate the veins, then pressure by hand or tourniquet is applied to the saphenofemoral junction (Fig. 21-19). With the patient standing, the lower leg is observed for the rate of filling of the varicosities. Gradual filling occurs in normal patients when the perforating veins are competent. Rapid filling occurs if the perforators are incompetent. The second phase of the test consists of release of the pressure to see if the upper thigh varices fill rapidly, indicating incompetence of the saphenofemoral valve. There are four possible results of this test. A *negative-negative* result occurs when there is only gradual filling in the distal one-third of the leg with compression in place and only continued slow filling when the compression is released. This indicates that the valves of the perforating veins (phase I) and superficial veins (phase II) are competent. In a *negative-positive* result, the release of compression is followed by a rapid filling of the saphenous vein, indicating that its valves are incompetent. A *positive-negative* result indicates that the perforating veins are incompetent, but the superficial veins are competent. A *positive-positive* result indicates that both systems have valvular incompetence. These principles have been refined by the use of color-flow duplex scanning. Changes in the direction of flow are detected by changes in color, and venous valves may be seen on the grey- scale image.

In the Perthes test, a tourniquet is placed around the upper leg and the patient is instructed to walk. If the varicose veins disappear, the deep venous system is patent and the perforating veins are competent. If pain occurs with walking, the deep system is obstructed and the superficial system represents the major source of venous outflow. It would be a serious error to excise superficial veins under these circumstances. Sequential tourniquets also may be used to define and isolate areas of incompetent perforating veins (Ochsner-Mahorner test).

Treatment

The majority of patients can be managed by conservative methods, but if these fail to control symptoms or if additional complications of venous stasis develop, such as dermatitis, bleeding, thrombosis, or superficial ulceration, the patient may become a candidate for more aggressive management.

The two methods of treatment currently used are injection sclerotherapy and ablative surgery. Sclerotherapy should be reserved for those patients who do not have evidence of axial saphenous reflux. Large varices of the thigh also should be removed surgically because they are subject to superficial thrombophlebitis after sclerotherapy and are often associated with large perforating veins. Injection sclerotherapy destroys the endothelium of the vein and promotes its obliteration by scarring. Pressure must be applied to the vein after injection of the sclerosant to prevent thrombus formation and later recanalization. The technique for injection involves placement of the needle and syringe with the patient standing followed by elevation of the leg, injection of the agent, and bandage compression of the area for 2 to 3 weeks. Sodium chloride 23.4% is the agent most preferred, but a wide selection is available. Current indications for sclerotherapy include superficial venules (<1 mm), varicosities 1 to 3 mm in diameter, postoperative residual veins, small congenital vascular malformations of venous predominance, bleeding varices, and large varices around an ulcer. The most common complications include hyperpigmentation, skin necrosis, pain, anaphylaxis, and matting.

The goals of operative treatment are the elimination of the hydrostatic forces of saphenous reflux, the removal of the hydrodynamic forces of perforating vein reflux, and the eradication of the varicosities in as cosmetic a manner as possible. Each case must be planned thoroughly because routine stripping of the greater saphenous vein from groin to ankle usually is not required. Patients with saphenous reflux should have groin-to-knee stripping. It is unnecessary to strip the below-the-knee portion of the vein unless it is varicose. Stab avulsion of vein clusters, which are marked preoperatively, supplements the stripping.

Removal of the greater saphenous vein requires its detachment from the common femoral vein and ligation of its tributaries at the saphenofemoral junction (Fig. 21-20). If an ankle incision is made, care must be taken to avoid injury to the saphenous nerve. Bleeding can be reduced by the use of a tourniquet and leg elevation during the stripping. The incisions made for stab avulsion of varices are 1 to 2 mm in length and are oriented in the skin lines. Ecchymosis is the most common complication after operations for varicose veins. The incidence can be reduced by carefully placed elastic support. Recurrences are usually due to incompetence at the groin or in the mid thigh from perforating veins.

Chronic Venous Insufficiency

Chronic venous insufficiency or the postthrombotic syndrome develops in approximately 50 percent of the patients with deep venous thrombosis. It is estimated that there are 500,000 patients in the United States with venous ulcers. Homans noted in 1917 that "overstretching of the vein walls and destruction of the valves upon which the mechanism principally depends bring about a degree of surface stasis which obviously interferes with the nutrition of the skin and subcutaneous tissues." It is now known that recanalization of the deep veins results in valvular incompetence, which in turn results in a long column of blood that transmits pressures of over 100 mmHg to the venules, causing the development of abnormal capillaries. These new vessels have an increased permeability to fibrinogen and red blood cells. Lymphocyte and macrophage recruitment occurs in response to extravasated protein. Pericapillary cuffing, an attempt by the endothelial cells to limit extravasation, occurs and results in widened endothelial gap junctions. The result is thickening and lipodermatosclerosis of the subcutaneous tissues that produce a characteristic "brawny" edema. The loss of red cells results in hemosiderin deposits, producing the characteristic pigmentation. A deterioration of mononuclear cell function is associated with chronic venous insufficiency. A decreased capacity for lymphocyte and monocyte proliferation in response to various challenges translates into poor or prolonged wound healing. When the distal perforating veins become incompetent, there is additional pressure, with skin atrophy leading ultimately to necrosis and chronic stasis ulceration (Fig. 21-21).

Diagnosis

The diagnosis of chronic venous insufficiency usually is made by inspecting the leg. Physical findings do not provide information about the presence, extent, or location of valvular incompetence or obstruction. Duplex scanning is the most reliable method of identifying valvular incompetence and venous obstruction.

Venous valvular incompetence is identified easily with the duplex scanner. The vein to be studied is identified with B-mode imaging. While the velocity spectrum is displayed, various maneuvers are performed to reverse the normal peripheral-to-central gradient. Retrograde flow is indicated by an inverted spectrum and a change in color from blue to red. Reflux is evaluated in the groin by having the patient perform a Valsalva maneuver. A period of reversed flow exceeding 1.5 s is considered abnormal. Manual compression is used above and below the vein in question. Some prefer to examine the veins for reflux while the patient is standing. A pneumatic cuff is placed at various levels beginning at 5 cm below the vein in question. The velocity spectrum is recorded continuously as the cuff is inflated and deflated. Normal valves close rapidly in response to temporary flow reversal. Perforating veins are studied with the patient in the reversed Trendelenburg position. Perforators are identified as veins arising from the superficial veins and penetrating the deep fascia into the muscular compartment. Outward flow with calf compression indicates valvular incompetence. Venous valves are identified with B-mode imaging. Normal valves are thin and mobile; diseased valves are shortened and thick, often with attached echogenic material.

Venous obstruction is identified with the same techniques used to diagnose acute venous thrombosis. After the vein is identified with B-mode imaging, its patency is assessed by its compressibility and Doppler spectrum. With partial occlusion or incomplete recanalization, there will be an encroachment on the flow image that no longer fills the entire vein. Collateral veins will be seen, and that finding is particularly useful in distinguishing between acute versus chronic occlusions. Another distinguishing feature of chronic occlusion is the shrunken size of the vein when compared to the distention seen in acute DVT.

The physiologic response to venous reflux can be measured. A needle is placed in a dorsal foot vein and secured in place. The patient's venous pressures can be determined in the resting and active state. The pressure in the standing position is slightly higher than the hydrostatic force of a column extending from the atrium to the foot. Resting pressures in patients with and without venous insufficiency are similar. In contrast to normal patients, who reduce their distal venous pressure with walking, patients with the postthrombotic syndrome gain no benefit from their muscle pump and their pressure increases (Fig. 21-22). If there has been failure of recanalization with persistent obstruction, the increase in blood flow with exercise may increase venous hypertension to produce ischemic pain referred to as venous claudication.

Nonoperative Management

The goals of treatment are to alleviate symptoms, heal ulcerations, and prevent ulcer recurrences. The vast majority of patients can be managed nonoperatively. Although the mechanism of benefit is unknown, compression therapy is the most important aspect of patient management. Conflicting hypotheses include a reduction in ambulatory venous pressure, improvements of the microcirculation of the skin and subcutaneous tissue, and increase in the pressure of the subcutaneous tissue that reduces the leakage of fluid from the capillaries. The latter is the most plausible because cutaneous metabolism may improve after fluid resorption, allowing an enhanced diffusion of oxygen and other nutrients.

The initial treatment of patients with venous ulceration should include a period of strict bed rest to reduce edema. Systemic antibiotics are given for the surrounding cellulitis. Elastic stockings are fitted when the edema has subsided. Surrounding areas of dermatitis are treated with topical steroids. Patients are then instructed to wear the elastic stockings for life. Two pairs are prescribed to allow for daily laundering of alternate pairs. Ulcer recurrence is 16 percent in compliant patients, but long-term compliance is difficult to achieve with patients who are reluctant to wear the stockings after their ulcer is healed. Some physicians prefer the paste gauze boot (the Unna boot) during the ulcer healing phase. This dressing contains calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum silicate. Patients whose ulcers fail to heal after prolonged outpatient care require hospitalization.

Operative Management

Patients selected for operation have severe, disabling symptoms and a history of recurrent ulceration despite aggressive medical therapy. Candidates for operation should undergo ascending and descending venography in addition to duplex scans and ambulatory venous pressures. These tests provide data allowing an individualized treatment plan that addresses specific areas of obstruction or reflux.

Perforator Vein Ligation

Healing of chronic stasis ulcers is not likely unless the perforating veins responsible for the ulcer are identified and ligated. The typical location of these veins is posterior and superior to the medial malleolus. Ligation of the perforator vessels should be the initial procedure for recurrent ulceration. Treatment failure occurs in 10 percent of patients despite vigorous medical therapy, including support stockings, leg elevation, wound care, and patient education. These patients should be considered for venous reconstruction.

Venous Reconstruction

The present attitude of most surgeons toward venous reconstruction is critical and pessimistic. The venous system, unlike the arterial system, tends to recanalize, thus making it more difficult to quantitate the obstruction and identify the patient who may benefit from venous reconstruction. Dale estimated that the percentage of patients with chronic venous insufficiency who could benefit from reconstruction was 1 to 2 percent.

Primary valvular dysfunction can be treated by valvuloplasty. The valve most suitable to direct valve repair usually is the most proximal valve in the superficial femoral vein. After DVT, most patients have scarred and thickened valves that do not lend themselves to this type of reconstruction. Kistner, after studying 200 limbs with ascending and descending venography, found 28 that could be treated by valve repair, and 72 percent had an excellent result. In this procedure, floppy, incompetent valves are tethered against the vein wall or shortened using interrupted 8-0 monofilament suture (Fig. 21-23). Recent technical advances have allowed this procedure to be done under direct visualization using an angioscope. Results of this procedure are difficult to interpret because the operations are often combined with saphenous vein stripping and perforator ligation. Most investigators have reported improvement in symptoms for prolonged periods in approximately 60 to 80 percent of the patients.

Direct repair is not possible for postthrombotic valvular dysfunction. The two recognized options for surgical candidates are transposition of a deep femoral or saphenous vein valve or transplantation of a valve-bearing segment of the axillary vein to the superficial femoral or popliteal vein (Fig. 21-24). Results are not as good as those achieved by valvuloplasty for primary incompetence. Taheri and coworkers described 66 patients with good results in 78 percent. In this series, 31 patients had postoperative venograms, 28 of these were found to have valvular competence. A number of other investigators report symptomatic relief in 50 to 92 percent and ulcer recurrence in 6 to 54 percent of patients. Most of these patients had good results initially; however, at 1 year, a high proportion of the affected limbs had reverted to their preoperative condition. Bergan and colleagues have pointed out that for venous valve surgery to be successful, it usually must be accompanied by saphenous vein stripping and perforator ligation. The difficulty in identifying patients who could benefit from these procedures was put into perspective by Dale, who, after 2 years of investigating, failed to identify a group of patients who would benefit from venous valve transplantation or valvuloplasty. Husni found that venous reconstruction fails in three situations: when the bypass graft is too small in caliber, when venous hypertension is mild to moderate (less than 80 percent of the standing venous pressure), and when a thrombectomy or endophlebectomy has to be performed before anastomosis. In these patients who are at high risk for failure, he has recommended a distal arteriovenous fistula.

Approximately one-third of patients with chronic venous insufficiency have a predominant obstructive component because of inadequate recanalization after a DVT. Patients typically complain of swelling and pain on ambulation. The pain often is described as bursting, but patients with valvular incompetence refer to their pain as aching. Because the pain of chronic venous obstruction requires the patient to be off his or her feet to obtain relief, it is referred to as venous claudication. Ambulatory venous pressure measurements document the diagnosis, and venography identifies the site of obstruction.

Venous obstruction of the iliofemoral venous system can be bypassed by a saphenous vein cross-over graft, first described by Palma and Esperon in 1958. The procedure consists of isolating the normal contralateral saphenous vein and dividing it distally. The vein is tunneled suprapubically and anastomosed to the contralateral femoral vein, distal to its

obstruction. In 1982 Dale described 59 patients who had the Palma bypass with excellent results in 63 percent, good results in 17 percent, and a failure rate of 20 percent. Husni, in 1983, and Smith and Trimble, in 1977, reported similar results. The saphenous vein cross- over graft generally has been accepted as useful; however, the natural history of iliac vein occlusion is recanalization, and very few patients with iliofemoral thrombosis become candidates for surgery.

Use of the saphenous vein for popliteal-to-femoral vein bypass was described in 1954 by Warren and Thayer with good results in 10 of 14 patients. This operation provides the muscle pump system a means of emptying the calf by bypassing the occluded superficial femoral vein. With rich collateral veins in the thigh, identifying the patient with an obstructed superficial femoral vein who might benefit from the saphenous-to-popliteal vein bypass is difficult. The saphenous vein is dissected free below the knee and anastomosed to the popliteal vein, which is obstructed proximally. Husni has popularized this procedure and has reported the outcome in 27 patients with a good result in 63 percent. Dale reported good results in 10 patients (60 percent), and Smith and Trimble, in a collected series of 59 patients, reported good results in 76 percent.

The majority of iliofemoral thromboses occur on the left side. This is attributed to the right iliac artery compressing the left iliac vein as it crosses the fifth lumbar vertebra. Various autopsy series and operative studies have documented the presence of left iliac vein webs and scarring in patients who have had iliofemoral thrombosis. There was interest in this problem in the 1960s by Calnan and associates and by Cockett and Thomas, who advocated surgical correction of these lesions. Dale reviewed eight such patients identified by venography and subsequently operated on four, trimming out anterior webs or scar tissue and using a venous patch for closure. Two of the patients had excellent results; edema developed later in one patient, and a fourth patient had a complicated postoperative course, complaining of excruciating pain and postoperative swelling. Dale recommended operation only for the patient whose symptoms are severe and who accepts the operation with the understanding that the results are not predictable. Smith and Trimble have followed 30 patients with this problem and have operated on 14, with an 85 percent postoperative improvement rate. Cockett and Thomas, conversely, found the results unsatisfactory, and after operating on 30 patients using several different methods they recommended abandoning the procedure.

Venous Trauma

Venous injuries of the extremities usually are associated with arterial injuries because of their anatomic proximity. Direct ligation of injured superficial veins is appropriate treatment except when they are the sole remaining venous drainage of the extremity, which mandates their repair. Treatment of injuries of the deep veins changed dramatically as a result of the military experience in Korea and Vietnam, as reported by Rich and associates. It was well demonstrated that ligation of major extremity veins resulted in higher rates of disability and limb loss than repair or replacement by autogenous vein segments. The concept of primary repair of venous injuries by suture vein patch or vein graft interposition has been extended to civilian injuries by Agarwal and associates with favorable results. The rationale for primary repair is based in part on the adverse hemodynamic effects in the first 72 h after major venous ligation. Current recommendations are that repair of the common femoral and popliteal veins should be done whenever possible. Repair of the superficial femoral vein is controversial.

LYMPHATICS AND LYMPHEDEMA

Anatomy and Physiology

The exact origin of lymphatic vessels is a matter of disagreement among embryologists. The original theory of Sabin traced the origin from the venous system, while Huntington and McClure suggested that lymphatics form by fusion of mesenchymal spaces or clefts, which has been labeled the centripetal theory. By the sixth week of gestation, there are paired lymph sacs in the neck and lumbar areas, and at the eighth week, there is a retroperitoneal lymph sac with a developing cisterna chyli. These systems develop communicating channels that ultimately form the thoracic duct by merger of the right lymphatic duct with the left across the fourth to sixth thoracic vertebrae, which then drains into the left subclavian vein. Smaller lymphatic ducts persist that drain into the right subclavian vein.

Developmental arrest or abnormalities can result in primary hypoplasia or absence of ducts and lymph nodes. Abnormal growth of jugular lymph sacs can produce unilocular or multilocular lymph cysts termed cystic hygromas. These cysts also may be found in the axilla, mediastinum, retroperitoneum, or intestinal mesentery. Hyperplastic changes may occur to produce lymphangiomas with or without other vascular malformations.

The function of the lymphatic system begins with lymphatic capillaries, which collect fluid and protein from the extravascular spaces. In addition to the protein that cannot be reabsorbed by the venules, red blood cells, bacteria, and other larger particles can be evacuated only through the lymphatics. This permeability is facilitated by the absence of a basement membrane beneath the lymphatic endothelial cells. The lymphatic capillaries are found beneath the epidermis in the superficial dermis. These vessels drain into valved channels in the deep dermis and subdermal tissues, forming larger channels that follow the vascular pathways superficial to the deep fascia. Although lymphatics can be found in the intermuscular fascia, they are absent in muscles, tendon, cartilage, brain, and cornea.

Lymph is transported by afferent vessels to regional lymph nodes that vary in size according to their function and activity. Within the medullary sinuses of the node, circulating lymphocytes are replaced and initial contact of foreign material with the immune system is made. Efferent lymph leaves the node via hilar channels, which are less numerous than the afferent channels that enter the convex side of the node. In addition to direct thoracic duct drainage into the subclavian vein, there are other lymphovenous communications within nodes and in peripheral vessels. Central lymphatic flow is promoted by the lymphatic valves, muscular contractions in larger ducts, respiration, arterial pulsation, and external massage. The main function of the lymphatic system is to clear the interstitial spaces of excess water and particulate matter.

Lymphedema

Classification of Lymphedema

The original classification of Allen was into two types, one in which there was no known cause, and the other secondary to a known disease or disorder. The primary lymphedemas were called *congenital* when present at birth and *praecox* when there was onset in childhood. Kinmonth added the term *tarda* for when the onset was not until later life. With the advent of lymphography it became possible to classify the primary lymphedemas structurally into hyperplasias and hypoplasias. The original classification as proposed by Kinmonth has largely been abandoned for the more simplified version presented in Table [21-6](#).

The congenital lymphedemas are hypoplastic in 92 percent of cases. Their subgroups are defined by lymphography and behave differently. Those with distal hypoplasia have a mild, nonprogressive form of the disorder provided that their proximal pathways are normal. Most of these patients are women and notice the onset after puberty. In proximal hypoplasia, the lymphedema is more extensive, involving the entire extremity, and it occurs equally among males and females. The combination of proximal and distal hypoplasia shows features of both groups and tends to be progressive.

The primary hyperplastic lymphedemas are uncommon (8 percent), and those with bilateral hyperplasia usually can be recognized by diffuse capillary angiomas on the lateral sides of the feet. Lymphography shows dilated lymphatics with normal valves, in contrast to the findings in the megalymphatic group, in which no valves can be seen. In this latter group, chylous reflux may produce chylometorrhea, skin vesicles, or chyluria.

The most common cause of secondary lymphedema in this country is malignant disease metastatic to lymph nodes. Surgical removal of nodes, especially when combined with radiation therapy that produces lymphatic fibrosis, is another common cause. In tropical and subtropical countries, filariasis is the most common cause of secondary lymphedema, producing the typical appearance of elephantiasis. Other infective and chemical agents, such as silica, can enter the lymphatic system via barefoot walking and cause fibrosis of lymphatics and lymph nodes.

Clinical Manifestations

Lymphedema is a clinical diagnosis and should be restricted to situations where other causes of edema have been excluded or a specific lymphatic abnormality has been demonstrated. The presence of bilateral dependent “pitting” edema usually indicates a renal or cardiac etiology. Other generalized hypoproteinemias may be seen in malnutrition, cirrhosis, and protein-losing enteropathy, or they may be idiopathic. Allergies or hereditary causes are unusual. In unilateral edema, venous disease is the most likely cause and can be recognized by the examinations described in the previous section.

The patient with lymphedema complains of swelling and fatigue. Limb size increases during the day and decreases at night but is never normal. It is important to determine whether there is a family history of primary lymphedema and whether the patient has visited any countries where filariasis is endemic. The presence of weight loss and diarrhea suggests small bowel lymphangiectasia. On examination, lymphedema is characteristically firm and rubbery but nonpitting. Lymph vesicles may be present containing fluid of high protein concentration. Complications of lymphedema such as infection, cellulitis, erythema, and hyperkeratosis may be present. It is important to document limb size to identify isolated limb gigantism and the Klippel-Trénaunay syndrome that may have hypoplastic lymphatics in addition to venous abnormalities, capillary nevus, and limb elongation. The patient should be examined for upper extremity and genital lymphedema, hydroceles, and amelogenesis imperfecta.

Diagnostic Studies

Dye Injection

Lymphatics can be visualized by dye injection in the extremities and mesentery, and also by ingestion of cream or milk to visualize intestinal lacteals and major ducts.

A highly diffusible dye such as patent blue, introduced by Hudack and McMaster, or sky blue dye, recommended by Butcher and Hoover, can be injected in 0.2 mL amounts subcutaneously into each interdigital web. Massage of the skin and movement of the joints usually defines a network of fine intradermal lymphatics (Fig. [21-25](#)). If the collecting vessels are obstructed or inadequate, the dye diffuses through the dermal lymphatics to produce a marbled appearance called “dermal backflow.”

Lymphography

The technique of lymphography was developed by Kinmonth, who demonstrated that it was possible to cannulate the lymphatics visualized by dye injection and then inject contrast medium (Lipiodol). This is a meticulous and tedious procedure that may require general anesthesia, as proposed by Kinmonth. If the lymphatics in the foot are not usable, it is possible to cannulate lymphatics adjacent to groin nodes or to inject the node directly. With adequate visualization, the lymphatics in the extremity will be identified, often as parallel tracks that are of uniform size and bifurcate as they proceed proximally in contrast to the venous system. Normally, there is some dilatation at the level of the valves.

Radionuclide Lymphatic Clearance

Radionuclide scanning using human serum albumin labeled with radioactive iodine or technetium 99m colloid has been used to monitor lymphatic clearance by serial scanning. Although the technique is simpler than standard lymphography, it has major disadvantages because of the haziness of the scan, radiation dosage, and distribution of the radionuclide into the extracellular fluid, making calculations of clearance dependent on leg volume.

Analysis of Tissue Fluid

Tissue fluid or lymph can be aspirated or collected from a tube in the subcutaneous tissues but contributes little to the diagnosis of lymphedema. Characteristically, lymphedema fluid has a protein content of more than 1.5 g/dL, in contrast to that of edema fluid from venous hypertension, which usually is less. The ratio of albumin to globulin also is higher in lymphedema fluid than in plasma, which is helpful in the presence of an inflammatory exudate in which the protein content is high but the albumin-to-globulin ratio is normal.

Management

Supportive Treatment

There are significant anatomic and physiologic limitations to the treatment of lymphedema. From the standpoint of physiology, the removal of fluid is not as effective as in edema of other causes because of the residual protein in lymphedema. In addition, from an anatomic standpoint, the development of fibrosis produces irreversible changes in the subcutaneous tissues. Therefore, the options are limited and the primary objectives remain for control of edema, maintenance of healthy skin, and avoidance of the complications of cellulitis and lymphangitis.

The initial objective of control of edema can be approached by elevation and the use of sequential pneumatic compression boots to massage the leg. These treatments can be done at home with equipment rented for this purpose. Once the leg has reached optimal size, the patient should be fitted with firm elastic stockings as described earlier for venous insufficiency. The stockings should be removed at night and the foot of the bed elevated to maintain the pressure gradient from leg to right atrium. Massage therapy was used in the treatment of lymphedema as early as 1882 and has current advocates.

The onset of redness, pain, and swelling usually signifies early cellulitis or lymphangitis, which can be recognized by red streaking up the leg. The usual causative organism is staphylococcus or beta-hemolytic streptococcus, which must be treated vigorously, usually with intravenous antibiotics. In the absence of treatment, the infection may obliterate more lymphatics and produce constitutional signs of fever, malaise, nausea, and vomiting. Another frequent complication is eczema, which usually will respond to hydrocortisone cream. Antifungal agents may be necessary, topically and systemically, for chronic infections, particularly between the toes. In contrast to the stasis edema of venous insufficiency, ulceration is unusual, although fissures and lymph fistulas can develop and require surgical excision.

The secondary lymphedemas may lend themselves to treatment of the underlying disorder, such as using diethylcarbamazine for filariasis or appropriate antibiotics for tuberculosis or lymphogranuloma venereum. In rare cases of long-standing secondary lymphedema, such as in the arm after radical mastectomy, a lymphangiosarcoma may develop, appearing as a raised blue or reddish nodule. Satellite tumors and early metastases may develop if it is not recognized and widely excised.

Operative Treatment

Only 15 percent of patients with primary lymphedema become candidates for operative treatment, which usually is directed to reducing leg size. The indications for operation are related to functional rather than cosmetic improvement, because the appearance of the extremity even after a successful procedure will still be abnormal and show extensive scarring. The best results are obtained when the bulk of the extremity has severely impaired movement or when there have been recurrent attacks of cellulitis. Although some efforts have been made to develop techniques to improve lymphatic drainage, most of the established procedures consist of excisional operations.

Three of the excisional procedures were based on the incorrect assumption that the deep fascia acted as a barrier to lymphatic drainage, and the efforts of Kondoleon and associates to excise fascia or insert a dermal flap into muscle proved ineffective in improving lymphatic drainage. The original procedure devised by Charles consisting of wide excision of lymphedematous tissue followed by skin grafting still is useful when the overlying skin is in poor condition, as in elephantiasis. The procedure used most often, however, is Kinmonth's modification of Homans's procedure, in which skin flaps are raised to allow excision of the underlying subcutaneous tissues.

The most logical, albeit technically demanding, approach has been directed to establishing lymphaticovenous anastomoses. Initial efforts in this area were made by Nielubowicz and Olszewski, who divided a lymph node, removed the pulp under magnification, and sutured the node capsule with its afferent lymphatics into a vein. This procedure is more suitable for secondary lymphedema than primary, in which the disorder lies in the lymphatic channels themselves. Another promising technique of direct lymphovenous connection was developed by Cordeiro and modified by Degni, who used a special needle for insertion of lymphatic vessels directly into veins and fixed them there by a single suture. Using this technique, Fox and associates treated eight secondary and 12 primary lymphedema patients, with follow-up as long as 4 years. Good results were obtained in two of four postmastectomy lymphedemas, with poor results in the other two, who had postoperative lymphangitis. Nine of 11 patients with primary lymphedemas had good functional results, allowing them to resume normal activity. The authors recommend long-term preoperative anti-inflammatory and antimicrobial therapy to avoid postoperative lymphangitis.

It is difficult to evaluate the results of such procedures when combined with resectional operations and in the absence of postoperative lymphography to demonstrate patency of the anastomoses. However, the deleterious effects of lymphangiographic contrast on lymphatics were well demonstrated by O'Brien and associates, who measured limb volume after lymphangiography in 100 patients and found that 32 percent had a significant increase in leg volume and 19 percent developed lymphangitis. Therefore, it seems advisable to use lymphangiography only for diagnostic studies and not for pre- or postoperative evaluation until safer contrast material becomes available. Additional efforts to combine resectional operations with microlymphovenous anastomoses as reported by O'Brien and Shafiroff may offer some brighter prospects for improvement of these debilitating disorders.

CHAPTER 22 - Manifestations of Gastrointestinal Disease

Josef E. Fischer
Michael S. Nussbaum
William T. Chance
Frederick Luchette

Pain

Pain (from the Latin *poena*, meaning penalty, punishment, torment) is the most common symptom of gastrointestinal disease and leads to surgical intervention more than any other gastrointestinal manifestation. Most disturbances in gastrointestinal function and diseases of the abdominal viscera are associated with pain at some time during their course.

General Considerations

Although there is no unequivocal proof that each peripheral nerve fiber is devoted to one type of sensory modality (pain, touch, cold, or warmth), most physiologists subscribe to the *specificity theory*, which contends that pain is a separate sensory modality with its own specific neural apparatus. Melzack and Wall, in 1965, proposed the *gate-control theory*, which suggested that the amount and quality of perceived pain are determined by many physiologic and psychologic variables. Modulation of nociceptive impulses occurs at the dorsal horn and various levels of the ascending afferent systems. The gate-control theory has been the basis for methods of pain-inhibiting electrical stimulation, e.g., with transcutaneous nerve stimulation (TNS).

Appropriate stimuli initiate impulses in skin, muscle, or viscera. These sensory impulses are transmitted to the posterior horn of the spinal cord in the primary sensory neuron that has its cell body in the dorsal root ganglion. The secondary sensory neuron in the posterior horn transmits the impulses in the contralateral spinothalamic tract to the posterolateral nucleus of the thalamus. The tertiary sensory neuron transmits the impulses from the thalamus to the postcentral gyrus of the cerebral cortex (Fig. 22-1). Three kinds of pain have been described: superficial, or cutaneous pain; deep pain from muscles, tendons, joints, and fascia; and visceral pain. The first two can be combined in the category of somatic pain.

Pain Pathways

Until well into the twentieth century, the viscera were thought to be completely insensitive. William Harvey noted when observing a boy who had sustained a chest wound leaving the heart exposed that touching the heart caused no sensation. In 1901 Lennander stated that the viscera are insensitive to cutting, crushing, and burning and that only traction or irritation of the parietal peritoneum could cause abdominal pain. In 1911 Hurst demonstrated that distention of any hollow viscus is painful. Ryle amplified this by emphasizing that contraction of smooth muscle of hollow viscera is adequate to cause pain.

The current and preferable terminology is *visceral afferents* to denote all afferent fibers from the viscera, including those that give rise to visceral reflexes as well as those that subserve pain. The terms *autonomic*, *sympathetic*, and *parasympathetic* are reserved for the visceral efferent fibers.

Pain impulses from the abdominal cavity reach the central nervous system by three routes: from the viscera via visceral afferents that travel with the (1) sympathetic and (2) parasympathetic nerves; and from the parietal peritoneum, body wall, diaphragm, and root of mesenteries via somatic afferents that travel in the (3) segmental spinal nerves or phrenic nerves. Primary sensory neurons for pain, both visceral and somatic, are mostly small (1 to 2 mm) unmyelinated fibers, but with some small (3 to 4 mm) myelinated fibers (Gasser classes C and A delta, or groups IV and III in Lloyd's terminology).

The route of a typical afferent from an abdominal viscus is as follows: The axons of nerve endings in the wall of the viscus follow the artery to the aorta and then through the collateral sympathetic ganglion without synapsing. They then enter the splanchnic nerve, traverse the paravertebral sympathetic ganglion, again without synapsing, and join the spinal nerve via the white ramus communicans. The cell body of this primary visceral afferent neuron is located in the spinal ganglion from which central processes are sent to the dorsal horn of the spinal cord via the dorsal root.

The central processes of the primary sensory neuron synapse with at least three distinct spinal tracts: (1) secondary pain neurons whose axons ascent for two or three segments and then cross in the anterior commissure to the anterolateral spinothalamic tract; (2) secondary sensory neurons whose processes ascend the posterior columns; and (3) many small neurons in the substantia gelatinosa that contribute to the tract of Lissauer. As the secondary sensory neurons ascend, collaterals are given off to the reticular substance, forming the core of the brainstem, and to the hypothalamus. The role of these extraspinothalamic pathways is uncertain; they may be alternative pain pathways, may inhibit central pain responses, or may be involved in the affective aspects of pain. Sensory tracts synapse in the thalamus with tertiary neurons that project to the cortex. The cortical areas involved with pain are not completely known. Stimulation of various areas of the postcentral gyrus in the conscious human being produces contralateral paresthesia of small areas of the body, but even total hemispherectomy does not consistently abolish pain, though localization is defective. The functions of the thalamus in human beings, in contrast to animals, are largely expressed through the cortex, but one function that may have been retained in the evolutionary process is the expression of the affective aspects of sensation. Affectivity, pleasantness and unpleasantness, is considered a primitive function that has remained at the thalamic level despite development of the cerebral cortex.

Though the thalamus and frontal cortex are the principal areas of the brain involved with pain, they cannot be considered *the* brain centers, since the hypothalamus, limbic system, brainstem reticular formation, and parietal cortex also are involved in pain reception. Opiate receptors exist in the brainstem and spinal cord, and naturally occurring opiates are found in the brain and pituitary gland; these are collectively called *endorphins*. Pain relief from low-frequency electrical stimulation exerts its effect by increasing these endorphin levels, an effect that can be blocked by the opiate antagonist naloxone.

Abdominal Pain

Visceral Pain

The visceral peritoneum has no somatic pain fibers and is innervated only (inadequately, at best) by autonomic C-type fibers. C fibers are slow transmitters; the sensation reported is dull, poorly localized pain, gradual in onset and longer in duration. These fibers are normally insensitive to stimuli that produce pain when applied to the skin, but respond to a limited number of noxious stimuli. These include changes in diameter of a hollow viscus, including distention and tension, e.g., rhythmic tension that is perceived as cramping. Spastic contraction, stretching of the capsules of solid viscera, ischemia, and certain chemicals also produce visceral pain. This perception of pain often is so poorly localized that it is of only limited value in determining the nature of the disturbance.

The role of chemical substances in visceral pain is not clear. Experimentally, pain can be produced by the intraarterial injection of acid, alkaline, or hypertonic solutions (lactate, potassium ions, or bradykinin). Potassium released from cells by injury or ischemia has long been known to be pain-producing, and some suggest that the release of intracellular potassium ions may be the actual physiologic stimulus for pain. Some pain receptors have been classified as chemoreceptors, and the pain of ischemia has been attributed to increasing concentrations of hydrogen ions. The pain of inflammation is thought to be caused by the accrual of algescic bradykinin peptides that activate pain receptors more or less selectively. The bradykinin effect is facilitated in the presence of prostaglandins, and it is this mechanism that is inhibited by aspirin.

Visceral pain is diffuse and poorly localized, has a high threshold, and exhibits an exceedingly slow rate of adaptation. The high threshold and poor localization are partially attributable to the relatively sparse distribution of sensory endings in the viscera. The pain is felt by the patient to be “deep” in those cutaneous areas or zones that roughly correspond to the segmental distribution of somatic sensory fibers that originate from the same segments of the spinal cord as the visceral afferent fibers from the viscus in question.

With severe visceral or deep somatic pain, concomitant responses, presumably due to autonomic reflexes, may be prominent. These include sweating, nausea (sometimes with vomiting), tachycardia or bradycardia, fall in blood pressure, cutaneous hyperalgesia, hyperesthesia or tenderness, and involuntary spastic contractions of abdominal wall musculature. The muscular rigidity accompanying severe pain is most marked when the body wall is involved by the pain-inciting lesion, e.g., the boardlike rigidity associated with perforated peptic ulcer. The distribution is regional rather than segmental, and it involves sustained reflexes in several segmental nerves. Maintained muscular rigidity may become painful, so that occasionally the deep muscular tenderness outlasts and outweighs the original visceral pain.

The parietal peritoneum and the abdominal wall are innervated by somatic pain fibers. These A-delta fibers are distributed not only to the parietal peritoneum but also to muscle and skin, and they transmit sharp, well-localized pain sensations of limited duration to the spinal nerves. Pain from these locations yields information that localizes well and that may vary in character depending on stimulus. Zachary Cope first emphasized that the pelvic peritoneum has no significant pain fibers, and significant disease can occur in the true pelvis without pain detection.

Unreferred Visceral Pain

The location of the noxious stimuli from various portions of the gastrointestinal tract influences the type of pain reported. Abdominal viscera are innervated by afferent autonomic innervation bilaterally, and visceral pain usually is perceived as midline. Exceptions include the kidneys, ureters, cecum, and ascending and descending sigmoid colon, which are unilaterally innervated. The pain is poorly localized because most viscera contain multisegmental innervation and few nerve endings compared to the skin. The characteristics of the pain are gnawing, cramping, and associated with nausea, sweating, vomiting, perspiration, and pallor. When the nociceptive stimulus is intense, the pain also is referred to the skin and deeper somatic tissue. The midline location is the result of the embryologic development of the gut. Midline (epigastric, periumbilical, and hypogastric) pain is caused by a wide variety of diseases, each of which is localized to its corresponding dermatome on the basis of embryologic development. Since the gastrointestinal tract comprises a foregut, midgut, hindgut, and cloaca, each develops its own separate embryologic blood supply and innervation.

Epigastric pain is a characteristic of a foregut disturbance. The foregut is that part of the digestive tube extending from the oropharynx to the duodenum, generally terminating at the entrance of the common bile duct at the junction of the second and third portions of the duodenum, and it includes the liver, biliary tree, pancreas, and spleen. Midepigastric pain also can result from pylorospasm, a nonspecific reflex response to any disturbance in the abdominal viscera, from appendicitis to the prodrome of epigastric pain that may be a harbinger of carcinoma of the colon. Midgut pain is manifested as periumbilical pain. The midgut comprises the distal duodenum, jejunum, ileum, appendix, and ascending colon as well as the proximal transverse colon vascularized by the superior mesenteric artery. Lower abdominal or hypogastric midline pain, especially cramping pain, reported as transverse across the lower abdomen, is a manifestation of hindgut pain. The hindgut comprises the remainder of the colon and rectum down to the cloaca, and endoderm-lined cavity giving rise to the anorectal canal, and is in direct contact with the surface ectoderm at the level of the dentate line.

Suprainguinal pain is an important and highly reliable differential sign. It often is seen in the female and rarely in the male, and it almost always indicates gynecologic inflammation or disease. It sometimes is associated with hyperesthesia immediately above the inguinal ligament. Pain in this location probably is a result of stimulation of the parietal peritoneum

just above the true pelvis, because the parietal peritoneum within the true pelvis transmits no pain sensation. With a purulent inflammatory process involving the fallopian tubes or the uterus, pain and tenderness perceived in the suprainguinal area usually are present.

Referred Visceral Pain

This is more localized than true visceral pain. It is localized to the dermatomes and myotomes that are supplied by the same spinal cord segments as the affected viscus. For example, distention of the intestine with a balloon causes a vague, aching, poorly localized discomfort at first, but with greater distention the pain is referred to the abdominal wall and the back.

Parietal Pain

Unreferred Parietal Pain

Unreferred or local parietal pain occurs when the inflammation of the viscus involves the adjacent nociceptive fibers of the parietal peritoneum. The pain is localized in the body wall directly over the site of the inflammation, such as in the localized pain of acute appendicitis at McBurney's point.

Referred Parietal Pain

This is characterized by pain felt in an area remote from the site of the nociceptive stimulation. A classic example is Kehr's sign (left shoulder pain) with traumatic rupture of the spleen.

Perception of Stimulation

Stimulation of the visceral peritoneum usually does not result in pain in a normal sense; only distention, contraction, torsion (probably as a result of ischemia), and occasionally certain chemicals or other inflammatory agents result in pain. The neural receptors for the transmission of these perceived noxious stimuli are supplied by autonomic nerves (sympathetic and parasympathetic) and are located within the walls of the hollow organs or on the serosal structures, such as the capsules of solid organs. Visceral pain may or may not signal the need for surgical therapy. The pain of intestinal ischemia, for example, perhaps perceived by sustained contraction of the intestinal wall musculature and intramesenteric receptors associated with large mesenteric vessels, signals the need for surgical intervention, whereas gastroenteritis with severe cramping does not.

The response of the visceral receptors also reflects the state of the adjacent serosa and mucosa. A good example is the gastric mucosa; acid or food touching a noninflamed gastric mucosa does not result in pain. If the mucosa becomes inflamed, however, as in alkaline reflux gastritis, food ingestion results in significant pain.

Pain arising from the parietal peritoneum is mediated principally by somatic nerve fibers that transmit through the posterior tracts of the spinal cord. Even if fibers cross, pain can be localized and usually is limited at least to one of the four quadrants, and often is considerably more focused. These nerve endings are stimulated by chemical irritants, changes in pH, inflammatory mediators, and probably by local transudation of bacteria and products of polymorphonuclear leukocyte destruction. When a somatic component is added to visceral pain it is likely that surgical intervention will be necessary.

One type of pain associated with gastrointestinal disease is a direct result of neural infiltration. The back pain associated with pancreatic cancer, or infiltration of the celiac axis and left gastric nodes by gastric cancer are examples of severe, unrelenting pain resulting from direct invasion of pain-transmitting nerves. This type of pain makes operative intervention likely, if only for pain relief. In pancreatic cancer severe, persistent back pain usually indicates unresectable disease, because of the size of the tumor, invasion of adjacent structures, or lymph node metastases.

The various causes of gastrointestinal, intraperitoneal, and abdominal pain are outlined in Table 22-1. Pain of intraabdominal origin may emanate from the peritoneum, hollow intestinal viscera, solid viscera, mesentery, or pelvic organs and can be caused by inflammation, mechanical processes such as obstruction and acute distention, and vascular disturbances. The extraperitoneal causes of abdominal pain are listed in Table 22-2. The intrathoracic causes of upper abdominal pain are confusing, because their segmental distribution is similar to that of the referred pain from abdominal pathologic conditions, but they usually are not accompanied by tenderness or muscular rigidity. Inflammation of peripheral nerves, as in herpes zoster, may be painful before the lesion becomes apparent.

Referred Pain

Referred pain is the result of afferent neurons that innervate two entirely separate, anatomically distinct structures that have a common embryologic origin. Three common examples of referred pain in gastrointestinal disease are the fourth cervical nerve route, the sixth to eighth thoracic nerves, and the tenth thoracic nerve route. The parietal peritoneum of the diaphragm, the area around the shoulder, and the supraclavicular hollow are innervated by C4. Pain under the left diaphragm is manifested as left-shoulder pain (Kehr's sign) and occurs secondary to a ruptured spleen or pancreatic inflammation. Right supraclavicular pain can be caused by blood or bile under the right hemidiaphragm. The thoracic afferents of T6–T8 that innervate the right subscapular area also innervate the biliary tree, liver, and peripancreatic area. The pain at the tenth thoracic nerve route usually is the result of irritation to the kidney or ureter and is usually manifested as flank and genital pain, and classically as testicular pain in the male. Pain referred to the labia in the female is far less common but may occur with renal colic. Possible sources of referred pain are listed in Table 22-3.

Acute Abdominal Pain Clinical Manifestations

The nature of the onset of pain is critical to the diagnosis (Table 22-4). Sudden onset of abdominal pain is more likely to result in operative intervention, because it usually is the result of perforation, volvulus, passage of a stone or other obstructing material in a hollow viscus, or embolization in the arterial supply of a hollow viscus. Gradual onset of pain usually indicates an inflammatory process or a slower progressive obstructive process. The relationship of other symptoms to the onset of pain also is important to the diagnosis. Acute onset of pain followed shortly by nausea and vomiting suggests high intestinal obstruction following a volvulus. Nausea and vomiting 6 to 12 h after the onset of pain suggests a site of obstruction lower in the gastrointestinal tract, and pain of even longer duration suggests colonic obstruction secondary to neoplasm, diverticulitis, or volvulus. Inflammation in the foregut or midgut often is followed by anorexia, nausea, or vomiting because of the sensory afferents that are carried by vagal fibers, and hindgut inflammation usually is not associated with these symptoms unless complicated by luminal obstruction. Conversely, anorexia, nausea, and vomiting that precede the onset of pain generally indicate a disease process that does not require operative intervention.

The character of the pain also is important. The patient may describe pain as pressure, sharp pain, dull steady pain, or crampy pain. Each suggests a different type of disease process. Epigastric pressure, particularly in the upper epigastrium, raises the suspicion of myocardial ischemia, reflux esophagitis, gastric distention, or inflammation. Colicky pain in the right upper quadrant radiating to the subscapular area suggests a stone in the cystic or common duct; back and flank colicky pain radiating to the labia or to the testicle in the male suggests a stone in the ureters (Fig. 22-2).

It is important to note what aggravates the pain (Table 22-5)—posture, bodily functions such as eating, moving the bowels, passing gas, vomiting, etc. Patients with significant peritoneal irritation do not move; they lie still, legs flexed, to avoid aggravating the pain by sudden movement. Patients with ureteral colic often writhe, moving around more with the exacerbation of pain.

The progression of the pain with time is important; is the pain becoming more severe, or is it subsiding? Referral of the pain might give a clue to the anatomic area and the nature of the process. Changes in location and severity with time also are important. The relationship between the onset of abdominal pain, especially lower abdominal pain, and the menstrual cycle should be noted. Previous episodes or whether any family members have had similar episodes should be determined. The nature of the medications taken by the patient, including any medications taken in an attempt to relieve the pain, should be elicited. Patients often do not think of acetaminophen or aspirin, for example, as medications that should be reported.

Different inflammatory processes occur in different age groups. Acute colicky pain is suggestive of intussusception in young children. Cholecystitis is most commonly seen in the 20-to-40-year age group, and diverticulitis rarely occurs before age 35, although it is increasingly seen in younger patients.

Physical Examination

Probably the most important aspect of the physical examination is a general visual assessment. Is the patient sick? What is the breathing pattern? Are the nares flaring? Is the patient experiencing tachypnea? Is the facies drawn, tense, with sunken eyeballs, implying dehydration or acute volume loss? The patient's chest and abdomen should be undraped for observation. Slanting light from across the bed or examination table may reveal rib retraction or the splinting of one side of the chest. Right upper quadrant movement may be inhibited in acute cholecystitis. The patient's response to pain is an important clue. Is the patient still or writhing? In breathing, do both sides expand, or is there limitation on one side, suggesting peritoneal irritation?

Inspection

A scaphoid abdomen is unlikely to harbor significant acute disease. A diseased abdomen is most likely to be distended. The abdomen should be inspected in indirect light for bulges or other irregularities in the abdominal wall pattern. In thin individuals it is possible to see a ladder pattern if there is intestinal obstruction or masses indicating neoplastic disease, volvulus, etc. The ventral, inguinal, and femoral regions should be evaluated for the presence of hernias.

Examination of the chest anteriorly and posteriorly in a good oblique light enables the physician to evaluate movement of the ribs. The chest should be inspected for movement of equal excursions on a deep breath (Fig. 22-3). There should be an attempt to elicit tenderness in the supraclavicular area (C4) or subscapular area (T6–8), in the area where the pain is referred. If the pain is referred from a thoracic structure, there will be no tenderness, but occasionally there is hyperesthesia. Additional examination should be performed for pleural fluid, tactile fremitus, or egophony. Percussion of diaphragmatic movement is performed. A normal diaphragmatic excursion, even in a smoker, is 4 to 6 cm. In pneumonitis, referred abdominal pain may mimic cholecystitis or pancreatitis (see Table 22-3).

Auscultation

Auscultation of the lungs should be done to identify any crepitus in the lung fields or mediastinum, rales, or bronchial breathing. Auscultation of the abdomen is performed before percussion or palpation to avoid any alteration in peristalsis by palpation. Stethoscopes are not all equally suitable for abdominal auscultation. Stethoscopes designed for cardiac auscultation, for example, are not ideal for evaluation of bowel sounds. Stethoscopes should be warmed before use. The stethoscope can be used to evaluate tenderness because the patient is distracted.

Examination should determine whether bowel sounds are present. If bowel sounds are not heard within 1 min over various parts of the abdomen, the conclusion is that the patient has "no bowel sounds," which usually means profound ileus, hypokalemia, hypomagnesemia, narcotic overdose, peritonitis, or mesenteric thrombosis. If bowel sounds are heard, are they hyperactive or hypoactive? Hypoactive bowel sounds may result from hypokalemia, inflammation, and ischemic bowel. In the early stages of diverticulitis, when obstruction

is prominent and peritonitis is not, bowel sounds tend to be hyperactive. After arterial thrombosis or embolus bowel sounds are very hyperactive, and they become hypoactive as bowel viability is impaired. Bowel sounds also may be correlated with cramps, nausea, or vomiting.

Percussion

Percussion is less important in abdominal evaluation, but it may be useful in identifying areas of localized or referred rebound pain. Percussion distinguishes between gas and fluid causes of distention. Ascites is determined by percussing areas of dullness, and shifting dullness, with changes in patient position. A “fluid wave” is elicited by pressing vertically on the midabdomen and tapping the flanks. If there is suspicion of ascites, the stigmata of liver disease or neoplastic disease, including a prominent abdominal venous pattern, umbilical hernia, caput medusa, palmar erythema, spider angiomas, Dupuytren’s contracture, testicular atrophy, rhinophyma, etc., are confirmatory.

Palpation

Palpation of the abdomen should be directed by the history as well as the physical findings noted on inspection, auscultation, and percussion. Examination of the abdomen should proceed in a systematic fashion. A light touch is essential. Palpation should include all sites of possible hernia—inguinal, femoral, or umbilical. If an acute inflammatory or other process is suspected, examination should begin away from the pain and the painful quadrant examined last. Once a painful or tender area is palpated, the abdominal wall may spasm, making additional information difficult to obtain. If the significance of the tenderness is uncertain, the patient should be distracted while palpation continues.

Rebound tenderness indicates inflammation of the parietes of the abdominal wall by an adjacent viscus. Rebound tenderness is subjective. Rebound tenderness also may be elicited by having the patient breathe deeply, cough, or by striking the bed suddenly. Indirect rebound tenderness—palpating another area of the abdomen and letting go, with increased pain in another quadrant—usually indicates significant intraabdominal surgical disease. In advanced stages of peritonitis, “boardlike rigidity” can occur. This regularly occurs in patients with perforated peptic ulcer. The rigidity of perforated diverticulitis with generalized peritonitis is unlike, and less severe than, the boardlike rigidity of a perforated ulcer.

Hyperesthesia over the involved area usually corresponds to the involved intraabdominal viscus. Hyperesthesia in the right lower quadrant may be present in patients with appendicitis. Hip flexion (psoas sign) indicates a retroperitoneal abscess or invasive neoplasm. With deep but gentle palpation, a mass may be appreciated. Bimanual pelvic and rectal examinations, with stool samples examined for occult blood, are routine components of examination of the abdomen.

Laboratory Evaluation

Laboratory evaluation should include white blood cell count and differential, especially the number of polymorphonuclear leukocytes and immature polymorphs (bands), the number of eosinophils, which may indicate an allergic reaction, and mononuclear cells and lymphocytes, which may suggest a viral or tubercular process. Urine is examined for red blood cells (calculi), white blood cells (infection), diabetes mellitus, and porphyria. In the female of child-bearing age, b-HCG or other accurate pregnancy test is essential. Blood urea nitrogen (BUN) and creatinine elevation indicate dehydration, hypovolemia, or upper gastrointestinal bleeding (elevated BUN). In patients with epigastric pain, amylase, lipase, and liver chemistries are essential to rule out pancreatic and biliary disease. In suspected pancreatitis, a lactic dehydrogenase (LDH) study should be added for prognostic purposes (Ranson’s criteria) as well as tests for calcium and phosphorus. In African-American patients, the status of sickling should be determined. An electrocardiogram may reveal a myocardial infarction that might mimic reflux or cholecystitis.

Radiologic Examination

An upright anteroposterior and a lateral chest x-ray and an upright and a supine abdominal film constitute the usual standard. In addition to reviewing all the bony structures, the diaphragmatic sulci should be examined for evidence of fluid and the lung parenchyma for evidence of a pneumonic process or neoplastic disease. The bowel should be evaluated for abnormal amounts of intraluminal air. Proceeding from the upper abdomen, the gastric bubble (the amount of fluid in the stomach) as well as the thickness of the gastric wall should be evaluated. If the gastric wall between the diaphragm and the gastric air bubble is thick, gastric neoplasia should be suspected. Biliary air suggests gallstone ileus or a previous biliary tract procedure. The thickness of the small bowel wall, the presence of fluid within the bowel, a stepladder pattern, biliary calculi, pancreatic calcifications, ureter calculi, vascular calcification, and fecaliths should all be ruled out. Properitoneal fat lines should be present, and their obliteration provides evidence of inflammation. Obliteration of pelvic lucent fat lines also suggests fluid or inflammation.

Ultrasonographic examination of the acute or posttraumatic patient is rapidly becoming the province of the surgeon, because it is noninvasive, easy to perform, readily available at the bedside, and reproducible. Ultrasonography is useful in evaluating suspected pancreatic or hepatobiliary disease. Gallstones, dilated ducts, liver tumors, ascites, edematous pancreatitis, and complications such as phlegmon, abscess, and pseudocyst are apparent in ultrasonographic examination. In patients with blunt abdominal trauma a focused abdominal sonogram for trauma has been reported to have a sensitivity of 93.4 percent, a specificity of 98.7 percent, and an accuracy of 97.5 percent in detecting hemoperitoneum and organ injury. In the patient with ambiguous clinical findings, ultrasonography can diagnose appendicitis or diverticulitis. Ultrasonography is particularly helpful in identifying gynecologic abnormalities that can mimic gastrointestinal inflammatory processes. Bedside ultrasonographic evaluation of the abdomen in patients with suspected bowel obstruction is as sensitive and more specific than plain roentgenograms in identifying a specific point of obstruction.

Computerized tomography (CT) scanning of the abdomen often is helpful, but it requires oral or rectal contrast agents, which the examiner may be reluctant to administer, particularly when there is any question of perforation. CT is very accurate, however, in demonstrating small-bowel obstruction and may be the technique of choice, particularly when extraluminal abnormalities are suspected or when prompt intervention is required. Magnetic resonance imaging (MRI) has proved useful in some situations.

The administration of a water-soluble contrast enema usually can be performed safely in the acute phase of diverticulitis, e.g., CT of the abdomen and pelvis with oral, intravenous, and water-soluble rectal contrast. Routine administration of rectal contrast in the patient with suspected diverticulitis is discouraged. CT scanning can identify diverticulitis and serve as a guide to percutaneous drainage of diverticulitis-associated abscess (Fig. 22-4). Arteriography or digital subtraction venography may be required in cases of suspected intestinal ischemia. Paracentesis for fluid or blood, laparoscopy, culdoscopy, and culdocentesis are useful adjuncts, and celiotomy is, in some cases the definitive diagnostic procedure.

Surgical Decision Making

The diagnosis is made primarily by the history. Physical examination is confirmatory. Laboratory examinations are confirmatory of the presumptive diagnosis based on the history and physical examination. Laboratory tests are focused, depending on the suspected diagnosis. The nature of surgical decision making, especially in the acute abdomen, is that it does not require a specific diagnosis, but a plan of action. Surgical decision making consists of (1) presumptive diagnosis, (2) indication for operation, (3) timing, and (4) approach.

In some cases of acute abdomen, symptoms can be masked, particularly in the pediatric population (Table 22-6), the elderly, those on steroids, the immunocompromised (Table 22-7), and patients who do not mount a normal inflammatory response. In the immunocompromised patient and in elderly patients who are unaware of their surroundings and do not have family, ethical issues arise. Patients in a prolonged vegetative state who have no interested family pose ethical problems. Patients with functional complaints, with psychologic abnormalities, those habituated to drugs, or patients who want an operation (Munchausen syndrome) should not be operated on.

Intermittent and Recurrent Pain

Various hematologic disorders can produce abdominal pain as part of their symptom complex. The majority of those disorders include pain as a prominent feature during a “crisis” only. Throughout their lives, patients with sickle cell disease are plagued by recurrent painful crises.

Autoimmune hemolytic anemia, thrombotic thrombocytopenic purpura, and other hemolytic disorders can begin abruptly and cause moderate to severe abdominal pain. The accompanying muscular spasm and rigidity may simulate an acute surgical emergency.

Chronic hemolytic anemias, hereditary spherocytosis, thalassemia, and glucose 6-phosphate dehydrogenase (G6PD) deficiency can cause abdominal pain. Clinical manifestations relate to the occurrence of crises, anemia, jaundice, splenomegaly, and cholelithiasis. This group of patients commonly has mild to moderate enlargement of the spleen. In some patients, symptoms of cholelithiasis or cholecystitis are the initial manifestation of a hemolytic crisis.

Acute intermittent porphyria is a dominantly transmitted inherited disorder that can exist in latent form indefinitely or present as an acute attack of neurologic dysfunction precipitated by various environmental and endogenous factors. The basic enzyme defect in this disease is a 50 percent decrease of uroporphyrinogen synthetase. Consequently, d-aminolevulinic acid, porphobilinogen, and uroporphyrinogen are produced in excess by the liver and excreted in the urine. An attack is precipitated by one of four factors: drugs, starvation, sex hormones, and infection. Drugs implicated include barbiturates, sulfonamides, phenytoin, griseofulvin, meprobamate, among others. Starvation and crash dieting precipitate attacks of porphyria. This is because of the ability of glucose and certain other carbohydrates to normally block the induction of hepatic d-aminolevulinic synthetase.

Acute attacks result in mental or abdominal neurologic symptoms. Symptoms of an acute attack result from nervous system damage. Any part of the nervous system can be involved; the specific clinical findings depend on the areas affected. Symptoms rarely occur before puberty. Abdominal pain frequently is the initial and most prominent symptom of the porphyric attack, occurring in about 95 percent of the patients. The pain can be moderate but often is severe and cramping or colicky, and it is typically localized in one of the lower quadrants or in the periumbilical region, with radiation to the back or flanks, but may be felt throughout the abdomen. Vomiting, constipation, and mild abdominal tenderness are common. The pain might result from autonomic neuropathy that causes disturbed gastrointestinal motility or alternating areas of spasm and dilatation. Other autonomic manifestations include labile hypertension, sinus tachycardia, postural hypotension, and sweating.

Chronic Pain

The pain pattern in patients with chronic abdominal pain can provide important diagnostic clues. Bouts of pain with entirely normal intervals usually are explained by a discrete intermittent disorder of physiology. Examples include acute intermittent porphyria, internal hernias, endometriosis, and, occasionally, choledocholithiasis. Chronic abdominal pain that is persistent usually is due to a clear pathophysiologic abnormality, such as chronic pancreatitis or pancreatic or colonic malignancy. Other cases of chronic abdominal pain may have no specific pathophysiologic abnormality. Nonulcer dyspepsia and irritable bowel syndrome are examples.

Pain arising from the abdominal wall frequently is misdiagnosed. Specific diagnoses include iatrogenic peripheral nerve injuries, hernias, myofascial pain syndromes, the rib tip syndrome, abdominal pain of spinal origin, and spontaneous rectus sheath hematoma. Carnett’s test is performed by palpating the abdomen of the supine patient in the usual way. With the palpating fingers located over the tender spot, the patient is asked to contract the abdominal muscles by raising his or her head from the bed. Once the muscles are tensed, pressure is reapplied and the patient is asked if the pain is changed. If the cause of the symptoms is intraabdominal, the tensed muscles should shield the viscera and result in diminished tenderness. On the other hand, if the source is in the abdominal wall, the pain will be worse or no better.

Many psychiatric disorders are associated with chronic abdominal pain. Diagnoses include primary affective disorders, somatization disorders, psychogenic (conversion) pain,

hypochondriasis, anxiety states, substance abuse disorders, schizophrenia, chronic factitious disorder with physical symptoms (Munchausen syndrome), and malingering.

Intractable Pain

The control of pain associated with diseases that cannot be satisfactorily treated is one of the most challenging and often frustrating problems. Examples are unresectable carcinoma of the pancreas and chronic pancreatitis. Opiate analgesics, if given in sufficient dosage, usually can control abdominal pain, but at the risk of addiction and undermining the patient's ability to function effectively. This probably is the best therapy for a patient with incurable disease and a life expectancy of a few weeks or months, but it should not be used in patients with severe pain from nonmalignant causes with an unpredictable life expectancy. Narcotic addiction before surgery usually compromises the outcome, because an addicted patient continues to be addicted even though pain is relieved by the procedure.

Neurosurgical interruption of the pain pathways, though disappointing at times, is the treatment of choice for intractable pain in properly selected patients with malignancy. Splanchnicectomy and celiac ganglionectomy can control abdominal pain effectively if somatically innervated structures are not involved in the pain-producing process. When both visceral and somatic pain fibers are involved, posterior rhizotomy or tract interruption is indicated. The spinothalamic tracts are usually interrupted, by surgical incision or by injection of sclerosing chemicals, into the spinal cord, a few segments above the segments where the noxious impulses are entering. The interruption also has been done at medullary and mesencephalic levels. After anterolateral cordotomy pain and temperature sensation are lost and proprioception and touch are virtually unimpaired. Paresthesia often replaces pain in the anesthetic areas, and in a significant number of patients, after about 1 year the paresthesia becomes disagreeable and painful. For this reason, root or tract interruption is most useful in patients with intractable pain and a short life expectancy.

For patients with pain arising from areas too great to be controlled by peripheral interventions, prefrontal lobotomy may be considered. Such lesions do not abolish pain but diminish the reaction to pain. The price paid for such relief, however, includes inability to experience pleasure, a flattening of all affect, and development of a more or less apathetic state.

A dorsal column stimulator is commercially available. Impulses arising from electrostimulation of descending dorsal column fibers are used to inhibit, in accordance with the gate-control theory, prolonged small-fiber afterdischarge that is uniquely related to pain. Electrodes are implanted four to eight segments above the pain input. The external transmitter is controlled by the patient. There is a buzzing or tingling sensation below the site of the stimulator, but pain usually is controlled without significant alteration of normal sensory function. Transcutaneous electrical stimulation has been used effectively to control postoperative pain. The results of these forms of therapy are variable.

Fever

Fever is not dangerous unless it is unusually high, e.g., in malignant hyperthermia. Fever may, by raising the temperature, improve host defense activity such as ingestion, killing, diapedesis, and other functions of neutrophils. More commonly fever is an indication of illness such as infection, inflammation, autoimmune disease, and, less commonly, neoplasia. Fever is a normal postoperative event, often a consequence of thermostat reset, heat generation as a response to intraoperative body cooling, and the result of normal cytokine activation and other inflammatory mediators from operative trauma. Persistent fever usually indicates an infectious complication.

Pathophysiology

The inflammatory response activates cytokines that are released locally within the brain or peripherally into the bloodstream and act on the hypothalamus in endocrine fashion. Activated macrophages also liberate pyrogens (interleukin-1, tumor necrosis factor, and interferon). These pyrogens cause an upward resetting of a thermoregulatory apparatus, which in turn triggers two physiologic mechanisms for increasing body temperature: vasoconstriction, which limits heat loss, and increased heat production, manifested by shivering. These two processes, in combination, increase body temperature until the temperature reaches the level required by the new hypothalamic set point. The response to alterations in body temperature is closely linked with behavioral changes. During a febrile episode, a patient might curl up in bed under layers of blankets, as if cold. This is because the patient's temperature, while elevated, is below the thermoregulatory set point. Removing the bed covers to reduce body temperature brings no relief and heightens stress; the preferred approach is to administer an antipyretic at an adequate dosage. The patient will start to sweat and remove the blankets as soon as the set point has been readjusted downward or as soon as the fever breaks.

Behavioral adaptation allows patients to establish what environmental temperature is most comfortable for them. This temperature is called thermoneutrality. Certain groups of patients tend to select an ambient temperature that is much warmer than that preferred by the hospital staff. For example, when burned patients without known infection were placed in an environmentally controlled chamber and allowed to regulate the ambient temperature by means of a bedside remote control, the mean ambient temperature they selected as most comfortable was significantly higher than the temperature selected by normal individuals. When comfortable, the burn patients had significantly higher core and mean skin temperatures than did the normal subjects. These results indicate that in burn patients the thermoregulatory set point is reset upward, probably because of the pyrogens that are produced during the inflammatory process that is associated with the injury. Other hospitalized patients also feel cold at temperatures that normal persons consider comfortable, e.g., persons with large wounds, peritonitis, pancreatitis, sepsis, and multiorgan failure; all have an elevated central set point.

Clinical Considerations

Fevers of gastrointestinal origin usually result from infection within the abdominal cavity, which are either monomicrobial or polymicrobial. Classic monomicrobial infections include biliary tract infections and spontaneous or primary peritonitis. Most cases of intraabdominal sepsis are polymicrobial, including both aerobic and anaerobic bacteria derived from the normal intestinal flora. The infections arise from the leakage or perforation of a hollow viscus within the abdominal cavity. Intraabdominal abscesses require drainage, except for most amebic liver abscesses.

Fever also is a presenting complaint in 50 percent of patients with Crohn's disease. Such fevers are low grade and usually associated with reactivation of the disease and its characteristic symptoms of crampy pain, diarrhea, and abdominal masses. Postoperative fevers are common, occurring in 15 to 30 percent of patients after celiotomy. Only 10 to 20 percent of postoperative fevers are caused by established infections. Common causes include pulmonary complications, urinary tract infections, wound sepsis, and thrombophlebitis. Acalculous cholecystitis should not be overlooked. Fever is the presenting symptom in 75 percent of patients with acute hepatitis from halothane or infectious causes. Occult tumors also present initially with fever. Twenty percent of fevers of unknown origin are secondary to cancers, either primary or metastatically involved in the abdomen. About 5 percent of fevers in patients with neoplasms are related to the tumor and not a complication. The most commonly implicated tumors are hypernephromas, liver tumors, lymphomas, and carcinomas of the stomach, colon, and pancreas.

Anorexia

Anorexia complicates many illnesses. In inflammatory disease, it is not necessarily prognostic; anorexia can occur even in mild illnesses. Anorexia usually indicates a significant degree of inflammation, but it is not necessarily the direct result of inflammation. One common clinical dictum is that if a patient is hungry, the diagnosis of appendicitis is probably incorrect.

Anorexia also complicates various endocrinopathies, including hyperparathyroidism, especially with extreme elevations of calcium, and adrenocortical insufficiency. Anorexia is common in liver disease, presumably through a central nervous system mechanism, probably mediated, at least in part, by a combination of ammonia and *neuropeptide Y (NPY)*.

A common cause of anorexia is carcinoma. In this circumstance, the presence of anorexia carries with it a grim prognosis, because it usually accompanies a significant tumor burden. Tumors that produce anorexia without significant tumor burden include carcinoma of the pancreas and small-cell carcinoma of the lung.

Postoperative anorexia is common and may be associated with a loss of taste, especially in patients with diarrhea whose zinc stores are chronically low. Zinc replacement (220 mg daily) will return taste in 10 days to 3 weeks, and, with it, perhaps appetite. Other than zinc, there is no mechanism for stimulating appetite. This is especially true of patients who have been on total parenteral nutrition or enteral feeding for a prolonged period, and who may have difficulty resuming their oral intake. Some patients find alcohol a stimulant; bringing food from home may be useful in others.

Pathophysiology

The physiologic mechanisms that control feeding and satiety are complex and multifaceted, and involve receptors in both the brain and the periphery that must interact to maintain normal nutrient intake and body weight. Several independent variables have been observed to alter food intake consistently in normal animals, including: (1) changes in glucose utilization rate, (2) changes in the rate of lipid metabolism, (3) alterations in brain and peripheral peptides, (4) imbalance in plasma and brain amino acid profiles, (5) increases and decreases in neurotransmitter activity, and (6) alteration in cytokine levels.

Central Nervous System Control

The hypothalamus is the "feeding center" of the brain. Lesions of the lateral area produce anorexia, and lesions of the ventromedial region cause hyperphagia and obesity. Conversely, electrical stimulation of the lateral and medial areas elicits and inhibits feeding, respectively. Other brain areas are important for the modulation of feeding as well as some degree of neurochemical specificity subserving hunger and satiety. Neurons ascending from brainstem indoleamine and catecholamine nuclei and passing through the hypothalamus appear to be as important as local hypothalamic circuits for the modulation of feeding. The nucleus accumbens and central amygdala contribute to the reinforcement value of food and appreciation of food quality, respectively. Vagal afferents are important for communicating peripheral nutrition-related information from the gastrointestinal tract or from glucose-sensitive cells in the liver. This information begins to be processed in the dorsal nucleus of the vagus, which sends inputs to the nucleus tractus solitarius. After bifurcation in the parabrachial nucleus of the pons, branches of these neurons synapse in the paraventricular hypothalamus or continue in the limbic system to terminate in the central amygdala. This pathway, which includes glucose-sensitive neurons, not only provides for communication between the periphery and the central nervous system but also allows the interaction of several neurotransmitters, neuropeptides, and neuromodulators.

Influences of Peripheral Metabolism

Although pathologic alteration in circulating glucose levels affects nutrient intake, smaller decreases in blood glucose level have been related to the onset of hunger. According to the glucostatic hypothesis of feeding, increased use of glucose should signal satiety, and decreased glucose metabolism is associated with hunger. The degree of control, however, appears to be for short-term regulation only.

Increased lipolysis and oxidation of lipids decreases feeding and produces satiety. This "lipostatic" theory of feeding and satiety is thought to be major controlling factor in the diurnal feeding pattern observed in rats. Fat mobilization and oxidation produces the satiety pattern observed in the light phase of the light/dark cycle, while fat synthesis elicits the dark phase feeding pattern. The discovery of the obese gene protein (leptin) provides a proposed mechanism for modulation of food intake and body weight that is directly related to adipose tissue mass. Since leptin is synthesized in adipocytes, levels of circulating leptin increase as the amount of adipose tissue increases. Elevated circulating leptin concentrations have negative effects on the synthesis and release of hypothalamic NPY, resulting in reduced food intake and increased metabolic rate. Therefore, leptin level may serve as a negative feedback mechanism for long-term body weight regulation. Obese rats and mice appear to produce faulty leptin or to have a deficit in leptin receptors.

Central Nervous System Neurotransmitters

The preponderance of evidence for neurotransmitter involvement in the control of feeding suggests that alpha-adrenergic neuronal activity, particularly in the medial hypothalamic area, stimulates feeding, and increased beta-adrenergic activity causes satiety. Dopamine systems also are involved in feeding, with an *optimal* dopamine input necessary to maintain food-associated reinforcement (perhaps localized in the nucleus accumbens), or the motor activity (perhaps in the corpus striatum) necessary for feeding to occur. Increasing dopamine activity beyond this normal level, however, reduces feeding. Stimulation of dopamine neuronal activity is the primary mechanism of amphetamine- and cocaine-induced anorexia. Elevated activity in serotonin neurons also inhibits feeding; reducing serotonin levels usually increases the amount of feeding elicited by orexigenic agents. Serotonergic systems appear to exert a type of tonic inhibition over feeding circuits, with food intake increasing in magnitude when this inhibition is released by blockade of central serotonergic postsynaptic receptors.

Gamma-aminobutyric acid (GABA) also has been implicated in the control of feeding, with stimulation of GABA-a receptors in the medial hypothalamus or central amygdala eliciting feeding, and GABA-a stimulation in the hypothalamus inhibits feeding. It has been suggested that a GABA- benzodiazepine receptor interaction mediates hedonic aspects of taste and palatability. Alterations in circulating levels of other amino acids elicit rapid and severe hypophagia. Changes in meal pattern and meal frequency have been described in normal rats with exposure to dietary amino acid imbalance, deficiency, and excess. As with GABA, the amygdala appears to be a focal area for the effects of amino acid imbalance on food intake.

Peptides participate in the control of feeding and satiety. Evidence exists for involvement of NPY, endorphins, galanin, *cholecystokinin (CCK)*, *corticotrophin-releasing factor (CRF)*, calcitonin, glucagon, insulin, enterostatin, and bombesin in the control of feeding. NPY, endorphins, and galanin stimulate feeding, and the remaining peptides produce satiety.

NPY is abundant in the central and the peripheral nervous systems, and it is colocalized with norepinephrine. It is the most potent orexigenic agent investigated in rats to date. In particular, carbohydrate intake appears to be under NPY control. Although NPY is localized in several hypothalamic nuclei, the arcuate and paraventricular nuclei have particularly high concentrations of this peptide. Some NPY neurons in the paraventricular nucleus arise from brainstem catecholaminergic sources, but NPY also is synthesized in the arcuate nucleus with projections terminating in the paraventricular nucleus. Hypothalamic NPY levels and messenger RNA expression are altered in normal and pathologic feeding. Genetically obese Zucker rats and experimental diabetic rats, both hyperphagic, exhibit increased hypothalamic NPY concentrations in the paraventricular and arcuate nuclei. NPY message also is elevated in the arcuate nucleus of these rats. Food-deprived rats also exhibit elevated NPY levels in hypothalamic tissue, with tissue concentrations declining with feeding.

Galanin is located in several brain regions, including the hypothalamus, and it elicits feeding when injected into the paraventricular nucleus. This peptide appears to selectively stimulate the intake of fat. Enterostatin, a pentapeptide released during fat digestion, reduces the intake of fat after peripheral or central administration. Endorphins appear to be involved in the control of fat intake, which increases after the injection of beta- endorphin into the paraventricular nucleus, and is reduced after treatment with the opioid antagonist naloxone.

The release of CCK during feeding may serve as a satiety signal. CCK a and b receptors are found in the brain and periphery, but a central location for CCK-induced satiety has not been identified. Localization of CCK a receptors within the nucleus tractus solitarius and the area postrema suggests that CCK-induced satiety may share conditioned taste aversion effects. This phenomenon occurs when a taste is associated temporally with a noxious stimulus.

Apart from their regulation of glucose synthesis, uptake, and metabolism, insulin and glucagon both appear to reduce food intake when administered into the hypothalamus. Although large doses of insulin have been associated with hyperphagia, the increased feeding is because of the extreme hypoglycemia.

CRF has been reported to reduce food intake after its injection into the paraventricular nucleus. This peptide controls the release of adrenocorticotrophic hormone from the pituitary gland and corticosterone or cortisol from the adrenal glands. Adrenalectomy reduces feeding elicited by intrahypothalamic NPY or norepinephrine primarily through removal of feedback inhibitory influences on CRF. A balance of many of these peptides must be maintained for normal control of hunger and satiety.

Cytokines (tumor necrosis factor and interleukins) reduce food intake after peripheral infusion or direct injection into the cerebral ventricles or the hypothalamus. Tolerance to the anorectic effect of tumor necrosis factor develops after continuous intravenous infusion of tumor necrosis factor.

Despite our increased knowledge of feeding and its control, anorexia is a nonspecific symptom, but its presence requires investigation. Inflammatory, neoplastic, and viral diseases of the gastrointestinal tract result in anorexia, as does advanced renal disease, congestive heart failure, and endocrine disorders, such as pan-hypopituitarism, adrenocortical insufficiency, and hyperparathyroidism. Many drugs cause anorexia, but there is no medication that restores appetite.

Cancer Anorexia

It is likely that cancer anorexia results from tumor-induced aberrations of neurochemical mechanisms that normally control hunger and satiety. Anorectic tumor-bearing rats do exhibit significant changes in many of these nutrition-related variables. Although tumor-bearing rats exhibit altered glucose metabolism, including decreased insulin and increased glucagon concentrations in the blood, the glucostatic hypothesis of feeding proposes only short-term regulation of food intake by changes in glucose dynamics. Alterations in insulin and glucagon levels in tumor-bearing rats may be secondary to the anorexia.

Significant aberrations in plasma and brain amino acid profiles have been reported in tumor-bearing organisms. Correcting plasma amino acid alterations by providing diets deficient in histidine, lysine, threonine, and excess in tryptophan did not improve anorexia. Glutamine, citrulline, serine, arginine, and the branched-chain amino acids (leucine, isoleucine, valine) are reduced in the plasma of tumor-bearing rats early in the course of anorexia, while concentrations of alanine and phenylalanine are elevated. The brain amino acid profile of tumor-bearing rats, however, reveals a different pattern, with increases in the concentrations of the large neutral amino acids tyrosine, tryptophan, methionine, phenylalanine, histidine, threonine, and glutamine.

Since tyrosine and tryptophan are precursors for catecholamine and indoleamine neurotransmitters, respectively, the alterations in these amino acids observed in anorectic tumor-bearing rats also may affect neurotransmitter synthesis and metabolism. Increased brain serotonin neuronal activity usually has been associated with satiety. A variety of studies have implicated alterations in tryptophan and serotonin in cancer anorexia, but it appears that these alterations might be the result of anorexia/cachexia, rather than the cause.

Although dopamine metabolism is elevated in the hypothalamus, nucleus accumbens, corpus striatum, and amygdala of anorectic tumor-bearing rats and is normalized when the tumor is resected and normal feeding returns, a variety of dopamine receptor blockers were ineffective against cancer anorexia.

CCK-induced anorexia does not synergize with cancer anorexia, and the absence of increased CCK in plasma and brain of anorectic tumor-bearing rats suggests that this peptide is not a primary mediator of cancer anorexia. CCK levels were reduced in the hypothalamus of anorectic tumor- bearing rats, suggesting possible down-regulation of putative CCK satiety systems in response to cancer anorexia. Endogenous opioid systems have been investigated and no evidence for involvement of endorphins in cancer anorexia has been elicited.

NPY, a very potent orexigenic agent, appears to be dysfunctional in anorectic tumor-bearing rats. NPY is a less potent feeding stimulus in tumor-bearing rats, even before the onset of overt anorexia. Hypothalamic concentrations of NPY are reduced in tumor-bearing rats before the onset of anorexia, and continue to decrease as anorexia develops, while pair-fed control rats exhibit the opposite response. Release of hypothalamic NPY and binding affinity of NPY to hypothalamic membranes taken from tumor- bearing rats is decreased. These and other results strongly point to a dysfunction of NPY feeding mechanisms as one neurochemical mediator of experimental cancer anorexia.

Factors produced by tumor tissue may contribute to anorexia directly or induce alterations in host metabolism that cause anorexia. Glucose and glutamine are primary fuels for tumor. Since anaerobic glycolysis is the principal route of tumor metabolism of glucose, considerable amounts of lactic acid are produced. Metabolism of glutamine by tumor tissue releases ammonia into the circulation. Both of these metabolites contribute to anorexia, and their detoxification also presents a continuous energy drain on the host. Hyperammonemia, in particular, appears characteristic of larger tumor burdens and experimentally may produce anorexia. Patients with large tumors have hyperammonemia.

Cytokines may be involved in tumor-related anorexia/cachexia. Mice transplanted with a xenograft that produced human *tumor necrosis factor (TNF)* exhibited cachexia, while those transplanted with xenografts that did not produce TNF were not cachectic. Treatment of tumor-bearing mice with TNF antibodies delayed but did not prevent the appearance of anorexia. The blood concentrations of TNF are not high enough to be measured in anorectic tumor-bearing organisms, and large doses (relative to endogenous levels) of TNF are required to reduce food intake. Interleukins have been suggested as anorexia-producing candidates.

Weight Loss and Cachexia

Weight loss and cachexia have significant negative prognostic implications. Weight loss of 10 to 15 percent during 3 to 4 months is one of the two prime indicators that a patient may be nutritionally or immunologically impaired.

The history taking should discover whether intake has diminished and, if so, for what reason and to what degree. Anorexia also may have been present. Confirmatory laboratory values include serum albumin levels of less than 3.0 g/dL in the hydrated state and decreased short-turnover proteins (retinol-binding protein, thyroxine-binding prealbumin, and transferrin). A functional history emphasizing the inability to carry out normal functions, such as walking, mowing the lawn, taking out the garbage, etc., should be obtained. Inability to perform these functions has serious negative prognostic complications.

Decreased intake and weight loss may result from obstruction, as in neoplastic disease of the esophagus or stomach. Oral intake may be voluntarily restricted because of postprandial pain generated by eating, as in chronic mesenteric ischemia, or because of postprandial cramps and diarrhea in Crohn's disease. In chronic pancreatitis, intake may be normal, but fat malabsorption can result in weight loss.

Chronic infection also causes weight loss. Examples include tuberculosis, chronic low-grade infection such as a blind-loop syndrome, and an increasingly large group of immune-deficiency diseases such as HIV infection. Patients who have had a transplant also may contract diseases such as cytomegalovirus enteritis, with late complications resulting in malabsorption, diarrhea, and significant weight loss.

Thyrotoxicosis and Addison's disease are associated with rapid weight loss over a short period. Diabetes mellitus may result in weight loss if unrecognized; before the diagnosis is

made, polydipsia, polyphagia, polyuria, fatigue, and weight loss are prominent presenting symptoms in new-onset diabetes.

The most common cause of weight loss is malignancy. Cachexia is commonly associated with advanced malignancy. Up to 70 percent of cancer patients die from the effects of starvation, with infection the final common pathway. Cancer cachexia usually is seen in the late stages of pancreatic cancer and small-cell lung cancer, but cancer anorexia can be an early symptom of localized disease with small tumor burden; the mere presence of cachexia should not be a contraindication to surgery. Cancer cachexia is not always associated with diminished intake, but in many cases intake is decreased. More obvious causes of cachexia in patients with neoplastic disease include obstruction of the esophagus, gastric cardia, or colon. There may be aversions to certain foods.

Weight loss and malnutrition in the elderly population is particularly common, requiring special attention, especially when it results from treatable causes, such as poorly fitting dentures. The elderly may gradually lose weight over time. This is associated with loss of height secondary to osteoporosis, and loss of muscle mass because of decreased exercise and decreased exercise ability. Of patients who present with weight loss, the weight loss is related to illness in about 75 percent, and is of psychologic origin in about 10 percent; 15 percent remain undiagnosed.

Hiccups (Singultus)

Hiccups, or singultus, usually is a transient and benign annoyance but can be quite debilitating if persistent. Hiccups can be a manifestation of an underlying severe pathologic process. They remain a medical enigma, with no known useful function to the organism. The origin of the word “singultus” is from the Latin *singult*, which means “the act of attempting to catch the breath while sobbing.”

The relationship between phrenic nerve irritation and hiccups has been recognized for many years. There is believed to be a hiccup reflex arc. The afferent portion of this arc comprises the phrenic and vagus nerves and the sympathetic chain arising from thoracic segments T6 to T12. The central connection between afferent and efferent limbs of the reflex arc is not ascribable to a specific anatomic location. It appears that the center controlling hiccups is a nonspecific anatomic location between spinal cord segments C3 and C5.

Hiccups have been categorized into those that are benign and self-limited, and those causing persistent or intractable episodes; the latter are more likely to result from a serious pathophysiologic process. Benign self-limited hiccups are caused by gastric distention, sudden changes in ambient temperature, alcohol ingestion, and tobacco use. Intractable hiccups are classified as organic, psychogenic, or idiopathic. The organic causes are divided into central, peripheral, and toxic. The surgeon's interest mostly is in the peripheral causes from phrenic or vagal nerve stimulation or direct diaphragmatic stimulation.

Irritation of the vagus nerve along its course may cause hiccups. In the chest, stimulation may result from trauma, neoplasm, myocardial infarction, pulmonary edema, inflammatory or infectious processes, or intraoperative manipulation of thoracic viscera. Phrenic nerve irritation within the chest caused by intrathoracic inflammation, tumor, infection, or trauma also can lead to hiccups.

A diverse group of abdominal conditions can stimulate the afferent vagal branches, e.g., gastric distention, peptic ulcer disease, pancreatic and biliary disease, bowel obstruction, appendicitis, inflammatory bowel disease, hepatitis, and trauma or intraoperative surgical manipulation. Intraabdominal phrenic nerve stimulation can arise from hiatal hernia, diaphragmatic eventration, subphrenic abscess, neoplastic disease, perihepatitis, and intraoperative manipulation. Several toxic causes are relevant to surgical practice, including anesthetics and drugs such as intravenous steroids, barbiturates, benzodiazepines, and methyldopa. Metabolic causes include acute alcohol toxicity, uremia, hypocalcemia, and hyponatremia.

The treatments of hiccups are diverse. Nonpharmacologic hiccup treatments usually rely on some method of nasopharyngeal stimulation; examples include forcible traction on the tongue, gargling or sipping iced water, swallowing a tablespoon of granulated sugar, grape jelly under the tongue, and inhalation of noxious fumes (ammonia). Direct pharyngeal stimulation with a rubber catheter is reportedly successful in 90 percent of cases. Pharmacologic treatments include administering continuous positive- pressure ventilation at 25 to 35 cmH₂O, chlorpromazine, haloperidol, phenytoin, phenobarbital, carbamazepine, and sodium valproate. Other agents sporadically reported in the literature include metoclopramide, amitriptyline, chloral hydrate, and ketamine.

Symptoms Related to Specific Components of the Gastrointestinal Tract

Esophagus, Stomach, and Duodenum

Heartburn and Dyspepsia

Heartburn and dyspepsia are common, and many normal individuals have experienced heartburn while lying down or bending over after overeating. Gastric capacity is exceeded and reflux occurs, resulting in pain and substernal pressure, at times radiating to the interscapular region, blades, the neck, or the left arm. With more regular occurrence, the patients has gastroesophageal reflux disease.

The esophagus normally is protected from damage by four defense mechanisms: a competent lower *esophageal sphincter (LES)*, rapid esophageal clearing of refluxed material, neutralization of refluxed acid by bicarbonate-rich saliva, and an intact mucosal diffusion barrier. The most common clinical abnormality of esophageal motility is incompetence of the LES. As incompetence becomes more frequent and reflux becomes more voluminous, salivary bicarbonate can no longer keep up and esophageal pH falls. This leads to compromise of the mucosal barrier with damage to the subepithelial structures, especially nerves, with resulting spasm and dysmotility further delaying clearing of the distal esophagus, and relaxation of the LES. This cycle set the stage for additional reflux and the development of esophagitis.

Heartburn usually is described by the patient as a substernal burning, often associated with a bitter taste, and, when severe, frank regurgitation of gastric contents. Approximately 40 percent of Americans (100 million people) experience an episode of heartburn monthly, nearly 40 million experience weekly episodes, and 18 million have chronic daily heartburn. Eighteen percent of Americans (45 million) take some form of nonprescription or prescription medication for this problem, and 1.75 million Americans do not respond to these therapies. Most gastroesophageal reflux dysmotility does not result in any serious long- term sequelae, but esophagitis occurs in approximately 1.1 percent of the world's population and is present in approximately 19 percent of patients undergoing upper endoscopy for upper abdominal symptoms.

Dyspepsia is a nonspecific term given to a collection of symptoms involving the esophagus, stomach, duodenum, biliary tree, and pancreas. Dyspepsia generally is a postprandial complaint involving substernal pressure, epigastric distress, nausea, and bloating. In the case of dyspepsia and heartburn, the symptom is described as substernal pressure. Classic esophageal pain radiates directly through the back between the scapulae. It also can radiate to the left shoulder, to the neck and teeth, and down the left arm, mimicking angina. In 15 percent of patients heartburn and substernal pressure with reflux can be so difficult to distinguish from angina pectoris that coronary angiograms, stress tests, echocardiograms, and other forms of cardiac evaluation, such as multiple gated acquisition (MUGA) scans, may be required. Only 3 percent of patients with dyspepsia have true angina pectoris. Another symptom related to reflux is deep pain immediately under the left costal margin, pointing toward the left shoulder.

If there is serious concern that a patient might be suffering from dyspepsia, the work-up should include cinefluoroscopy, contrast radiography, or an upper gastrointestinal series, endoscopy, and biopsy. If esophageal spasm is suspected, manometry will be helpful in distinguishing among achalasia and other motor disorders, scleroderma, and dysmotility complicating reflux esophagitis.

The relationship of symptoms to eating and other activities may give clues in the diagnosis of dyspepsia. *Duodenal* ulcer pain is relieved by food, particularly protein-containing food, which is a good acid neutralizer. *Gastric* ulcer pain may be provoked by food, and may be slightly more central than duodenal ulcer, which is typically slightly to the right of the midline. In alkaline reflux gastritis with severe inflammation, any food results in pain. Constant nausea and periodic clear bile vomitus without food may be present.

In patients with gallbladder and pancreatic disease, not all foods provoke pain. Classically in patients with gallbladder disease, fried, fatty, or greasy foods, chocolate, and, in some patients, cabbage and turnips, provoke right upper quadrant pain with right subscapular radiation. In patients with chronic pancreatitis dietary indiscretions, such as “fast and surfeit”—that is, gluttonous intake after a period for relative fasting—or alcohol with large meals, may provoke panceratitis, which characteristically is associated with central epigastric or left upper quadrant pain radiating to the center of the back.

Dysphagia

Disturbances in swallowing can be categorized according to the etiologies of degenerative, functional, inflammatory, mechanical (sometimes as a result of inflammatory), autoimmune (or collagen-type), and neoplastic diseases. Additional esophagus-related symptoms include painful swallowing (odynophagia) or the inability to swallow. Either symptom requires investigation. The history taking should focus on whether the pain is entirely new or is associated with previous episodes. An example is dysphagia that follows previous chronic odynophagia secondary to heartburn or to spasm associated with reflux esophagitis. The focus should center on chronic medications (e.g., nonsteroidal anti-inflammatory drugs), dietary habits, and substance abuse, particularly smoking or taking alcohol undiluted by water, because this history is significant in patients with squamous-cell carcinoma of the esophagus. Regurgitation of undigested foul-smelling food or a feeling of a bulge in the neck both suggest Zenker's diverticulum. For causes of dysphagia, see Table [22-8](#).

Pain is almost always due to inflammation or spasm. Spasm may be due to a primary dysmotility disorder (diffuse esophageal spasm), or secondary to chronic inflammation associated with gastroesophageal reflux. Diffuse esophageal spasm may simulate angina pectoris, because it is often precipitated or worsened by stress. When gastroesophageal reflux dysmotility is associated with severe pain and spasm it usually indicates associated ulceration, with at least grade II and perhaps grade III esophagitis. Spasm or substernal pressure also may accompany the dysphagia and nocturnal aspiration from achalasia.

Radiologic examination should be followed by upper gastrointestinal endoscopy. The location of the Z line, its relationship to the diaphragm, the presence or absence of a hiatal hernia or esophagitis and ulceration should be noted. The esophagus should be biopsied and, if Barrett's esophagus is suspected, multiple biopsies at various levels should be performed to evaluate the extent of the metaplasia as well as the presence and degree of dysplasia. The stomach and duodenum should be carefully inspected to make certain that there is no duodenal obstruction. If esophagitis, Schatzki's ring, neoplasm, or reflux are not diagnosed, further studies, including manometry and 24-h pH monitoring are required. Zenker's diverticulum must be ruled out. Even if the esophagitis is severe and reflux symptoms are well established, manometry and 24-h pH monitoring should be undertaken to discern what type of repair is necessary. Other diagnoses that can be clarified include achalasia, in which a large, distended, tortuous esophagus and a spastic sphincter are causes of this symptom. Achalasia initially may be amenable to hydrostatic dilation or to esophago- cardiomyotomy.

The esophagus is the most common part of the gastrointestinal tract to be affected buy progressive systemic sclerosis (scleroderma). This chronic connective tissue disorder is characterized by collagen deposition and atrophy of the smooth muscle of the esophagus, resulting in the characteristic decreased amplitude of contractions of the lower

esophagus and decreased LES pressure, which may lead to heartburn and dysphagia. Lower esophageal dysmotility can occur in association with other connective tissue disorders such as rheumatoid arthritis, Sjögren's syndrome, and mixed connective tissue disease. A distal esophageal web (Schatzki's ring) may be visualized above a hiatal hernia and, when associated with dysphagia, may be amenable to graduated mercury bougie (Maloney) dilation. If nothing is evident on endoscopy, and cinefluoroscopy or manometry suggests diffuse spasm or dysmotility, beta blockers or nitroglycerine can be used if these medications are tolerated without significant side effects. Dysphagia lusoria is caused by an aberrant origin of the right subclavian or pulmonary artery. This rare condition is suggested by the observation of a posterior indentation of the upper esophagus and can be confirmed with angiography.

If neoplasm is diagnosed, further studies depend on its location. CT scan of the chest, mediastinum, and upper abdomen may be useful, and, in carcinoma of the midesophagus, bronchoscopy may be useful. Depending on the extent of the disease seen on CT scan, the presence or absence of celiac or other adenopathy, preoperative chemotherapy and radiotherapy may be useful.

Dysphagia is a relatively common manifestation of psychologic disturbances. Inability to swallow may accompany conversion hysteria, anxiety, and anorexia nervosa.

Nausea and Vomiting

Nausea and vomiting may be related or unrelated to diseases of the gastrointestinal tract. Nausea and vomiting can occur independently of each other, but generally are so closely related that they can be considered together. Whenever any part of the upper gastrointestinal tract becomes excessively irritated, overdistended, or excitable, vomiting may result. In the early stages of such excessive gastrointestinal irritation or distention, antiperistalsis begins to occur. This antiperistaltic wave may begin in the ileum, and a large portion of the intestinal contents may be pushed back to the duodenum and stomach. Duodenal distention is a particularly potent stimulus for vomiting. Impulses from the gastrointestinal tract are transmitted by both vagal and sympathetic afferents to the bilateral vomiting center of the medulla. This center lies near the tractus solaritus at the level of the dorsal motor nucleus of the vagus and controls and integrates the act of emesis. Once the vomiting center has been sufficiently stimulated, motor impulses are then transmitted to the upper intestinal tract via cranial nerves V, VII, IX, X, and XII, and to the diaphragm and abdominal muscles through the phrenic and spinal nerves. The vomiting act results from a squeezing action of the muscles of the abdomen associated with gastric and duodenal contractions along with sudden relaxation of the esophageal sphincters, allowing the forceful oral expulsion of gastric contents. The act of vomiting depends on the coordinated closure of the glottis, contraction and fixation of the diaphragm in the inspiratory position, and closure of the pylorus.

In addition to receiving stimuli from the intestinal tract, the vomiting center receives input from other parts of the body, from higher cortical centers, and from the chemoreceptor trigger zone (CTZ). The CTZ is a small area located near the area postrema bilaterally on the floor of the fourth ventricle. Activation of this zone results in efferent signals that stimulate the vomiting center. Many stimuli activate the CTZ via the dopamine receptors present there. In particular, many drugs (e.g., apomorphine, morphine, digitalis, levodopa, quinidine, acetylcholine, ergot alkaloids, atropine, tartar emetic, ipecac) may directly stimulate the CTZ receptors and initiate activation of the vomiting center. Rapidly changing directions of motion may stimulate receptors in the labyrinthine apparatus, from which impulses are carried via the vestibular nuclei into the cerebellum, then to the CTZ, and finally to the vomiting center, leading to emesis associated with "motion sickness." Higher cortical centers also can stimulate the vomiting center directly after various psychic stimuli, such as distressing visual input, foul odors, and other psychologic disturbances.

Vomiting usually is preceded by the sensation of nausea. Nausea represents the conscious recognition of excitation of an area of the medulla that is closely associated with or part of the vomiting center. The same irritative impulses (intestinal, lower brain, cortical) that lead to vomiting may produce nausea. Nausea often is accompanied by anorexia, skin pallor, perspiration, salivation, and altered autonomic activity, which, when severe, may lead to bradycardia and hypotension (vasovagal response). It appears that only certain areas of the vomiting center are associated with nausea, because vomiting may occur in certain circumstances without any prior sensation of nausea.

Nausea and vomiting are commonly associated with central nervous system (CNS) abnormalities. Reduction of the oxygen supply to the vomiting center has been implicated in the vomiting associated with increased intracranial pressure, anemia, vascular occlusion, shock, and severe pain. Any CNS disorder that leads to an increased intracranial pressure may be accompanied by vomiting. There may be no antecedent nausea. Vomiting usually is sudden in onset and often projectile. Migraine may increase intracranial pressure, followed by an interference of blood flow to the cerebromedullary center and the induction of vomiting. Vertigo associated with acute labyrinthitis or Meniere's disease often is associated with nausea and vomiting. Vomiting commonly accompanies migraine headache and acute meningitis.

In many systemic disorders nausea and vomiting are associated symptoms. These include acute systemic infections, particularly in pediatric patients, acute myocardial infarction (posterior wall), congestive heart failure, and endocrinologic or metabolic illnesses. The vomiting associated with diabetic acidosis, uremia, and Addisonian crisis has been related to changes in electrolyte levels and, more specifically, acidosis and hyperkalemia affecting the emesis center. The vomiting associated with thyrotoxicosis appears to be related to an augmented irritability of the emesis center. The hormonal changes of early pregnancy lead to the nausea and vomiting of "morning sickness" in many women. When extreme and unrelenting, this may lead to hyperemesis gravidarum, and the patient may require hospitalization for intravenous hydration, enteral nutrition, and, occasionally, parenteral nutrition. Pain of any origin may be associated with nausea and vomiting. Inflammatory illness of any sort is associated with a generalized malaise and can trigger nausea and vomiting. Acute inflammatory diseases of the intestine and pelvic organs are associated with nausea and vomiting through visceral reflexes. When the inflammatory illness is associated with gastrointestinal tract disorders, such as appendicitis, cholecystitis, hepatitis, and pancreatitis, nausea and anorexia are prominent.

A wide variety of medications can provoke nausea and moving by central mechanisms. Examples include morphine via the chemoreceptor trigger zone, glycosides (overdosage), or chemotherapeutic agents. A variety of antibiotics, including erythromycin, bactrim, and neomycin, may cause nausea and vomiting by direct effects on the gastrointestinal tract.

Any disturbance within the gastrointestinal tract may cause nausea and vomiting. Inflammation or infectious agents affecting the gastrointestinal tract, neoplastic disease, or mechanical obstruction at any level may lead to acute nausea and vomiting. Malignant tumors of the stomach and obstructing gastric or duodenal ulcers are common causes of gastric outlet obstruction. Obstructing prepyloric or gastric ulcer typically interferes with the propagation of the peristaltic wave and normal rhythmic emptying associated with the opening of the pylorus rather than creating a tight mechanical obstruction. Disturbances in the stomach and inflammation such as in gastritis, gastric and duodenal ulcer, and duodenitis as well as cholecystitis, pancreatitis, and various inflammations of the small bowel, such as viral gastroenteritis, can give rise to nausea and vomiting. Obstruction of the colon and diverticulitis also can result in nausea and vomiting.

The patient with an eating disorder is becoming more common in our appearance-conscious society. If bulimia is suspected, a study indicating a normal gastrointestinal tract should be followed by a referral for psychiatric consultation. The surgeon may be needed for nutritional support in these patients. Symptoms may be related to gastric dysfunction or to small- bowel dysfunction.

Consequences of Vomiting

Nausea and vomiting can produce dehydration and volume contraction, resulting in hemodynamic instability. Elevations of blood urea nitrogen (BUN) and creatinine are late features of such dehydration. Electrolyte changes include subtraction hypokalemia by the vomiting of material relatively rich in potassium and hydrogen ions, resulting in hypokalemic alkalosis.

When hydrogen ion is excreted into the gastric juice, there is a shift of bicarbonate ion into the plasma, and to maintain electric neutrality of the blood, chloride is excreted into the gastric juice. Concentration of bicarbonate in the plasma is augmented by the loss of chloride and excessive sodium in the vomitus. In general, an inverse relation exists between the concentration of hydrogen ion and sodium ion in the vomitus. Even in the achlorhydric state, when vomiting results in a depletion of sodium chloride and potassium chloride, chloride is excreted in excess of the physiologic proportions of plasma, i.e., 145 mEq of sodium and 100 mEq of chloride. As the plasma bicarbonate rises, the body compensates by increasing renal excretion of bicarbonate and reducing the rate and depth of respiration to decrease the respiratory loss of HHCO_3 to maintain the acid/base ratio. These compensatory features may maintain the normal blood pH while the urine is alkaline because of excretion of bicarbonate. Determination of plasma electrolyte levels is only partly informative, because it is dependent upon the relative loss of electrolytes and water and on the solutions ingested.

With continued vomiting, the plasma and extracellular potassium concentration become reduced as a result of the increased quantities of potassium excreted in the urine in exchange for sodium, which in turn is related to the lack of availability of hydrogen ions depleted by loss in the vomitus. Adrenocortical stimulation intensifies the potassium loss and potentiates the absorption of bicarbonate by the renal tubular cell. The extracellular and subsequently intracellular potassium concentrations become reduced, sodium cations shift into the cell, and, in order to conserve sodium an acid urine is formed in the face of generalized alkalosis. This paradoxical aciduria intensifies the alkalosis and sets up a vicious cycle that includes the shifting of more potassium out of the cell in exchange for sodium.

The fluid loss results in reduction in the circulating blood volume, and in time the consequences of starvation such as cellular breakdown of protein and increased renal load of nitrogenous waste products cause a rise in the BUN level. Fat stores are used. Ketone bodies are formed, and since they require sodium for excretion, there is additional depletion of the body stores of sodium.

Acute treatment of hypokalemic alkalosis includes administration of large amounts of sodium chloride-containing solutions, and, once diuresis is established, the addition of potassium until the serum potassium level is increased, allowing the kidney to start excreting hydrogen ion. A somewhat uncommon manifestation of profound depletion and extensive vomiting is paradoxical aciduria; this occurs when the extent of potassium depletion is so great that there is no potassium to exchange for hydrogen, and the kidney will then continue to excrete hydrogen rather than potassium ion, compounding the alkalosis. Therapy with potassium alone may not reverse paradoxical aciduria and must include a disposable cation such as ammonium chloride or arginine hydrochloride in addition to potassium. If this treatment fails, administration of 0.1 N hydrochloric acid slowly through a central vein will trigger urinary hydrogen ion excretion and correction of the alkalosis.

Gaseous Distention, Eructation, and Flatulence

A common presenting complaint from patients with gastrointestinal disorders is intestinal gas. Gaseousness cannot be underestimated as a source of social difficulty to patients. Most of these patients are aerophagics; they swallow too much air when they eat, eat too quickly, or talk too much when they eat. There is little question that some patients have demonstrated physiologic changes in which there is greater sensitivity of the stretch receptors to a normal amount of gastrointestinal gas. This may be part of a more generalized motor dysfunction.

Symptoms and signs include gas, bloating, left shoulder pain (splenic flexure syndrome), borborygmi, bowel sounds that the patient believes are audible in public (and they may be), some nausea, dyspepsia, eructation and flatulence. Hyperactive bowel sounds are the rule. Similar symptoms also are present in the early postoperative period but generally resolve spontaneously in 3 to 4 months. Patients may be reassured and treated symptomatically with activated charcoal or simethicone.

Eructation, or belching, usually is due to aerophagia and is relatively normal after a meal to rid the patient of air associated with swallowing. A variety of foods may increase eructation; although these foods vary among patients, usually they include onions, tomatoes, and peppers. Chronic eructation may be an indication of chronic pathology, but it

remains a voluntary phenomenon. Cholelithiasis, peptic ulcer disease, and esophageal reflux disease may be associated with eructation, which partially relieves the symptoms. Anxiety is part of the syndrome, and belching may become habitual. The importance from a surgical standpoint is to make certain that these patients are not operated on needlessly. Patients who do not have decreased LES sphincter pressure or short LES intraabdominal length should not undergo fundoplication, because the combination of fundoplication and aerophagy will result in the patient's being unable to belch (gas bloat syndrome), causing distress.

Small intestine gas usually is present in amounts of less than 1 L, perhaps as little as 200 mL at any given time. Production of gas ranges between 600 to 800 mL per day, which usually is passed anywhere from 10 to 25 times per day. Components of the expelled gas include nitrogen, oxygen (a major source is swallowed air), carbon dioxide (resulting from bacterial fermentation), and methane (a product of bacterial fermentation). Minor components of intestinal gas, probably less than 1 percent, include the volatile short-chain fatty acids, ammonia, hydrogen sulfide, and various volatile amino acids from which the odor is derived. Distention of the colon may reflect chronic partial obstruction secondary to diverticulitis. The splenic flexure syndrome can be manifested as pain in the left shoulder. Hepatic flexure distention is less common.

Lactase deficiency can result in both eructation and flatulence. Excessive flatulence usually is a result of intestinal dysmotility, such as that preceding diverticular disease, or aerophagia from increased amounts of swallowed air. Diet plays a major role; a trial of dietary therapy, eliminating legumes, beans, cabbages, and similar foods may result in improvement. With suspicion of lactase deficiency, lactose-free milk products can be prescribed, or milk can be eliminated from the diet. In patients with diverticular disease who are taking psyllium seed preparations or other soluble fiber, the contained pectin may result in increased production of methane.

If bacterial overgrowth is suspected, a trial of metronidazole or tetracycline is a reasonable therapeutic test. Activated charcoal, simethicone, or both are given as symptomatic therapy. Newer treatments, such as enzymes to aid digestion of legumes and vegetable products, may be helpful in some patients, but the overall results have been disappointing.

Small and Large Intestine

The fate of ingested food is determined by hormonally and neuromuscularly controlled events. Initial digestion is in the stomach. Hyperosmolar gastric contents will not pass the pylorus, and they must be rendered isoosmotic by secretion, at which point the pacemaker begins to fire. The peristaltic waves move down the greater and lesser curve, with rhythmic opening of the pylorus every 30 seconds, transferring 2 to 4 mL of digested chyme. Total gastric emptying is achieved within 3 to 4 hours, and sometimes sooner. Once in the duodenum, 3 to 4 L of biliary and pancreatic secretions per 24 h are added to the duodenal chyme. Additional secretion of 2 L of succus entericus per 24 h occurs in the small bowel. The digested chyme traverses the small intestine, normally at about 1 inch per minute, and its passage through the entire small bowel is complete in 3 to 4 h. Under normal circumstances, protein absorption is complete within the first 120 cm, and carbohydrate absorption within the first 150 to 180 cm. Water absorption takes place mostly in the right side of the transverse colon, with a net water gain in the colon of up to 1,500 mL per 24 h. The remaining stool is approximately 70 percent water. Elimination occurs 24 to 72 h after food ingestion, depending on composition.

Constipation

Constipation is defined as an abnormal retention of fecal matter, a delay in bowel evacuation as compared to the patient's previously normal bowel habits, or stools that are abnormally hard, diminished in quantity, or relatively infrequent. It is estimated that at least \$400 million is spent on laxatives each year, not including the amount spent on evaluation and investigations of constipation. The public perception appears to be that one regular bowel movement daily is normal. In reality, normal bowel movement frequency ranges from three per day to one bowel movement every third day.

One reason for the lack of regularity in the United States is the low fiber consumption. Because processing carbohydrate removes most of the fiber in our diet, the average daily fiber consumption is less than 20 g, stool and average daily weight is about 200 g. In relatively underdeveloped countries, in which diverticulitis is a medical rarity but volvulus is very common, average daily fiber consumption is 75 g, and stool weight approximately 500 g. Investigation is required for a change in bowel habits, but the findings rarely reveal neoplastic disease. Because diverticulosis is endemic in the United States, with close to 60 to 80 percent of the adult population over 60 years of age probably having significant muscular disorders of diverticulosis, these patients appear in physicians' offices more often than with most other disease states.

Physiology of Defecation

The fecal bolus normally is stored in the sigmoid. When defecation is about to occur, longitudinal peristaltic waves move the fecal bolus into the rectum. At the same time, the circular muscle at the rectosigmoid junction relaxes. The normal reservoir function of the rectum also triggers afferent signals via the hypogastric and pelvic nerves to the cauda equina area and where efferent spinal cord impulses are generated. Abdominal and diaphragmatic muscle contraction and voluntary relaxation of the external sphincter usually accompany normal defecation. The external sphincter is a voluntary muscle that receives input from the conus terminalis.

The central nervous system can cause diarrhea or constipation. Parasympathetic nerves augment intestinal motility, while sympathetic stimulation inhibits bowel movements. Anticholinergics and opiates inhibit motility and defecation, whereas cholinergic agents, caffeine, nicotine, potassium, and vasopressin stimulate intestinal motility.

Etiology

(Table 22-9).

Acute constipation is most often mechanical in origin because of intestinal obstruction of the small bowel by volvulus and incarcerated hernia, or diverticulitis and neoplastic disease of the large bowel. Ulcerative colitis or Crohn's disease may be responsible for stricture. In ulcerative proctitis acute constipation might be the principal symptom. Reflex acute constipation may complicate trauma with a retroperitoneal hematoma. In patients with anal fissures, acutely thrombosed hemorrhoids, or after a rectal procedure, acute constipation is common. In neoplastic disease (such as carcinoma of the sigmoid) or diverticulitis, patients may present with acute obstruction.

Constipation can be a result of psychologic factors, dietary constituents, laxatives and drugs, neurogenic causes, decreased skeletomuscular power, and mechanical factors that are intrinsic or extrinsic to the gastrointestinal tract. Psychogenic constipation may be related to improper training, and the symptom frequently dates from early childhood. The eventual result may be a functional megacolon, which is more common than Hirschsprung's disease. Dietary factors include a lack of bulky foods and the use of laxatives, which leads to overstimulation of the bowel, with eventual fatigue. Decreased muscular power in the skeletal muscles of the diaphragm, abdominal wall, and pelvic floor can cause constipation. Weakness of the diaphragm may be associated with a variety of chronic pulmonary diseases, and weakness of the abdominal wall can occur in pregnancy, in the presence of large, rapidly expanding intraabdominal masses, and in patients with marked ascites. Weakness of the pelvic floor usually is a consequence of pregnancy.

The role of atony of the intestinal muscle is difficult to evaluate and may be of minimal importance. Hypokalemia causes ileus. Collagen and endocrine disorders are thought to be associated with intestinal atony. Neurogenic causes include tabes dorsalis, multiple sclerosis, spinal cord tumors, and trauma. These lesions result in deficient reflex activity or directly destroy or depress the autonomic innervation of the intestine. In Hirschsprung's disease, the neurologic deficit in the myenteric and submucosal plexuses interrupts the peristaltic action to that segment. Factors intrinsic to the gastrointestinal tract that contribute to the symptom of constipation include tumors, fecal impaction, intussusception, and volvulus. The mechanical factor is also implicated at the anal sphincter, when spasm and the voluntary avoidance of defecation because of pain occur in patients with hemorrhoids, fissures, or proctitis. Extrinsic causes include large intraabdominal masses such as ovarian cysts, fibroids, pregnancy, and obstructing adhesions.

Clinical Evaluation

The history should focus on previous bowel habits and subsequent changes. Dietary history is essential. Nausea and vomiting may be present. The nature of the changes in stool caliber, color, consistency, blood, mucus, or undigested fat should be determined. Abdominal distention may be present. Physical and rectal examination may reveal a mass. A stool sample to be tested for occult blood should always be obtained. Rigid or flexible proctosigmoidoscopy may define the presence of inflammation, tumors, or melanosis coli (cathartic dependence). If these studies are unrewarding, radiographic examination with barium enema or colonoscopy is indicated. In all cases of acute intestinal obstruction, barium examinations of the colon are essential to determine whether the obstruction is colonic in origin. The exception is toxic megacolon, in which acute obstipation may be present, and acute diverticulitis, in which it is not necessary to perform further diagnostic maneuvers if the diagnosis is clinically apparent.

Chronic Constipation

Chronic constipation can be caused by congenital disorders, motility disorders, functional problems of the defecatory mechanism in the pelvic floor, specific problems of the elderly, medications, diverticulosis with chronic scarring, and neoplastic disease. An early age of onset suggests a congenital cause such as Hirschsprung's disease, requiring a rectal biopsy. Colonic dysmotility, or slow-transit constipation, is a poorly understood colonic motility disorder that affects mostly young men and women but is increasing throughout the population. Stool markers and transit times may reveal the diagnosis. The constipation of irritable bowel syndrome also contributes to this large catch-all area of diagnoses; alternating diarrhea also may be present in this disorder. In the elderly, prolapse can lead to constipation, and, in a vicious cycle, constipation leads to further prolapse. A variety of pelvic floor abnormalities in the elderly result in significant difficulties with constipation. These include failure of the striated muscles of the pelvic floor to relax on straining, failure of the internal sphincter to relax on rectal distention, pelvic floor laxity, rectal intussusception (occult rectal prolapse), acute rectal herniation (rectocele), or deficient or ignored rectal sensation. Medication plays a major role in chronic constipation, such as in laxative abuse or use of sucralfate (for peptic disorders), anticholinergics, and phenothiazines. Chronic diverticulitis, especially repeated episodes, results in narrowing of the sigmoid and consequent alternating diarrhea and constipation, change in stool caliber, and, in many of these patients, a feeling of tenesmus. On physical examination, there usually is tenderness along the sigmoid colon, which in most patients is easily palpated and feels rigid. The most difficult and most important motility disorder to diagnose is neoplasia; the patient may give a history of chronically increasing constipation, stool guaiac usually is positive, and a mass sometimes is palpable.

Directed laboratory examination should include anoscopy, proctosigmoidoscopy, and colonoscopy or barium enema. If indicated, evaluation of pelvic floor abnormalities should be performed, including electromyography, scintigraphic balloon topography, endorectal ultrasonography, rectal defecography, balloon expulsion, and rectal manometry. Pudendal nerve latency testing may rule out some functional abnormalities. After the diagnosis is made, appropriate therapy can be undertaken, including the repair of pelvic floor abnormalities, discontinuation of certain medications, appropriate operation for diverticulitis or neoplastic disease, rectal biopsy if Hirschsprung's disease is suspected, and changes in diet and medications.

Diarrhea

Because the volume of material secreted by the stomach, hepatobiliary tree, and small bowel is large (5 to 8 L per 24 h), diarrhea can result in hemodynamic instability. Five to 10 million individuals die worldwide of acute infectious diarrhea annually, and most are children.

Pathophysiology

There are at least four major pathophysiological mechanisms that can result in excessive loss of fecal water: (1) luminal secretion of solute or water; (2) exudation, or the loss of protein, blood, and mucus; (3) osmotic retention of water; and (4) abnormal or disordered contact between chyme and the absorptive surface of the bowel.

Secretory diarrhea is the result of stimulation of small bowel or colonic mucosa to secrete rather than absorb fluid. The fluid secreted has the composition of extracellular fluid. After ileal resection, bile acids are not absorbed and enter the colon as dihydroxy bile acids, which irritate the colon and cause secretion. Cholestyramine in patients who have had less than 100 cm of ileum resected is effective in preventing the loss of bile salts and the accompanying decrease in bile salt pool, and reducing the diarrhea. Steatorrhea, as in the pancreatic insufficiency of chronic pancreatitis, or improper mixing of bile and pancreatic juice, such as after Billroth II gastrectomy, also allows fatty acids to reach the colon. Binding these fats with calcium decreases the diarrhea.

Pancreatic islet cell tumors may cause diarrhea by two different mechanisms. Approximately 20 percent of gastrinoma patients have diarrhea-based acid hypersecretion. Diarrhea stops with effective nasogastric suction. The Werner-Morrison syndrome includes watery diarrhea, hypokalemia, and achlorhydria or hyperchlorhydria, and alkalosis. Approximately one-third of the patients have hypercalcemia. Vasoactive intestinal peptide (VIP), prostaglandins, pancreatic polypeptide (a marker for islet cell tumors), and peptide histidine leucine have been implicated as etiologic agents. The syndrome also is called pancreatic cholera. The diagnosis is made by elevations in serum VIP and pancreatic polypeptide levels. VIP secretion may be periodic, and several fasting serum VIP values should be obtained. Resuscitation of these patients before operation is difficult because up to 10 L of potassium-rich fluid may be secreted. Octreotide, a long-acting somatostatin analog, decreases serum levels of VIP and ends the diarrhea. More than half of these tumors are malignant, and most are found in the body and tail of the pancreas. In less than 20 percent of the patients, diffuse islet cell hyperplasia is the cause of the syndrome. If the tumor has spread and is malignant, debulking is indicated. A rare somatostatin-producing tumor may present with steatorrhea as a predominant symptom.

Carcinoid tumors are the most common gut endocrine tumors, constituting 55 percent of gut endocrine tumors and 13 to 34 percent of all tumors of the small bowel. They are rare, with an incidence of 1.5 per 100,000 of the general population. Symptomatic carcinoid tumors generally occur in the ileum, appendix, bronchus, or stomach. Carcinoids of the rectum usually are not functional. Products of carcinoids include largely 5-hydroxytryptamine (serotonin) but also histamine and dopamine, tachykinins including kallikrein, substance P, and neuropeptide K, various peptides such as pancreatic polypeptides, chromogranins, neurotensin, human chorionic gonadotropin, and motilin, and prostaglandins.

Almost 30 percent of patients with medullary carcinoma of the thyroid have a secretory diarrhea that is attributed to increased jejunal water and electrolyte secretory stimulation by high plasma calcitonin levels. Plasma calcitonin levels usually are in excess of 1,000 pg/mL. In extensive disease, basal plasma levels may exceed 2,000 to 3,000 pg/mL. If medullary thyroid carcinoma is suspected and calcitonin levels are normal, calcium and pentagastrin stimulation may elicit high calcitonin levels. Treatment is by total thyroidectomy. In the case of multiple endocrine neoplasia (MEN) syndromes secretion of other hormones may result in diarrhea.

Secretory diarrhea also can be caused by various bacterial toxins such in cholera or shigella infection. The toxins of *Vibrio cholerae* activate adenylyl cyclase of the basolateral membrane of mucosal cells, causing a rise in intracellular cyclic adenosine monophosphate concentration, which results in chloride and bicarbonate secretion into the lumen, carrying water passively with it. Other toxins, such as those of *Escherichia coli* and *Cryptosporidium*, have different mechanisms. Laxative abuse, such as ingestion of anthraquinone cathartics, provokes secretory diarrhea.

Exudative diarrhea results from the copious luminal release of serum proteins, blood, or mucus from sites of inflammation, ulceration, or infiltration. Inflammatory bowel disease, parasitic and bacterial infestation (amoeba, salmonella), and infiltrative disease (lymphoma, Whipple's disease) will produce diarrhea.

Disordered contact between the intestinal contents and the absorptive surface has many causes. Bowel resection or bypass, Billroth II gastrectomy, or motility disorders result in altered exposure time that can impair mixing and shorten contact times, not allowing complete digestion and absorption. Lactase deficiency can result in rapid transit and prevent absorption of nutritional moieties. Abnormal motility, as an intrinsic mechanism or as a result of superinfection, prevents sufficient time or contact for reabsorption of the fluid that is secreted into the bowel.

The causes of diarrhea are summarized in Table [22-10](#).

Clinical Evaluation

The history is important in ascertaining whether this is a new, chronic, or recurrent problem. The frequency of the diarrhea and any associated pain or other symptoms may give important clues. The stool should be evaluated: is it foul smelling, or are there fat globules that float on the water? The relationship to food intake is important. Associated symptoms such as fever, pain, nausea, and vomiting suggest an infectious or inflammatory process. If other individuals in the family or community also have diarrhea, this suggests an infectious cause.

Alternating diarrhea and constipation, with thin, ribbonlike stools and tenesmus, suggests diverticular disease or chronic laxative abuse; cancer and partial obstruction are less likely. Variants of irritable bowel syndrome also may be associated with this history.

Mucus secretion occurs with neoplastic disease, cancer, ulcerative colitis, and Crohn's disease, particularly in conjunction with classic postprandial pain. Tenesmus occurs in ulcerative colitis, rectal cancer, and diverticular disease.

A physical examination can reveal abdominal distention or a mass lesion, suggesting neoplasm or inflammation. The area around the anus should be carefully inspected for perianal fistulas. Examination also might reveal evidence of systemic disease, such as collagen diseases, endocrinopathies including Addison's disease, hypoparathyroidism, or hyperparathyroidism, or medullary carcinoma of the thyroid.

Fever suggests an inflammatory process, and rarely neoplastic disease, except with lymphoma, in which fever is common. Various skin disorders, such as pyoderma gangrenosum or erythema nodosum, and arthritis suggest inflammatory bowel disease. Acanthosis nigricans strongly suggests neoplasm. Digital examination of the rectum may reveal carcinoma, granulomas, lymphogranuloma venereum, diffuse polyposis, stricture, or fecal impaction. Stool should always be tested for occult blood.

General and specific laboratory evaluations should be performed. Since protracted diarrhea results in fluid and electrolyte loss, it can result in hypovolemia, acidosis, renal failure, and death if the patient is not replenished. Hematocrit concentration, white blood cell count, liver chemistry studies, and determinations of levels of electrolytes, calcium, phosphorus, and especially magnesium should be obtained. Zinc is almost certainly depleted in chronic diarrhea, which may result in loss of taste as well as inability to carry out certain essential enzymatic functions; it is difficult to measure, however. Malnutrition also may be present. Replenishment of the patient with chronic diarrhea while the work-up is proceeding may involve not only hydration but also the placement of a central venous catheter for total parenteral nutrition.

Once these examinations have been completed, anoscopy and rigid or flexible proctosigmoidoscopy should be performed to rule out Crohn's disease, lymphogranuloma venereum, amebiasis, and chronic ulcerative colitis. Rectal mucosal friability suggests ulcerative colitis or amebiasis; rectal sparing suggests Crohn's disease. Levels of fecal leukocytes and of *Clostridium difficile* toxin should be obtained. If steatorrhea is suspected, a 72-h quantitative fat excretion should be obtained. Microscopic examination for ova and parasites is particularly pertinent to the diagnosis of infestations, but if *Giardia* is suspected because of recent travel, duodenal aspiration is necessary. If these tests are negative, barium enema or colonoscopy and biopsy are appropriate.

Barium enema or colonoscopy will reveal inflammation, mucosal abnormalities, and villous adenoma with excessive secretion. Colonoscopy can uncover the terminal ileum regional enteritis or, rarely, tuberculous enteritis. Gastrocolic fistula, blind-loop syndrome, or inadvertent gastroileostomy may be diagnosed by upper gastrointestinal series. CT scanning may reveal chronic pancreatitis and pancreatic carcinoma. Laparotomy or laparoscopy are considered a diagnostic procedure. Small-bowel biopsy is indicated in the differential diagnosis of malabsorption syndrome, regional enteritis, Whipple's disease, or lymphoma.

Other diseases that can result in diarrhea include partial intestinal obstruction, Zollinger-Ellison syndrome (in which 20 percent of the patients have diarrhea), endocrine tumors, including those that may secrete vasoactive intestinal peptide, glucagon (in which there is a characteristic migrating rash), somatostatin, and substance P. In the Zollinger-Ellison syndrome, a nasogastric tube will reveal high acid output, and nasogastric suction should result in cessation of the diarrhea.

Treatment

Treatment of diarrhea depends on an accurate diagnosis. *C. difficile* should be treated with vancomycin or high doses of metronidazole. Crohn's disease and ulcerative colitis should be treated with asulfidine or its congeners, steroids, antibiotics, or anti-inflammatories. Nonspecific therapy includes opiate drugs, such as atropine with diphenoxylate, loperamide, paregoric, and probably the most potent of all, codeine. Kaopectate may be helpful. Bismuth subsalicylate (Pepto-Bismol) is effective against *Helicobacter pylori*, which probably does not cause diarrhea, and against some cholera, *E. coli*, and shigella species, which do. Other agents include prostaglandin synthetase inhibitors, such as indomethacin for some of the peptide-secreting tumors, verapamil, and somatostatin, as well as the new families of α_2 -adrenergic antagonists such as clonidine.

Intestinal Obstruction

Etiology

Intestinal obstruction accounts for at least 20 percent of all admissions to a surgical service. More than 9,000 deaths result from intestinal obstruction and operation annually. There are many ways to classify intestinal obstruction, among them extraluminal (including adhesions and neoplastic disease), intraluminal (such as gallstone ileus or stricture), and intramural (such as a Crohn's disease process). It is easier to divide intestinal obstruction into those patients who have had no previous abdominal surgical procedures, and those who have. The importance of previous abdominal procedures is that obstruction of the small bowel secondary to postoperative adhesions makes up 60 to 80 percent of admissions for intestinal obstruction; hernias are a distant second at 15 to 20 percent, and malignant tumors, intramural (which are rare) and extramural (which are far more common), make up 10 to 15 percent of admissions. Among patients who have had no previous operation, obstruction of the esophagus is possible by inflammatory stricture and neoplasm, or functional obstruction, such as achalasia. Obstructing duodenal ulcer comprises a large category of patients. Pancreatic cancer sometimes results in obstruction of the duodenum, although this is rarely a presenting symptom. Small-bowel carcinoma and carcinoma of the duodenum also are relatively rare. In the elderly patient with no previous operation who presents with intestinal obstruction, there is a possibility of gallstone ileus. Crohn's disease results in obstruction from the mass, from acute inflammation, and from an inflammatory or fibrotic stricture. The small bowel or, rarely, the colon may become incarcerated or strangulated in a hernia, and small-bowel volvulus can occur because of a narrowly based mesentery, although this is exceedingly rare. Colonic obstruction most often arises from cancer (60 percent), diverticulitis (15 percent), or volvulus, especially in the elderly.

Patients with previous intraabdominal procedures have a 5 percent incidence of intestinal obstruction secondary to adhesions. This does not increase with the number of previous procedures for lysis of adhesions unless the operation has been unsuccessful or incomplete. Postoperative obstruction usually occurs 4 to 5 days postoperatively, although most of these patients have difficulty from the first postoperative day.

The causes of intestinal obstruction are outline in Table [22-11](#).

Partial Obstruction and Pseudoobstruction

When obstruction is not total, chronic nausea and vomiting can occur. Distention often is present. Localized distention also may occur, such as left upper quadrant distention with gastric outlet obstruction. Bowel sounds reflect amphoric fluid-filled bowel loops when the obstruction is intestinal, or a succussion spasm when the obstruction is at the pylorus or duodenum. Other causes of chronic intestinal obstruction include Crohn's disease and motility disorders, of which the most common are diabetes and postvagotomy gastroparesis, resulting in a functionally obstructed gastropathy and bezoar formation.

Chronic intestinal pseudoobstruction is a heterogeneous clinical syndrome with a variety of causes and clinical presentations. The underlying process involves intestinal motility that is impaired from abnormalities in the intestinal muscle (myopathic) or the nervous system (myenteric neuropathic). Various disease processes may affect muscles and nerves. These diseases usually are diffuse, extending throughout the gastrointestinal tract.

The spectrum of altered motility includes a loss of normal peristalsis and transport, loss of the migrating motor complex, and spontaneous or uncoordinated contractile activity. Myopathic conditions cause hypomotility, with low-amplitude pressure activity. Neuropathic pseudoobstruction, which is far less common, is manifested by excessive uncoordinated activity. The presentation is varied. It may complicate a series of diseases or situations, including endocrine disorders such as myxedema and diabetes mellitus, chronic infection such as cytomegalovirus (especially common in immunocompromised patients) and Chagas' disease, infiltrative diseases such as amyloidosis, vasculitides such as dermatomyositis, progressive systemic sclerosis, systemic lupus erythematosus, various neurologic disorders such as multiple sclerosis, and muscular dystrophy, porphyria, various injuries, paraneoplastic syndromes, and a familial form. In the largest group of patients the cause is not known.

The presentation may be spontaneous or postoperative. Recurrent attacks of nausea, vomiting, crampy abdominal pain, and abdominal distention initially are variable in frequency, intensity, and duration. Constipation and diarrhea may occur. The recurrent episodes become more common until they are chronic, with abdominal distention, bacterial overgrowth, malabsorption, diarrhea, and weight loss. Anorexia may complicate the syndrome. In the postoperative situation, which is potentially the most dangerous, this usually involves patients who have undergone vagotomy or another type of intestinal operation and are thought to be obstructed in the postoperative period. The point of obstruction is never found at reoperation or in radiographic investigations. In the absence of recognition of the true cause, multiple reoperations may take place, often with disastrous results, with multiple enterotomies, bowel resections, leakage, and fistulas, leaving the patient as a small-bowel cripple on permanent total parenteral nutrition, habituated to drugs, and with chronic psychiatric abnormalities.

Early recognition of pseudoobstruction is critical to proper therapy. No specific laboratory studies aid in the diagnosis. One should rule out hypokalemia, hypomagnesemia, and hypoalbuminemia. Other tests include thyroid function tests, antinuclear antibodies, serologic markers, and studies for vasculitis, such as lupus. Manometric studies of the upper and lower intestine can be helpful if the capacity to carry them out exists. Infrequent low-amplitude contractions are characteristic of smooth muscle degeneration, and disordered cluster contractions are characteristic of nervous degeneration. Biopsy of the intestine may or may not reveal loss of myenteric plexi. Full-thickness rectal biopsy may be helpful if Hirschsprung's disease is suspected.

On radiographic examination there is prolonged transit time of barium to the stomach and colon, often as long as 5 h. Fluoroscopy will confirm decreased motility. Radionuclide-labeled pellets confirm the slow transit time and can be used to assess the effects of therapy.

Various drugs can cause pseudoobstruction. Tricyclic antidepressants, opiates, antihistamines, beta-adrenergic agonists, quinidine, and especially amitriptyline should be avoided if possible. Total parenteral nutrition usually is necessary for patients with chronic pseudoobstruction. Operation should be avoided unless a specific site of obstruction has been identified or there is a short segment amenable to resection.

A variety of operations have been proposed, including partial duodenectomy, tailoring of massively dilated segments, total colectomy, imbrication or excision of the antimesenteric border of massively dilated small bowel, and total abdominal colectomy. None of these has shown much efficacy. Radical resection and transplantation have been performed but have not been applied in large numbers of patients. The most successful treatment of idiopathic pseudoobstruction is subtotal colectomy with ileorectal anastomosis at the peritoneal reflection, which has been useful for patients in whom the pseudoobstruction is identified as primarily colonic. Palliative procedures include tube enterostomy, which may be opened periodically, and tube gastrostomy. If a site of obstruction cannot be identified, pseudoobstruction should be diagnosed; the patient should be placed on total parenteral nutrition, bacterial overgrowth (when suspected) should be treated, and no operation should be performed. Cisapride or metoclopramide may provide some relief.

Mechanical Obstruction Pathophysiology

The principal physiologic derangements of the mechanically obstructed intestine with intact blood supply are accumulation of fluid and gas above the point of obstruction and altered bowel motility, which leads to systemic derangements. Death from intestinal obstruction was for many years attributed to "toxins" that were absorbed from the intestine. In 1919 Hartwell and Hoguet were able to prolong the life of dogs with high intestinal obstruction by daily parenteral administration of physiologic saline solution. Gamble later demonstrated that the "toxic" factor in simple mechanical obstruction was the loss of fluid and electrolytes from the body by vomiting and by sequestration in the obstructed bowel.

Accumulation of large quantities of fluid and gas within the lumen of the bowel above an obstruction is progressive. The net movement of a substance across the intestinal mucosa is equal to the difference between the unidirectional flux from intestinal lumen to blood (absorption) and the opposite flux from blood to lumen (secretion). Accumulation of fluid within the bowel, a negative net flux, results if the flux from lumen to blood (absorption) is decreased or if the flux from blood to lumen (secretion) is increased. After 48 h of obstruction, the rate of entry of water into the intestinal lumen increases as a consequence of blood to lumen flux. The findings for sodium and potassium are parallel to those of fluid.

Normal fluxes occur in the direction of blood to lumen, but fluxes from lumen to blood are depressed or abolished in an obstructed ileal segment. As a result, water, sodium, and chloride (and presumably other ions) move into the obstructed intestinal segment but not out of it, distending it with fluid that has approximately the electrolyte composition of plasma.

Wright and associates studied net flux in patients with mature ileostomies. Closed loops were produced by proximal and distal obstructing balloons inserted through the ileostomy. Absorption of a test solution was found to increase at moderate elevations of pressure, but fell below normal at pressure three or four times normal. Conversely, secretion of fluid into the lumen increased progressively as pressure rose. They concluded that increased secretion is the primary cause of fluid loss and distention in intestinal obstruction, with decreased absorption playing a lesser role. Prostaglandin release in response to bowel distention is thought to be the mechanism by which secretion into obstructed loops is increased.

The bowel immediately above the obstruction is the most affected initially. It becomes distended with fluids and electrolytes, and circulation is impaired. With increasing intraluminal pressure, the fluid is dispersed orad until it reaches bowel that is still capable of absorption. When obstruction has been present for a long time, the proximal portions of the intestine also lose their ability to handle fluid and electrolytes, and the entire bowel proximal to the obstruction becomes distended.

A second route of fluid and electrolyte loss is *into* the wall of the involved bowel, accounting for the boggy edematous appearance of the bowel often seen at operation. Some of this fluid exudes from the serosal surface of the bowel, resulting in free peritoneal fluid. The extent of fluid and electrolyte loss into the bowel wall and peritoneal cavity depends on the extent of bowel involved in venous congestion and edema, and the length of time before the obstruction is relieved.

The most obvious route of fluid and electrolyte loss is by vomiting or gastrointestinal tube after treatment is initiated. The aggregate of these losses (1) into the bowel lumen, (2) into the edematous bowel wall, (3) as free peritoneal fluid, and (4) by vomiting or nasogastric suction, rapidly depletes the extracellular fluid space, leading progressively to hemoconcentration, hypovolemia, renal insufficiency, shock, and death unless treatment is prompt.

Much of the distention of the bowel above a mechanical obstruction can be accounted for by the fluid sequestered within the lumen. Intestinal gas also is responsible for distention. The approximate composition of small intestine gas (Table [22-12](#)) shows that the basic composition is swallowed air to which small amounts of gases not found in the atmosphere have been added.

Gases are absorbed from the intestine at rates that are directly related to the partial pressure of the particular gas in the intestine, in the plasma, and in the air breathed. In the case of nitrogen, there is little diffusion, since the partial pressures of the gas are virtually the same in intestine, plasma, and air. On the other hand, carbon dioxide diffuses very rapidly, because the partial pressure of carbon dioxide is high in the intestine, intermediate in plasma, and very low in air. For this reason, though carbon dioxide is produced in large amounts in the intestine, it contributes little to gaseous distention.

With obstruction of the lumen, peristalsis increases in an attempt to overcome the obstruction. After a short time, continuous peristalsis above the obstruction gives way to regularly recurring bursts of peristaltic activity interspersed with quiescent periods. The duration of the quiescent period is related to the level of the obstruction in the gastrointestinal tract; it is 3 to 5 min with high obstruction, and 10 to 15 min with lower ileal obstruction. These muscular contractions may be of sufficient magnitude to traumatize the bowel and contribute to the swelling and edema of the bowel wall. As bowel above the obstruction distends, bowel below the obstruction becomes progressively more quiet. This results from an inhibitory reflex initiated by distention of the bowel above.

Strangulated Obstruction

Occlusion of the blood supply to a segment of bowel in addition to obstruction of the lumen usually is referred to as strangulated obstruction. Interference with the mesenteric blood supply is the most serious complication of intestinal obstruction. This frequently occurs secondary to adhesive band obstruction, hernia, and volvulus.

The accumulation of fluid and gas in obstructed loops and the altered motility seen in simple mechanical obstruction are rapidly overshadowed by the consequences of blockage of venous outflow from the strangulated segment—extravasation of bloody fluid into the bowel and bowel wall. In addition to the loss of blood and plasmalike fluid, the gangrenous bowel leaks toxic materials into the peritoneal cavity. These have been variously identified as exotoxins or endotoxins, or toxic hemin breakdown products.

The consequences of strangulated obstruction are related to several factors. The toxic contents are produced by bacteria. In order for the toxins to have an effect, the mucosa must be disrupted and the toxins must pass into the circulation. Damage to intestinal vessels expedites absorption. Symptoms are a manifestation of the absorbed toxins.

Closed-Loop Obstruction

When both afferent and efferent limbs of a loop of bowel are obstructed, it is referred to as closed-loop intestinal obstruction. This is a dangerous form of obstruction because of the propensity for rapid progression to strangulation of the blood supply before the usual manifestations of intestinal obstruction become obvious. Interference with blood supply may

occur from the same mechanism that produced obstruction of the intestine—e.g., twist of the bowel on the mesentery or extrinsic band—or from distention of the obstructed loop. The secretory pressure in the closed loop rapidly reaches a level sufficient to interfere with venous return from the loop. Widespread distention of the intestine usually does not occur, and so neither does abdominal distention.

Colon Obstruction

The effects on the patient with colon obstruction usually are less dramatic than the effects of small bowel obstruction. Colon obstruction, with the exception of volvulus, usually does not strangulate. Also, because the colon is principally a storage organ with relatively minor absorptive and secretory functions, fluid and electrolyte sequestration progresses more slowly. Systemic derangements are of less magnitude and urgency than in small bowel obstruction.

Progressive distention is the most dangerous aspect of nonstrangulated colon obstruction. If the ileocecal valve is incompetent, partial decompression of the obstructed colon may occur by reflux into the ileum, but if the ileocecal valve is competent, the colon becomes essentially a closed loop. If the obstruction is not relieved, distention progressing to rupture of the colon is possible. The cecum is the usual site of rupture, because it is the segment of the colon with the largest diameter. According to the law of Laplace, the pressure required to stretch the walls of a hollow viscus decreases in inverse proportion to the radius of curvature. Thus, given an equal pressure throughout the colon, the greatest distention will occur in the portion of the colon with the largest radius, the cecum (Fig. [22-5](#)).

Clinical Manifestations

Acute intestinal obstruction, when it is due to volvulus around a mechanical adhesion, usually begins with a sudden onset of abdominal pain. The distance of the obstruction from the ligament of Treitz can be ascertained by determining how long after the onset of pain vomiting takes place, and by the nature of the vomitus: the more distal the obstruction, the more feculent its character. The frequency of crampy abdominal pain and the periods between the abdominal pain may give some hint of the level of obstruction. In the proximal small intestine, the serial cramps may be 3 to 5 minutes apart, whereas more distally they may be at 10- to 15-min intervals.

The four cardinal symptoms and signs of intestinal obstruction are crampy abdominal pain, nausea and vomiting, obstipation, and abdominal distention. Simple mechanical obstruction results in the accumulation of succus entericus above the obstruction, with deranged motility as the bowel distends. Fluid that usually is absorbed in the small bowel tends to be secreted, accumulates, and is lost to the circulation. Vomiting or nasogastric suction may result in hypovolemia. In the absence of resuscitation, renal insufficiency, at times shock, leading to cardiovascular collapse and death can occur.

The principal findings of localized tenderness progressing to rebound tenderness accompanied by fever, tachycardia, and leukocytosis suggest that bowel viability is compromised. Initially abdominal pain is crampy, coincides with peristaltic rushes, and is poorly localized. If progressive loss of bowel viability occurs, the pain evolves to a steady, generalized abdominal discomfort with a local point of rebound tenderness. There is no absolute way to distinguish between strangulated and nonstrangulated obstructions.

In early postoperative obstruction, abdominal distention may not be apparent, particularly in high obstruction. In most other patients with intestinal obstruction, progressive abdominal distention occurs. Tenderness is mild and there usually is little voluntary muscle guarding. Percussion reveals the absence of fluid, and on auscultation loud, high-pitched, and amphoric rushes of peristalsis are noted, with the frequency depending on the location of the obstruction. As mechanical obstruction becomes progressive, hyperperistalsis may give rise to less frequent peristaltic rushes, and the abdomen becomes quieter.

Laboratory Findings

Intestinal obstruction usually results in losses of 4 to 8 L of intravascular and extracellular fluid into the small bowel, with consequent compromise of the cardiovascular system. Elevation of blood urea nitrogen and creatinine levels, hemoconcentration, hyponatremia, and hypokalemia are the most common early laboratory signs. Urinary specific gravity of 1.025 to 1.030 is the rule; proteinuria or mild acetonuria may be present. Sodium-free water from proteolysis and catabolism of fat will partially replace the intravascular deficit, but hyponatremia, hypochloremia, and hypoosmolality will result. Urine volume gradually increases, though not to normal, with excretion of potassium, including the potassium freed by cellular catabolism. The previously noted progressive increase in the hematocrit concentration is halted or reversed by the ingress of endogenous water. Acid–base effects are determined by the nature of the fluid lost. Metabolic acidosis from the combined effects of dehydration, starvation, ketosis, and loss of alkaline secretions is most common. Metabolic alkalosis occurs infrequently, principally because of loss of highly acid gastric juice. With great distention of the abdomen, the diaphragm may be sufficiently elevated to embarrass respiration, resulting in carbon dioxide retention and respiratory acidosis.

Simple mechanical obstruction is accompanied by a modest increase in the number of leukocytes with some shift to the left. White blood cell counts of 15,000 to 25,000/mm³, and marked polymorphonuclear predominance with many immature forms, strongly suggest that the obstruction is strangulated, but this is not a sensitive indicator. Very high white cell counts, such as 40,000 to 60,000/mm³, suggest primary mesenteric vascular occlusion.

Serum amylase level elevations may occur in intestinal obstruction. Amylase gains entry to the blood by regurgitation from the pancreas because of back pressure in the duodenum, or by peritoneal absorption after leakage from dying bowel. No preoperative clinical parameters, including the presence of continuous abdominal pain, fever, peritoneal signs, leukocytosis, acidosis, hyperamylasemia, or any combination of these, are sensitive indicators of vascular compromise. The preoperative assessment of the presence or absence of strangulation is correct in only about 70 percent of cases.

Management

When a patient with intestinal obstruction is admitted, a complete set of blood chemistry tests, including electrolytes, amylase, calcium, phosphorus, magnesium, and lactic acid, should be drawn. After the nasogastric tube has been placed and resuscitation begun, anteroposterior, lateral, and upright and chest films, and abdominal films are obtained. The presence or absence of free air, the bowel gas pattern, whether there is stool in the colon, and whether there is air in the rectum can be evaluated. If a rectal examination has been performed, air in the rectum may have no significance. Many of these patients have had a reflexive bowel movement early after the onset of intestinal obstruction, and a bowel action means relatively little prognostically. If there is air throughout the colon, the diagnosis is likely partial intestinal obstruction, which may be treated expectantly with suction, as the condition often resolves spontaneously.

While placement of a Miller-Abbott tube (a long tube) in intestinal obstruction usually results in the amelioration of postoperative obstruction, there is controversy about whether a long tube offers any advantage other than in the postoperative period in the presence of acute small-bowel obstruction. The patient can be observed carefully to allow nasogastric or, when appropriate, long-tube suction to take effect so that, if possible, operation can be avoided. At the same time, operation should not be delayed if there are symptoms or signs of vascular compromise or the patient is getting sicker.

Once the diagnosis of mechanical obstruction is made, additional workup is indicated in the form of a barium enema to make certain that the obstruction is not in the colon. If barium can be refluxed into a collapsed distal ileum, it will aid in the diagnosis. If acute diverticulitis is suspected, contrast examination of the colon is contraindicated. It is recommended that a large amount of barium should not be used in an adynamic small bowel above an obstruction. Water-soluble contrast examinations of large or small intestine are of limited value because of lack of mucosal detail. Because they are hypertonic and draw the fluid in from the intravascular and extravascular space, water-soluble contrast materials can further distend the bowel and may add to the intravascular fluid deficit in the patient with intestinal obstruction.

Only 10 to 20 percent of patients with partial small-bowel obstruction come to operation. Nasogastric decompression suffices except in metastatic neoplastic disease, in which long-tube decompression may be more effective. In early postoperative obstruction, reoperation is necessary in only about 20 percent of patients, especially when a long tube is used. An average decompressive period of 4 to 6 days is necessary. When the patient's postoperative obstruction clears, the suction should be discontinued and the patient fed around the tube, only removing it when it is clear that the obstruction has totally resolved.

In the case of neoplastic disease and suspected metastasis as the cause of intestinal obstruction, operation is indicated only in those patients with a good performance status. Simple nasogastric or long-tube decompression is appropriate for approximately 3 days. If no benefit is achieved, then operation is indicated. A mortality rate of at least 10 percent can be expected; the morbidity rate approaches 50 percent. A gastrostomy tube should be placed if it is believed that the obstruction will recur.

Patients with simple mechanical obstruction who are operated on within the first 24 h of the disease do not need extensive preoperative preparation, because water and salt depletion and distention usually are not serious at this stage. After the history and physical examination have established the presumptive diagnosis, laboratory studies should be done, intravenous repletion completed, decompression started with a nasogastric sump tube in the stomach, and abdominal and chest x-ray films taken on the way to the operating room. This whole process should take less than 2 h. The mortality rate is less than 1 percent for patients with simple mechanical obstruction who are operated on within the first 24 h.

If the obstruction has been present for more than 24 h when the patients is first seen, depletion and distention may be severe. If strangulation or closed-loop obstruction seems unlikely, the patients is best served by a period of preparation before the obstruction is surgically relieved. In general, the longer the obstruction has existed, the longer it will take to prepare the patient for surgical treatment. To prepare patients with moderate derangements, particularly hypokalemia, usually requires 6 to 12 h; in patients with severe problems, up to 24 h may be necessary, because of the hazard of giving intravenous potassium ion faster than it can equilibrate.

With the possible exception of patients with early simple mechanical obstruction, all patients with intestinal obstruction should have a venous catheter threaded into the superior vena cava or pulmonary artery for frequent measurements of the *central venous pressure (CVP)* or wedge pressure. This line also is used for rapid administration of fluid, and an indwelling catheter should be inserted into the bladder for accurate measurement of the urinary output.

The initial hematocrit reading may be used to estimate the extent of extracellular fluid loss and the volume necessary for restoration. For example, if the hematocrit level has risen to 55 percent, this indicates a loss of approximately 40 percent of the plasma and extracellular fluid volume.

If acid gastric juice loss is prominent, normal saline solution is used; otherwise lactated Ringer's solution and 5% dextrose in water in about equal proportions are preferred to replace the lost fluid and to cover maintenance fluid needs. Potassium chloride also will be necessary but should not be given until a good urinary output is established. Antibiotics should be administered in generous dosage and may be added to the intravenous fluids.

The rate of fluid administration is best controlled by monitoring the CVP or pulmonary artery wedge pressure. Fluids may be given rapidly as long as the CVP remains below 10 to 12 cmH₂O. The end point of volume replacement is indicated by a sudden rise in the CVP or left atrial pressure. Other guides are return of skin turgor and the hourly rate of urine output. The goal of electrolyte concentration and acid-base balance is restoration of these to, or close to, the normal range by the time the volume deficit has been repaired. This usually is possible in patients with reasonably normal renal and pulmonary function.

When the possibility of strangulation exists, preoperative restoration to fluid-electrolyte normality is not possible or advisable. This is an emergency situation requiring vigorous preparation with fluids and electrolytes, antibiotics, nasogastric suction, and an operation at the earliest possible moment to remove the cause of the strangulation or nonviable bowel. Despite application of these principles, the mortality rate in strangulated obstruction is about 25 percent.

Operative Procedure

If operation is required, the critical aspect of the treatment of intestinal obstruction is that it be carried out at a time when obstruction is *simple*, and a lysis of adhesions, reduction of the volvulus, or other therapeutic maneuvers are sufficient. If one delays operation and compromised small bowel or closed-loop obstruction develops, the situation becomes much more dangerous to the patient, and mortality rates rise precipitously. Proper timing of the operation for intestinal obstruction is essential. There are four types of obstruction in which the operation should be done as soon as possible after admission: strangulation, closed-loop obstruction, colon obstruction, and early simple mechanical obstruction.

General anesthesia is safest for the patient. Endotracheal intubation, occasionally performed under local anesthesia, is particularly indicated to prevent aspiration for regurgitated gastric content. Local anesthesia should be used only when the surgeon knows the cause of the obstruction and plans a limited procedure, such as transverse colostomy.

A generous incision should be used to enable the surgeon to lyse all of the adhesions, including those that might be present in the pelvis. A long midline incision is preferred by most surgeons, but it may be possible to carry out a long transverse incision if that has been the previous approach, provided access can be gained to the pelvis. If the adhesions are extensive, all adhesions must be taken down; after they are all taken down, the patient must be checked carefully for inadvertent enterotomies. In compromised bowel, bowel resection and end-to-end anastomosis should be performed unless the disparity in the lumina is too great, in which case an end-to-side anastomosis should be undertaken. If there is encased bowel in the pelvis, colostomy or ileostomy may be necessary; the preoperative discussion with the patient should include this possibility.

Surgical procedures for the relief of intestinal obstruction are divided into five categories:

- (1) Procedures not requiring opening of bowel —lysis of adhesions, manipulation-reduction of intussusception, reduction of incarcerated hernia
- (2) Enterotomy for removal of obturation obstruction —gallstone, bezoars
- (3) Resection of the obstructing lesion or strangulated bowel with primary anastomosis
- (4) Short-circuiting anastomosis around an obstruction
- (5) Formation of a cutaneous stoma proximal to the obstruction —cecostomy (rarely performed), transverse colostomy

On opening the peritoneum, the presence or absence of free peritoneal fluid should be noted as well as the appearance of the fluid. Bloody fluid denotes strangulation, and clear straw-colored fluid is found with simple obstruction. The point of obstruction is best found by starting in the right lower quadrant. If the cecum is grossly distended, the obstruction is in the colon. If collapsed small bowel is found, this is followed back to the point of obstruction, avoiding evisceration of the proximal distended loops.

The surgeon is sometimes faced with the difficult decision of whether or not to resect a loop of intestine of questionable viability. Before release, the strangulated loop of viable bowel has a dull purple-red appearance and is devoid of motion. After release, there is a dramatic color change to bright red in an obviously viable loop, as well as a return of peristalsis. In obviously dead bowel there is no color change and no motion after release of the strangulating obstruction. The loop that only partially “pinks up” and has little or no motion is a problem. It is usually best to wrap the questionable segment in moist laparotomy pads and leave it completely undisturbed for 10 min. If the circulation is obviously better at the end of this time, the loop is replaced in the abdomen. If the viability of the segment is still in doubt, resection should be done. Fluorescein staining and Doppler evaluations have been used to distinguish between viable and dead bowel, but results are not consistent. If a very long segment of bowel is involved, then an attempt should be made to restore flow in the larger vessels supplying the segment. If this is unsuccessful, the surgeon probably should accept the risk of replacing nonviable bowel. After operation the patient is closely observed; if evidence of progressive toxicity develops, reoperation and resection are done. Reexploration and reevaluation of the status of the bowel about 24 h later may be advisable.

Decompression of grossly distended intestine during the operative procedure sometimes is necessary, particularly in late simple mechanical obstruction. Operative decompression is still a contentious point. The site of obstruction is more easily found, the uncontrolled eventration of distended loops through the incision is avoided, the bowel can be returned to the peritoneal cavity without the kinks that may cause segmentation and postoperative obstruction, and closure of the incision is facilitated. Relief of distention also improves the blood supply to the intestine, and peristalsis soon returns. Normal mucosa is impermeable to these toxins, but permeability is affected by impairment of the blood supply, and absorption can occur in compromised bowel.

Operative aspiration can be done in a variety of ways. Multiple needle aspirations are ineffective and increase the morbidity; studies have shown a wound infection rate of 20 percent versus a rate of 4 percent in a comparable group of patients without needle aspiration. Decompression with an ordinary suction tip through multiple enterotomies, though effective, is attended by an increased infection rate, plus the risk of small-bowel fistula. An effective, safe method of decompression is passing a tube from above downward, so that the entire gastrointestinal tract proximal to the obstruction is decompressed. A firm tube with a generous lumen (Baker tube) is introduced through a proximal jejunostomy. It may be preferable to pass the tube transnasally or through a gastrostomy and thread it into the small intestine. The tube is advanced by manipulation through the intact bowel until the entire length of involved bowel down to the obstructed segment is pleated on the long tube. The tube is secured in that position for postoperative decompression.

Postoperative Care

The principles of postoperative care are the same as the preoperative preparation of the patient with obstruction: fluids and electrolytes, antibiotics, gastrointestinal decompression, and, if postoperative ileus is prolonged, parenteral nutrition.

Fluid and electrolyte management is more difficult in the postoperative intestinal obstruction patient than in the usual postoperative abdominal surgical patient because of the large third space of sequestered isotonic fluid. There is continued loss in the immediate postoperative period into the sequestered fluid space. The rate of loss slows and is reversed after a variable period, usually about the third postoperative day. This large autotransfusion as fluid is picked up by the vascular compartment from the sequestered fluid must be allowed for in planning the daily ration of intravenous fluid therapy, because the patient might be watered into congestive failure. Serum sodium, potassium, and magnesium levels must be closely watched and kept in the normal range. A deficit of any of these ions, especially potassium and magnesium, is associated with prolonged paralysis of the gastrointestinal tract.

Decompression of the gastrointestinal tract also is more difficult than in the usual postoperative patient, because restoration of normal propulsive intestinal motility usually is significantly delayed after release of intestinal obstruction. Bowel function usually resumes about the third day after abdominal operation, but after intestinal obstruction it is often 5 or 6 days before gastrointestinal decompression can be discontinued. Because of this, gastrostomy is often desirable for patient comfort.

Ileus

Ileus can be divided into three types. The most common is *adynamic or inhibition ileus*, in which motility is diminished or absent because of inhibition of normal neuromuscular activity. *Spastic ileus* refers to bowel that is tightly contracted without coordinated propulsive activity. *Ischemic ileus* is the result of either low-flow (nonocclusive ischemia) or vascular occlusion, in which coordinated motility is impossible because of the dying musculature.

Spastic ileus is seen in heavy-metal (lead) poisoning and in porphyria. Coordinated hyperactivity of the intestine may return in crampy or colicky pain, particularly in children. Therapy is directed at the primary disease. Adynamic ileus, the most common form of ileus, occurs after a variety of abdominal operations. In the normal postoperative course, the small bowel continues to function. This is the basis of early small-bowel feeding using catheter jejunostomy. Gastric ileus and colonic ileus last for approximately 2 days and 3 to 4 days, respectively, and intake can be resumed on the second or third postoperative day, or sooner after minimally invasive surgery.

If ileus is prolonged, possible causes should be evaluated: metabolic, septic, mechanical, or inflammatory. Of the metabolic causes, drug-induced ileus resulting from narcotics is the most common. Morphine or meperidine given intravenously, by patient controlled analgesia (PCA), or even into epidural catheters, can result in prolonged ileus. Ileus may be prolonged by the use of epidural opiates. Opiates should be limited to the first 24 h; thereafter pure bupivacaine will give adequate analgesia.

Metabolic causes of ileus include hypokalemia, hyponatremia, and hypomagnesemia. Mechanical causes include hematoma at the anastomosis and within the mesentery, a leak from the anastomosis, or an infection adjacent to the anastomosis or in the abdomen. Most surgeons believe that the more extensive the laparotomy and the longer the operation, the more profound the ileus, but several studies have failed to correlate the degree of intraoperative bowel manipulation, the duration of operation, and the duration of ileus. Intraperitoneal and retroperitoneal inflammations such as pancreatitis or peritonitis, or any intraabdominal infection, prolong ileus. Other situations can contribute to an adynamic ileus. A retroperitoneal hematoma, spinal fractures, rib fractures, and pelvic fractures also may contribute, the latter presumably because of the peripelvic hematoma.

Clinical Manifestations

There is no specific period for duration of “normal” postoperative ileus. Instead of passing flatus and becoming hungry on about the fourth postoperative day, abdominal distention persists and there is tympany and scattered occasional bowel sounds. Metabolic and treatable causes such as anemia, sepsis, hyponatremia, hypokalemia, hypomagnesemia, hypoalbuminemia, and hypoosmolality should be identified and corrected.

Radiologic examinations can help to outline the differential diagnosis between postoperative ileus and mechanical obstruction (Table 22-13). Enteroclysis is especially useful. In adynamic ileus some contrast material should reach the cecum in 4 h; if the barium column is stationary for 3 to 4 h, mechanical obstruction is present. Postoperative mechanical obstruction usually responds to long-tube decompression.

Management

Treatment of ileus is supportive, with nasogastric suction or gastrostomy drainage, electrolyte replacement, and, if prolonged, parenteral nutrition. A long (Miller-Abbott or Kaslow) tube may be useful if there is confusion between ileus and obstruction. A gastrostomy tube after an extensive operation, such as lysis of adhesions and fistula resection, is very

useful. A catheter jejunostomy (usually a #12 latex catheter) gives ample latitude with respect tot the type and consistency of the enteral diet. Stimulating agents are not of much value. Agents that have been used to hasten the return of small-bowel activity include erythromycin (a motilin agonist), bethanechol, vasopressin, metoclopramide, and cisapride. Hydration and nutritional support remain the mainstay of therapy.

Gastrointestinal Bleeding

Gastrointestinal bleeding has high mortality and morbidity rates, particularly because gastrointestinal bleeding in the elderly has become increasingly common. Accurate diagnosis is critical, particularly in the elderly, who have limited reserves. A careful history should be taken, a directed physical examination performed, and pertinent studies obtained in these patients before a significant amount (4 to 6 units) of blood has been lost.

Bleeding can arise anywhere along the entire gastrointestinal tract, from oropharynx to anus; it may be occult, presenting late with weakness, anemia, and orthostasis, or it may be massive, presenting with sudden, rapid loss of blood. Bleeding represents the initial symptom of gastrointestinal disease in more than one-third of patients, and in 70 percent there is no history of a previous bleeding episode. Although the majority of gastrointestinal bleeding (80 percent) will stop spontaneously without intervention, the other 20 percent of patients present a diagnostic and therapeutic challenge. Flexible endoscopy and arteriography play an increasing role in the diagnostic and therapeutic management of these patients.

Definitions

Hematemesis is the vomiting of blood, which may be either digested in the stomach or fresh and unaltered. It may be painful or painless, and it indicates upper gastrointestinal bleeding. Usually it is the result of bleeding between the oropharynx and the ligament of Treitz. Hematobilia occasionally results in hematemesis that may be associated with melena. Vomiting gross blood and clots indicates rapid bleeding, while “coffee-ground” emesis usually is associated with slower rates of bleeding, with the blood retained in the stomach altered to form acid hematin.

Melena is the peranal passage of stools with altered blood that are black and tarry and have a distinctive odor. Hematochezia is the passage of liquid blood or blood clots of varied brightness or color, maroon to bright red if the bleeding is vigorous enough. While acute bleeding can be dramatic, chronic bleeding may be equally troublesome, and in the absence of diagnosis might require repeated transfusions. Melena almost always occurs from the upper gastrointestinal tract, but it can occur from the distal small intestine or from the right side of the colon. Melena without hematemesis usually indicates a lesion distal to the ligament of Treitz.

As little as 50 to 60 mL of blood in the intestinal tract produces a melena stool. Melena can persist for 5 to 7 days after a significant, 2-unit bleed. Occult blood (positive guaiac test) may persist in the stool for up to 3 weeks after a good-sized bleed with associated hematemesis or melena; it does not imply continued bleeding. The amount required to convert the stool from guaiac-negative to guaiac-positive is approximately 10 mL of bleeding per day. While a generous portion of red meat occasionally can result in a guaiac-positive stool, this is infrequent. Iron does not result in a guaiac-positive stool, but it can result in a greenish-black stool that can be confused with melena. The distinctive odor of melena is the result of production of sulfide from heme by the action of hydrogen sulfide on the iron of the heme molecule.

Consequences of Gastrointestinal Bleeding

Most patients can withstand a sudden loss of 10 to 15 percent of their intravascular volume (class I hemorrhage) without shock. Hypotension occurs with greater intravascular losses, depending on the rate of bleeding and the patient response. Blood counts and hematocrit determinations are unreliable estimates of the amount of blood that has been lost, since equilibrium takes approximately 24 to 48 h. Initially a vasovagal response results in bradycardia; continued bleeding results in hypotension, cardiovascular instability, oliguria, decreased myocardial perfusion and decreased cerebral perfusion, renal failure, or multiple organ failure syndrome. With upper gastrointestinal blood loss, blood urea nitrogen (BUN) levels may be elevated to 30 to 50 mg/dL. The BUN:creatinine ratio may have a prognostic and diagnostic value; if the ratio is greater than 36:1, the bleeding arises from an upper gastrointestinal source. There is little azotemia seen with a lower gastrointestinal bleed, the BUN:creatinine ratio is less than 20:1, provided adequate renal function is maintained. Azotemia usually clears in 3 days after cessation of bleeding, without renal damage. Hypotension and renal ischemia may result in acute tubular necrosis.

Upper Gastrointestinal Bleeding

Etiology

The demographics of upper gastrointestinal bleeding depend largely on socioeconomic factors. Peptic ulcer is more common in suburban areas; gastritis and bleeding esophageal varices are more common in urban hospitals. The incidence of gastritis reflects the number of patients taking nonsteroidal anti-inflammatory medications. Duodenal ulcers bleed four times as often as gastric ulcers. Ten to 15 percent of patients with peptic ulcer bleed massively.

Upper gastrointestinal bleeding can be caused by nosebleed, esophageal and gastric varices, Mallory-Weiss tears, hiatus hernia and reflux esophagitis, gastritis (associated with portal hypertension, nonsteroid anti- inflammatory medications, or other gastric irritants), gastric ulcers, gastric neoplasms, duodenal ulcers, and hematobilia. There may be significant bleeding from duodenal polyps, but this is uncommon.

The proportion of patients presenting with upper gastrointestinal bleeding in the over-sixty age group has increased from 10 percent in the 1920s to almost 60 percent today. The mortality rate from upper gastrointestinal bleeding in patients over 60 years of age is 20 to 25 percent; in patients under 60 years old, the mortality rate is 4 percent. Although elective gastric operations for duodenal ulcer has decreased because of the widespread use of histamine H₂-receptor antagonists and proton-pump inhibitors, the incidence of surgery for bleeding duodenal ulcers has not decreased. Sudden cessation of histamine H₂-receptor antagonists or proton-pump inhibitors may result in a sudden rebound in acid secretion, resulting in gastrointestinal bleeding.

Nosebleeds rarely are the source of major bleeding but must be ruled out by a careful examination of the posterior pharynx to make certain that blood is not running down the pharynx into the esophagus and stomach, only to be vomited up later.

Esophagitis

Hiatus hernia and reflux esophagitis are not commonly the causes of massive bleeding. Reflux esophagitis is more likely to result in chronic occult bleeding. Significant acute bleeding is more often associated with paraesophageal hernias. The bleeding usually is associated with grade II or III esophagitis with friable mucosa.

Varices

Bleeding esophageal varices or gastric varices in the presence of liver disease account for about 10 percent of upper gastrointestinal bleeding and are a life-threatening situation with a high mortality rate. Alcoholism is the most common cause of portal hypertension, but hepatitis B and hepatitis C are increasingly seen as causes of posthepatic cirrhosis. Hepatocellular carcinoma may complicate hepatitis B and result in sudden onset of portal hypertension with portal vein thrombosis and bleeding. In the pediatric population, 95 percent of all upper gastrointestinal bleeding is because of variceal hemorrhage, usually as a consequence of extrahepatic portal venous obstruction. In patients with cirrhosis and portal hypertension, variceal hemorrhage accounts for 50 to 75 percent of all episodes of upper gastrointestinal bleeding, with gastritis and gastric or duodenal ulcer constituting the remainder. Variceal hemorrhage usually is precipitated by ulceration of the varix secondary to reflux esophagitis or increased pressure within the varix. Recurrent bleeding and mortality follow the inability of the failing liver to synthesize reparative proteins and proteins necessary for coagulation. Initial therapy should include prompt sclerotherapy or variceal ligation accompanied by vasopressin infusion. Variceal ligation is as effective in controlling bleeding as sclerotherapy and is associated with fewer treatment-related complications and better survival rates. If ligation or sclerotherapy is unsuccessful, emergency shunting procedures or hepatic transplantation must be considered.

Mucosal Tear

Esophagogastric mucosal, or Mallory-Weiss tears account for 5 to 10 percent of all upper gastrointestinal bleeding. The Mallory-Weiss tear presents in a classic pattern. Initially vomiting is without blood, but after retching and vomiting with epigastric pain, bleeding and hematemesis begin. More than 90 percent of the patients stop bleeding spontaneously and require no specific therapy. If bleeding persists, endoscopic therapy, with injection of a vasoconstrictive agent into the surrounding area, or intravenous infusion of vasopressin, usually stops the bleeding. Occasionally, balloon tamponade with a Sengstaken-Blakemore (gastric balloon only), or Linton tube is necessary to control the bleeding.

Gastritis

Depending on the patient population, up to one-third of upper gastrointestinal bleeding can be caused by the acute mucosal lesions of diffuse gastritis. These erosions often are multiple and are found primarily in the fundus and body of the stomach. Chronic gastritis is most commonly associated with *H. pylori* infection and presents with pain and chronic slow blood loss. Acute gastritis frequently bleeds and usually is associated with ingested substances that are damaging to the gastric mucosa. These include nonsteroidal anti-inflammatory drugs, alcohol, corticosteroids, and oral potassium supplements.

Vasopressin infusion, iced saline or lactated Ringer's solution lavage, the use of sucralfate, histamine H₂-receptor antagonists, or proton-pump inhibitors may be useful in stopping the hemorrhage. Endoscopic electrocoagulation or laser therapy have been used with mixed success. If the hemorrhage does not stop with medical or endoscopic therapy, vagotomy and antrectomy is the procedure of choice, with ligation of individual bleeding points. Total gastrectomy occasionally is necessary. While vagotomy and pyloroplasty, or gastrojejunostomy, are advocated by some, our experience with these procedures has been disappointing. If gastritis complicates portal hypertension, portal decompression may be necessary to stop repeated bleeding.

Peptic Ulcer

Peptic ulceration is the most common cause of upper gastrointestinal bleeding, present in one-half to two-thirds of patients with upper gastrointestinal bleeding. Bleeding may be the initial presenting symptom in up to 10 percent of patients with peptic ulcer. Duodenal ulcer bleeding is four times more common than gastric ulcer bleeding. Benign gastric ulcers tend to bleed more often and to a greater extent than gastric neoplasms, which rarely bleed significantly but may be associated with chronic blood loss. Bleeding duodenal ulcers usually are posterior and generally involve erosion in a branch of the gastroduodenal artery. Significant bleeding occurs in 10 to 15 percent of all peptic ulcer patients, and surgical intervention is required in up to 20 percent of these patients. The elderly are more likely to bleed persistently, because atherosclerotic vessels contract less, and operation may be necessary in a higher percentage of patients over 60 years old. if operation is required, it should not be delayed until these patients have received so much blood that they have developed a coagulopathy.

Peptic ulcer at the stoma of a gastrojejunostomy should be considered in any patient who has had previous gastric surgery. Inadequate resection, retained antrum, or inadequate vagotomy may predispose to stomal ulceration.

Stress Ulcer

This term refers to the acute gastroduodenal lesions that arise after or during episodes of shock, sepsis, surgery, trauma, burns (Curling's ulcers), and intracranial pathology or

surgery (Cushing's ulcers). The current hypothesis about stress ulceration is that it is the product of bile reflux damage to the gastric protective barrier combined with decreased gastric blood flow secondary to splanchnic vasoconstriction, but sepsis, coagulopathy, and activation of cytokines and other mediators also may play a role. Stress ulceration is associated with eight documented specific risk factors: multiple system trauma, hypotension, respiratory failure, renal failure, sepsis, jaundice, recent surgery, and burns. The greater the number of risk factors, the greater the incidence of ulceration and bleeding. Curling's ulcers may be multiple and increase in frequency as the percentage of body surface area burned increases. They occur in 12 percent of patients with burns. Cushing's ulcers probably result from the same pathophysiology as stress ulcerations, although significant gastric hypersecretion may occur after certain neurosurgical procedures. In the past, stress ulceration was common in the intensive care unit, but as resuscitation and postoperative care have improved, stress ulceration has become less common. Gastric acid neutralization, with sucralfate and antacids, also has contributed to reducing the incidence.

Other Causes

Miscellaneous disorders may lead to upper gastrointestinal bleeding in 8 to 18 percent of cases. Gastric neoplasms, such as adenocarcinoma, adenoma, angioma, leiomyoma, leiomyosarcoma, lymphoma, and leukemia all may bleed. Dieulafoy's vascular malformations are rare submucosal dilated arterial lesions that may occur anywhere in the gastrointestinal tract but are most commonly found in the stomach. The cause of these lesions is unknown, and they may present with massive gastrointestinal hemorrhage. Bleeding from Dieulafoy's lesions usually can be managed by endoscopic injection treatment, with good long-term outcomes. Aortoenteric fistulas usually present as a sentinel or herald bleed that is followed by a massive bleed. Aortoenteric fistulas are seen in patients with prior aortic reconstructive surgery; low-grade sepsis may involve the graft at the upper suture line, which usually is contiguous with the posterior aspect of the third portion of the duodenum. Primary aortoenteric fistulas, although rare, also have been reported. Hematobilia rarely is seen and usually follows hepatic injury or manipulation (e.g., percutaneous transhepatic procedures and catheterization) in which there has been arterial damage adjacent to the biliary system. Colicky pain and jaundice sometimes are present, aiding in the diagnosis. Bleeding can be massive, requiring urgent intervention.

Clinical Manifestations

A careful history should be taken, with inquiries about peptic ulcer disease, medications, alcoholism, previous cirrhosis, heartburn, and reflux esophagitis. If the initial vomitus was without blood and the subsequent vomiting was with pain and blood, this suggests a Mallory-Weiss tear. Peptic ulcer pain, which disappears with bleeding, strongly suggests duodenal ulcer bleeding. Twenty percent of patients with bleeding ulcer have no previous history of ulcer. While patients with cirrhosis have an increased ulcer diathesis, esophagogastric varices accounts for more than one-half of the bleeding episodes in cirrhotics.

Patients should be questioned about medications, particularly ingestion of drugs implicated as causes of gastrointestinal bleeding: salicylates, alcohol, steroids, and anticoagulants. Heartburn and epigastric substernal pain suggest reflux esophagitis.

Physical examination should focus on the various diagnostic possibilities and should include careful palpation of the neck for the occasional rare palpable parathyroid adenoma and examination for spider angiomas, rhinophyma, palmar erythema, and Dupuytren's contracture of the hands, a prominent abdominal venous pattern, and other stigmata of cirrhosis, including testicular atrophy, caput medusa, ascites, malnutrition, and jaundice. The mucous membrane should be investigated for melanin spots of the Peutz-Jeghers syndrome. Hereditary telangiectasis lesions are most common on the lips, tongue, and ears. Virchow's (left supraclavicular) node suggests a malignant intraabdominal process. A rectal examination and stool guaiac test should be performed. Auscultation of the abdomen will reveal hyperactive bowel sounds secondary to the cathartic effect of blood, especially in upper gastrointestinal bleeding.

Management

Large-bore intravenous lines should be placed and a type and crossmatch for 4 to 6 units initiated. Crystalloid resuscitation proceeds until blood is available. The initial priority is to restore blood volume. A Foley catheter is essential to monitor the resuscitation; if resuscitation is insufficient, a central venous catheter or, preferably, a pulmonary artery catheter may be required. A nasogastric tube should be placed in all patients with gastrointestinal bleeding. Even if upper gastrointestinal bleeding appears unlikely, it cannot be excluded until guaiac-negative bile is seen in the nasogastric tube.

Once the patient is stabilized, appropriate diagnostic studies can be undertaken. The initial laboratory evaluation should include a complete blood and platelet count, determinations of prothrombin and partial thromboplastin time, measurement of electrolyte levels, and liver chemistry studies. The progress of resuscitation can be checked by determining whether the patient has orthostatic hypotension. If the patient has a blood pressure that falls 20 mmHg, a decreased pulse pressure, or the pulse rises more than 25 beats/min when sitting, it can be assumed that there has been a loss of at least 20 percent of circulating blood volume (class II hemorrhage), and transfusion is required.

If upper gastrointestinal bleeding is suspected, the stomach is lavaged with iced saline solution with a large-bore tube, and emergency esophagogastroduodenoscopy is performed. This should be the first diagnostic test performed as soon as the patient is hemodynamically stable. The accuracy of upper endoscopy for the determination of the cause of bleeding ranges from 74 percent to 96 percent and is approximately 90 percent accurate when performed within 48 h of initial presentation. Bleeding from a duodenal or gastric ulcer, acute gastritis, Mallory-Weiss tear, and varices may be controlled endoscopically by various methods of coagulation, injection, or ligation. Barium studies and upper gastrointestinal series are contraindicated, because the presence of barium in the gastrointestinal tract precludes radionuclide and angiographic studies. Radionuclide scanning with technetium-labeled red blood cells may identify bleeding at rates as low as 0.1 to 0.2 mL/min (Fig. 22-6), but it is not helpful in localizing the site of bleeding, particularly in the upper tract. It is most useful as a precursor to arteriography. Arteriography may localize acute bleeding points if blood loss exceeds 1 mL/min (Fig. 22-7). Embolization of specific lesions may be carried out. Embolization of hepatic arteries may result in total thrombosis of hepatic arteries and should be considered carefully. In the case of bleeding esophageal varices, no lesion will be seen on arteriogram, and there is no indication for arteriography; intraarterial vasopressin has no advantage over intravenous vasopressin.

If the patient with bleeding esophageal varices fails to stabilize after sclerotherapy, ligation, or intravenous vasopressin, sclerotherapy or ligation can be attempted a second time. The Sengstaken-Blakemore tube should be tested and then placed through the nostril down to the farthest point; the gastric balloon should be blown up to approximately 50 to 100 mL and its position verified by radiograph. The balloon is inflated to 300 mL and snugged against the gastroesophageal junction. One or two pounds of traction is added, and this may be sufficient to stop the hemorrhage; if not, the esophageal balloon is inflated to 40 mmHg. The balloon can be left in place for 24 h. If bleeding resumes when the balloon is deflated, this is an indication for operation. Additional temporization will only increase the risk to the patient.

Some have advocated *transjugular intrahepatic portosystemic shunting (TIPS)* as a procedure for the acutely bleeding patient with portal hypertension, especially those who are candidates for transplantation. Access is gained through a major intrahepatic portovenous branch by puncture through a hepatic vein. A parenchymal track between hepatic and portal veins is then created with a balloon catheter, and a 10-mm expandable metal stent is inserted, creating the shunt with a pressure gradient of less than 12 mmHg. The initial experience reported for acutely bleeding patients is that a shunt is obtained successfully in more than 90 percent. An in-hospital mortality rate of 35 to 56 percent has been reported, and incomplete control of bleeding occurred in 26 percent (Fig. 22-8). In patients who survive, the incidence of encephalopathy is approximately the same as it is in patients receiving portacaval shunts. Another disadvantage of the procedure is that shunt stenosis or occlusion develops in as many as 50 percent of the patients within 1 year of TIPS insertion, invariably caused by intimal hyperplasia. While stenosis can be remedied by balloon dilation, it requires repeated angiograms or Doppler ultrasonographic examinations. By 5 months, 50 percent of stents had a significant gradient, and 80 percent required angioplasty within 1 year. After an initial wave of enthusiasm, TIPS now is being reserved for patients who have failed other forms of nonoperative therapy such as sclerotherapy, vasopressin, or variceal ligation and in whom transplantation is being considered. It is used as a bridge for transplantation.

TIPS is the method of choice for the treatment of refractory complications of portal hypertension in the liver transplant candidate. In patients undergoing orthotopic liver transplantation, TIPS is associated with reduced operative transfusion requirements, operative time, and length of intensive care unit and hospital stays compared to surgical portosystemic shunts. Because of the low morbidity of an elective surgical shunt and the high cost of maintenance of TIPS, elective surgical shunt is still recommended for those stable patients considered unsuitable for orthotopic liver transplantation.

Orloff has proposed another approach, in which patients with demonstrated bleeding esophageal varices are taken to the operating room for emergency portacaval shunt within 8 h of presentation, after a rapidly carried out diagnostic series. An impressive mortality rate of 17 percent has been reported. While some authorities disagree with this approach, temporization of patients with bleeding esophageal varices leads to aspiration, pneumonitis, coagulopathy, and deterioration of hepatic function.

If upper gastrointestinal bleeding requires 4 units of blood within the first 24 h and continues, it is an indication for operation. This is particularly true in the elderly, in whom gastrointestinal bleeding is less well tolerated, and in whom underlying arteriosclerosis with vascular compromise more often leads to cerebrovascular accidents or myocardial infarctions. The surgical approach should be tailored to the underlying pathology, with the primary goal to control the bleeding and then to institute more definitive therapy, depending on the patient's general condition and ability to tolerate surgical stress.

Lower Gastrointestinal Bleeding

Small Intestine

Bleeding from the small intestine is uncommon, occurring in 10 to 15 percent of all lower gastrointestinal bleeding, and rarely is massive or life-threatening. Small-intestine bleeding is one of the more difficult diagnostic situations and usually is a diagnosis of exclusion after upper gastrointestinal and colonic sources of bleeding have been ruled out. Causes of small-intestine bleeding include Meckel's diverticula, Crohn's disease, intussusception, neoplasms, vascular malformations (such as hereditary telangiectasia, microaneurysm, and hemangioma), intestinal varices, blood dyscrasias, non-Meckel's diverticular, mesenteric thrombosis, drug reactions, enteric infections, and polyps, some of which are associated with the Peutz-Jegher syndrome.

A thorough endoscopic examination of the esophagus, stomach, entire duodenum, and colon is essential before assuming a small-bowel source. In approximately 10 percent of cases of small-bowel bleeding, blood is seen exiting the ileocecal valve on colonoscopy. Bleeding associated with a Meckel's diverticulum usually is seen in the pediatric population and is related to ectopic gastric mucosa within the diverticulum. Technetium scanning can be used to demonstrate a Meckel's diverticulum. Crohn's disease presents with melena or hematochezia in 20 percent of patients; the bleeding rarely is of significant quantity. Intussusception generally presents with a classic history and symptom complex of intermittent colicky pain with signs of partial obstruction along with the passage of the characteristic currant-jelly stool. This most commonly affects infants; the cause usually is not determined, and diagnosis and treatment are implemented together as a barium enema. Operative reduction or resection may be necessary. The adult who present with intussusception generally has a neoplasm at the lead point and should undergo operative exploration and resection.

A radionuclide ^{99m}Tc-tagged erythrocyte scan during the acute bleeding may be helpful in identifying the area of origin of the bleeding. Although it is advocated as capable of detecting blood loss as slow as 0.1 to 0.2 mL/min, a loss of 0.5 mL/min is more realistic; the scan can be repeated for up to 30 h when bleeding is intermittent (see Fig. 22-6). Arteriography will identify a bleeding site when the bleeding rate is higher, e.g., 1 to 2 mL/min (see Fig. 22-7). Arteriography also may identify a tumor blush or an arteriovenous malformation or angiodysplasia. Tagged-erythrocyte scans and arteriographic investigations may demonstrate a small-intestinal source and may localize it to the upper or lower small intestine. If the specific arterial arcade affected can be identified on angiography, it is helpful to select the specific branch and leave the catheter in place for intraoperative

localization. At operation, it may be necessary to transilluminate the small bowel or to carry out intraoperative enteroscopy, which is an effective tool in selected patients with occult gastrointestinal bleeding and correctly identifies a treatable source and prevents rebleeding in 41 percent of patients.

Colon Bleeding Etiology

Colonic bleeding can be acute and massive, or chronic. Chronic bleeding most often results from polyps or neoplastic disease (Table 22-14). Right-sided neoplastic lesions tend to be more silent and endocolonic rather than scirrhous and obstructive, and they come to attention because of anemia and a guaiac-positive stool. Melena occasionally is present, but usually the presentation is that of unexplained anemia, and perhaps orthostatic hypotension, fatigue, and weight loss. Diverticulosis rarely is the cause of chronic colon bleeding. Massive lower gastrointestinal bleeding is caused by diverticulosis or angiodysplasia. Angiodysplastic lesions are small and occur most frequently in the cecum and the right colon. These vascular lesions have the following characteristics: (1) they are not congenital or neoplastic, but degenerative; (2) they are not associated with other vascular lesions of viscera or skin; (3) they increase with age; (4) they usually are small (less than 5 mm in diameter) and pathologically may require injection and clearing techniques for demonstration; and (5) they can be diagnosed by colonoscopy, but most accurately by angiography.

Colonic bleeding from angiodysplasia is best diagnosed by arteriography or colonoscopy. Almost 80 percent of these patients will stop bleeding spontaneously, but the risk of subsequent rebleeding is significant; approximately 50 percent of patients rebleed within three years after the initial bleed. An operation offers the best potential cure, but rebleeding from other angiodysplastic sources has been reported. The risk of rebleeding after laser ablation or electrocoagulation of angiodysplasia, is great.

Ulcerative colitis rarely bleeds massively and is characterized by chronic bloody diarrhea in most cases, but occasionally massive bleeding occurs. Polyps, other neoplastic disorders, and other ulcerated lesions also may bleed. Cytomegalovirus infection is another possible cause of lower gastrointestinal bleeding and is becoming more common, especially in immunocompromised patients. Anorectal disorders, including hemorrhoids, particularly in patients with liver disease, occasionally result in massive hemorrhage. These usually are within easy reach of the anoscope or rigid sigmoidoscope.

Management

Massive lower gastrointestinal bleeding is a surgical emergency and the patient should be resuscitated rapidly. A Foley catheter should be placed, and upper gastrointestinal bleeding ruled out with the placement of a nasogastric tube. Crystalloids should be given rapidly through two large-bore intravenous lines, and type-specific blood should be given as soon as available. Anoscopy and proctosigmoidoscopy are performed as part of the initial evaluation. The technetium-labeled red blood cell scan is the least invasive method available for detecting bleeding. This technique can identify slow bleeding and may pick up intermittent bleeding, since the patient can be rescanned over a 30-h period as frequently as necessary once the tagged cells have been injected. Radionuclide scanning is 91 percent sensitive and 100 percent specific for bleeding. Although its accuracy in pinpointing a specific site of bleeding is poor, tagged red cell scintigraphy appears to be a useful screening examination for patients with lower gastrointestinal bleeding who are hemodynamically stable, those with recurrent or prolonged bleeding, those with inconclusive endoscopy or barium studies, and those who are high-risk surgical candidates. This may avoid the potential morbidity associated with an unnecessary angiographic study and can help the radiologist in focusing the angiogram on the area of greatest concern.

Angiography is the definitive method of locating the point of bleeding. A large proportion of scans and arteriograms define bleeding from diverticula or angiodysplasia in the hepatic flexure or right colon. The use of CT and MRI for identifying gastrointestinal hemorrhage has been reported. CT performed without oral contrast agents, immediately after a negative angiographic result, may identify a region of the bowel that has focally dense intraluminal contrast. If a long circulating macromolecular contrast agent is used to decrease the T₁ signal of extravasated blood, gastrointestinal hemorrhage can be easily detected with MRI. While colonoscopy often is performed during massive gastrointestinal bleeding, it rarely provides useful information, because the patient is poorly prepared, and the bleeding, particularly if it is right-sided, cannot be localized. Barium investigations are not recommended for patients with lower gastrointestinal bleeding. Once barium is in the colon, angiographic localization is impossible.

If operation is required, when angiographic localization reveals well defined left- or right-sided colon lesions, local resection is indicated. If bleeding cannot be localized, colectomy and ileoproctostomy is indicated.

Chronic lower gastrointestinal bleeding should be evaluated with a careful history with questioning on weight loss, abdominal pain, family history of carcinoma, and the characteristic crampy abdominal pain and altered bowel habits of diverticular disease. Physical examination should include careful abdominal examination, palpating for a mass or the rigid or spastic sigmoid of diverticulitis, and pelvic and rectal examinations. Anoscopy and proctosigmoidoscopy are carried out in conjunction with barium enema, but colonoscopy is preferable. Barium enema cannot identify angiodysplastic lesions, but colonoscopy is successful in identifying them in 70 percent of patients. Double-contrast barium enema is helpful if colonoscopy is difficult or if a poor preparation limits the information to be gathered by colonoscopy. In rare instances, when colonoscopy or double-contrast barium enema fail to reveal any lesions, angiography may be indicated.

Rectal and Anal Bleeding

Fresh, unchanged blood on the exterior of the stool usually is from hemorrhoids, fissure, or proctitis. Pain associated with bleeding is usually pathognomic of fissure. Bleeding that drips into the bowl water is most likely the result of hemorrhoids or fissure. Any rectal or anal bleeding should be fully investigated; it should not be assumed that the bleeding is caused by hemorrhoids, because carcinomas can occur in young patients and a proximal tumor can cause engorgement of hemorrhoidal veins.

Jaundice

The term *jaundice* is derived from the French word meaning yellow, and it refers to excess bile pigments in the tissues and serum. Jaundice is clinically recognizable when the level of bilirubin is approximately 2.0 to 3.0 mg/dL. For the surgeon, the most important question is whether the patient has “medical jaundice” or “surgical jaundice,” the latter caused by obstruction that must be relieved by a surgical procedure. With careful history taking and physical examination, and simple laboratory tests (including liver chemistry studies), an accurate diagnosis can be achieved in approximately 85 percent of patients.

Normal Bilirubin Metabolism

Bilirubin, a tetrapyrrole, is produced by the oxidation of heme and reduction of the resultant biliverdin (Fig. 22-9). The majority (80 percent) of bilirubin formed is derived from the catabolism of heme released from the destruction of senescent red cells, principally in the spleen. The other 20 percent of daily bilirubin production is derived from the rapid turnover of hepatic heme-proteins and from ineffective erythrocytes in the bone marrow. Bilirubin is water insoluble, and its elimination, carried out by the hepatocyte, is largely dependent on the liver, which conjugates it with sulfate and glucuronide and excretes it into the bile. Unconjugated bilirubin is rapidly removed from the circulation by the liver. Wherever it originates, bilirubin is bound to albumin in the systemic circulation and dissociates from albumin when transported into the hepatocyte.

Inside the hepatocyte, the bilirubin binds to the cytosolic proteins ligandin and Z protein. Bilirubin conjugation, primarily with glucuronic acid, occurs in microsomes and is mediated by a specific bilirubin uridine diphosphate glucuronic acid (UDPGA) transferase. The transfer of one glucuronic acid to either of the two linked carboxyethyl side chains yields two isomeric bilirubin monoglucuronides (BMG). Transfer of a second glucuronic acid to the remaining carboxyethyl side chain forms bilirubin diglucuronide. In human bile more than 85 percent of the secreted bilirubin is in the form of bilirubin diglucuronide. Deficiency of the enzyme or the nucleotides may result in impaired bilirubin conjugation and unconjugated hyperbilirubinemia.

Bilirubin in normal bile is at least 98 percent conjugated, but unconjugated bilirubin is present in small concentrations. The major source of the unconjugated bilirubin is hydrolysis and enzymatic activity on excreted bilirubin conjugates that may occur at alkaline pH. The sick or failing liver may conjugate only one glucuronide on bilirubin, and this may be partially excreted into the bile. On a routine laboratory test, this will be read as direct bilirubin and can make liver chemistry studies difficult to interpret.

Once conjugated and dissolved, the bilirubin is secreted across the canaliculus by a carrier-mediated transport system. The bile salts form a “micellar sink,” which augments passive diffusion of the pigment from the cell into the bile. The conjugated bilirubin is poorly absorbed and usually fecally excreted. Conjugated bilirubin may be deconjugated by bacterial or intestinal glucuronidases. Bacteria further metabolizes the conjugated bilirubin to urobilinogen and urobilin (Figs. 22-9, 22-10). The majority of the unconjugated bilirubin and urobilinogen is excreted in the feces. In adults, a minor amount undergoes an enterohepatic circulation, while in the newborn, absorption of unconjugated bilirubin may cause “physiologic jaundice.” Any conjugated bilirubin and urobilinogen that is reabsorbed may be excreted through the kidney. Normally, almost all conjugated bilirubin is in the bile and is not present in the plasma, and the 0.1 or 0.2 mg/dL of conjugated bilirubin reported in most normal liver chemistry studies is an artifact.

Etiology

A number of causes are responsible for jaundice (Fig. 22-11). These include:

(1) Congenital causes

(A) Enzymatic (glucuronyl transferase) deficiencies, e.g., Crigler-Najjar syndrome and Gilbert's syndrome

(B) Familial conjugative disorders, e.g., Dubin-Johnson syndrome and Rotor's syndrome

(C) Overproduction of bilirubin because of hemolytic diseases ineffective erythropoiesis

(2) Physiologic causes

(A) Neonatal jaundice secondary to “immature” or inadequate glucuronyl transferase

(B) Increased pigment production secondary to tissue infarction or large collections of blood in tissues

(3) Inflammatory disease

(A) Hepatitis —toxic, alcoholic, or infectious

(B) Infection elsewhere in a patient with cirrhosis, e.g., spontaneous bacterial peritonitis or subacute bacterial endocarditis

- (C) Appendicitis, complicated by coliform organisms, can give jaundice without pylephlebitis
- (4) Metabolic/nutritional deficiencies
- (A) Drug-impaired uptake of bilirubin and drug-induced hemolysis and cholestasis
- (B) Alcoholic malnutrition –induced hepatitis and cirrhosis
- (C) Gallstones, with manifestations, including common hepatic duct stones and common bile duct stones
- (5) Neoplastic disease
- (A) Primary tumors of the liver
- (B) Metastases from other primary tumors
- (C) Extrahepatic obstruction

((1))

Intrahepatic obstruction of cholangiocarcinoma or adenocarcinoma

((2))

Klatskin (common hepatic duct bifurcation obstruction) types of tumors

- (D) Carcinoma of the gallbladder, with obstruction of the common bile duct
- (E) Ampullary carcinoma, or carcinoma of the duodenum
- (F) Carcinoma of the pancreas
- (G) Obstruction of bile ducts by portal nodes secondary to lymphoma or metastases

Congenital or familial types of hyperbilirubinemia are characterized by increases in unconjugated or conjugated bilirubin. In the unconjugated type of hyperbilirubinemia, an inherited partial deficiency of glucuronyl transferase (or Gilbert's syndrome) is common and affects 3 to 6 percent of the population, more commonly males. Serum bilirubin is low, usually below 3 mg/dL and rarely exceeding 5 mg/dL. The jaundice may fluctuate and is exacerbated after prolonged fasting, surgery, fever or infection, excessive exertion, or alcohol ingestion. The diagnosis of this disorder usually is made by exclusion in a patient with low-grade unconjugated hyperbilirubinemia with no systemic symptoms, no obvious hemolysis, normal liver function tests, and a normal liver biopsy. The history will reveal mild intermittent jaundice. Crigler-Najjar syndrome can be manifested in two types: an absence of glucuronyl transferase occurs in the autosomal recessive type I, and a partial deficiency occurs in the autosomal dominant type II. Type I is a rare disorder that presents in infancy; type II is less severe and may not appear until adolescence. Acquired deficiencies of glucuronyl transferase occur when there is an inhibition of the enzyme by certain agents. Drugs such as chloramphenicol, novobiocin, or vitamin K are known to inhibit the enzyme. Because the enzyme activity is decreased in the neonatal state, inhibition is more evident at that time. Pregnan-3b, 20 a-diol in breast milk is a glucuronyl transferase inhibitor and may lead to the so-called breast-milk jaundice. Hypothyroidism delays the normal maturation of glucuronyl transferase and may prolong neonatal jaundice if unrecognized.

Hepatic uptake of bilirubin can be impaired by flavaspidic acid and novobiocin as well as some cholecystographic dyes. Disorders associated with hemolysis, such as the hemolytic anemias and increased pigment production, can lead to an increased rate of bilirubin production that may exceed the amount that can be cleared by a normal liver. Ineffective erythropoiesis in patients with thalassemia, pernicious anemia, and congenital erythropoietic porphyria can lead to an increased destruction of red blood cells or their precursors in the marrow. The resultant hyperbilirubinemia in all of these conditions is primarily unconjugated with small increases in conjugated bilirubin and serum bilirubin in the range of 3 to 5 mg/dL. There are some situations in which there is a combination of hemolysis and impaired liver function (cirrhosis, sepsis, neoplasm), and serum bilirubin levels may be higher. Unconjugated hyperbilirubinemia is rarely a surgical condition. The serum bilirubin tends to be low, below 4 mg/dL, because the production of bilirubin exceeds the liver's capacity to conjugate with glucoronide. While hemolytic disorders frequently result in gallstone formation, which may produce mechanical obstruction, uncomplicated hyperbilirubinemia of the unconjugated variety usually is a benign condition.

When jaundice is caused by primary liver disease, there usually are elevated plasma levels of conjugated and unconjugated bilirubin, and the urine contains bilirubin. In many familial hepatic abnormalities, in some forms of liver injury, and in extrahepatic biliary obstructive jaundice, the increase is in the conjugated bilirubin. The levels or proportions of unconjugated and conjugated bilirubin in the serum do not help in the differentiation between intrahepatic and extrahepatic causes of jaundice, but only differentiate parenchymal and obstructive disease from disorders associated with predominately unconjugated hyperbilirubinemia (Table 22-15).

Predominantly conjugated jaundice may be caused by the familial defects in hepatic excretory function of Dubin-Johnson syndrome and Rotor's syndrome. In the autosomally recessive Dubin-Johnson syndrome, also called chronic idiopathic jaundice, there is a cellular defect in biliary excretion of amphophilic anionic conjugates (i.e., bilirubin, cholephilic iodinated dyes, sodium sulfobromophthalein, epinephrine metabolites, porphyrins) from hepatocytes into the bile. The mechanism of this disorder is unknown, but it may be a result of the absence of the canalicular isoform of the multidrug-resistant protein (MRP) gene encoded conjugate export pump. The serum bilirubin level in these patients is typically between 3 and 15 mg/dL; it is predominantly conjugated, with the serum containing more deconjugated than monoconjugated bilirubin. Homozygous patients typically have significant levels of unconjugated bilirubin. There is an accumulation of a black pigment, believed to represent the accumulation of epinephrine metabolites in the liver, which leads to the characteristic "black liver."

Dubin-Johnson patients may be asymptomatic or may present with vague gastrointestinal or constitutional complaints. There may be slight hepatomegaly and tenderness. The biliary tract does not visualize with oral or intravenous cholangiography. Sodium sulfobromophthalein elimination rises late (90 min) and there is no secondary rise in the serum of dyes that are not conjugated in the liver (e.g., indocyanine green). Urinary excretion of coproporphyrin I is increased, while the normal urinary metabolite coproporphyrin III is decreased. Oral contraceptive use may accentuate the hyperbilirubinemia. The overall prognosis in Dubin-Johnson syndrome usually is excellent.

Rotor's syndrome is a rare autosomal recessive trait that results in an impairment of hepatic storage capacity of conjugated bilirubin. In contrast to Dubin-Johnson syndrome, the liver is not pigmented, serum conjugated bilirubin is predominantly the monoconjugate, the biliary tree visualizes on oral and intravenous cholangiography, there is no secondary rise in sodium sulfobromophthalein excretion, and total urinary coproporphyrin excretion is increased.

Other are causes of hyperbilirubinemia include benign familial recurrent cholestasis, recurrent jaundice of pregnancy, and drug-induced cholestasis. Benign familial recurrent cholestasis is believed to be congenital and is first manifested at a young age. This disorder is characterized by recurrent attacks of pruritus and jaundice; liver biopsy reveals a cholestatic morphology, but cirrhosis does not develop, and the course usually is benign. Recurrent jaundice or intrahepatic cholestasis of pregnancy usually occurs in the third trimester but may develop any time after the seventh week of gestation. The serum bilirubin level is elevated (usually > 6 mg/dL), as are alkaline phosphatase and cholesterol levels. Patients may complain of pruritus that responds to cholestyramine treatment. The cause is thought to be related to an increased sensitivity to the hepatic effects of estrogens and progesterone. The symptoms usually subside within 1 to 2 weeks after delivery but may recur with subsequent pregnancies.

Drug-induced cholestasis is commonly associated with oral contraceptive use and resolves with the discontinuation of these medications. The administration of certain testosterone analogues also can lead to jaundice but is associated with chronic liver disease and biliary cirrhosis. Many other drugs may cause cholestasis as well as liver injury along with other systemic features, including fever, rash arthralgia, and eosinophilia. Some of the common drugs associated with hepatic toxicity or jaundice are methimazole, erythromycin estolate, chlorpropamide, chlorpromazine, tetracycline, halothane, phenytoin, methyldopa, isoniazid, chlorothiazide, and acetaminophen.

The most common disorders associated with jaundice are hepatitis and cirrhosis. Inflammation result sin hepatocellular damage or dysfunction, and it is important to recognize these conditions, because operative intervention, especially requiring general anesthesia, can be fatal. Impairment of hepatic function occurs form viral hepatitis or hepatitis of other viral causes, including cytomegalovirus in the immunosuppressed patient. Hepatitis A, B, or C may adversely affect hepatic function. Infection elsewhere in the body also can give rise to a hepatitis, which might impair hepatic function, e.g., multiple organ failure syndrome. When patients have cirrhosis, infection may result in impaired hepatocellular function. When hepatitis is clinically significant, serum transaminase and lactate dehydrogenase usually are elevated, with alkaline phosphatase slightly elevated, and bilirubin variously elevated. In patients with jaundice and brown stools, the diagnosis almost always is related to hepatic disease rather than surgically correctable causes.

Metabolic/nutritional causes of jaundice include alcoholic hepatitis and cirrhosis and the hemolytic effects of associated liver disease. If jaundice complicates cirrhosis of the liver, it is a poor prognostic sign. In patients with established cirrhosis, remote infection can result in jaundice and hepatic dysfunction. Starvation, increased alcoholism, and any noxious stimulus, including general anesthesia, also will cause jaundice in a patient with cirrhosis.

Alcoholic hepatitis is the result of excessive ingestion of alcohol over a short period of time, and probably a deficiency of normal nutrients. An enlarged tender liver usually is present, often with fever and leukocytosis. High levels of conjugated serum bilirubin are recorded, and alkaline phosphatase levels may be two to three items normal; the serum transaminase levels rarely exceed 300 units/L, and the ratio of AST to ALT is almost always greater than 2:1. Histologic findings on liver biopsy include fatty infiltration, polymorphonuclear inflammation, cellular necrosis, and Mallory's hyalin in the cytoplasm. Operation on patients with alcoholic hepatitis should be avoided if possible. The therapy of alcoholic hepatitis is abstinence from alcohol, and nutritional support, enteral or parenteral. Conventional nutritional support formulas can be used if the patient tolerates them

without encephalopathy. If these regimens are not tolerated, patients should receive branched-chain enriched amino acid nutritional support, enterally or parenterally.

Extrahepatic biliary obstruction can be caused by gallstones, neoplasm, trauma, or injury at the time of operation. Patients with gallstones usually have a history of right upper quadrant pain, radiating to the back or to the right shoulder, in association with fried, fatty, or greasy foods. Alkaline phosphatase elevation in patients with jaundice is likely to be more significant than the increase in bilirubin, which is not often above 10 mg/dL. It is rare to have elevation of bilirubin higher than 15 mg/dL with gallstones obstructing the common duct. It also is rare to have an elevation of bilirubin above 15 mg/dL with any mechanical obstruction, and values higher than this usually indicate hepatitis or cholestatic jaundice, e.g., hepatitis secondary to medication. Injury to the common duct after cholecystectomy may be manifested immediately or may be delayed.

A host of intrahepatic neoplasms can produce jaundice, including primary cholangiocarcinoma, intrahepatic duct obstruction, and metastases from any gastrointestinal primary carcinoma.

Most jaundice is the result of extrahepatic biliary obstruction. Adenocarcinoma of the common hepatic duct bifurcation (or Klatskin's tumor) is common. Less commonly, adenocarcinoma affects the proximal common bile duct. Carcinoma of the gallbladder, which is a silent lesion, may present as jaundice when the carcinoma obstructs the common bile duct by external compression. Carcinomas at the distal end of the biliary tree, including carcinoma of the pancreas, ampulla, and duodenum, are the most common causes of surgically correctable jaundice. The elevation of alkaline phosphatase tends to be higher, and the bilirubin level rarely exceeds 15 mg/dL with these lesions. Early anorexia is a specific manifestation of carcinoma of the pancreas, even with a small tumor burden. Portal lymph nodes may obstruct the common bile duct from the metastases, e.g., colon carcinoma, or lymphoma.

Clinical Manifestations

History

The history taking should focus questions on previous episodes of jaundice and whether the urine is dark and the stool light. Brown stools with jaundice usually are associated with cholestatic jaundice and nonsurgical jaundice. Inquiries should be made about similar episodes or episodic pain in the right upper quadrant provoked by fried, fatty, or greasy foods. Hepatitis exposure is highly significant. Family history and ethnic background have some bearing on some of the hemoglobinopathies, such as thalassemia or sickle cell anemia. Loss of appetite, weight loss, and the use of alcohol, drugs, or medications should be determined. Although carcinoma of the pancreas is classically painless, 20 to 30 percent of patients complain of backache or epigastric distress. A history of pruritus preceding jaundice occurs more commonly with extrahepatic and intrahepatic obstruction.

Physical Examination

The stigmata of chronic liver disease should be investigated. The liver edge should be palpated, and the total liver span estimated. The presence of a palpable spleen is highly significant. Adenopathies in the axilla or in the neck are significant. A stool guaiac test should be performed. A palpable gallbladder is more commonly associated with extrahepatic ductal obstruction when the obstruction is below the entrance to the cystic duct. This finding, known as Courvoisier's law, is more common in neoplasia than with biliary calculi.

Laboratory Studies

Laboratory studies should include liver function tests, a urinalysis with particular attention to the presence of bilirubin and urobilinogen, a complete blood count, and determinations of serum electrolytes, prothrombin time, and serum amylase. The alkaline phosphatase level may give some indication of the presence and degree of obstruction. An extremely high alkaline phosphatase value is suggestive of an intrahepatic process. The degree of hyperbilirubinemia and direct or indirect fractions may give some evidence about the cause of the jaundice. The presence of bilirubin or urobilinogen in the urine generally indicates good hepatic function and obstruction. Elevation of the transaminases and lactate dehydrogenase can indicate an acute inflammatory pattern. Prothrombin time elevation and hypoalbuminemia provide evidence of impaired synthetic function (as in cirrhosis). Hypokalemia, alkalosis, and a low blood urea nitrogen level may be associated with chronic liver disease. Amylase elevation, if present, provides additional evidence of an extrahepatic (obstructive) cause.

Radiologic Examination

The simplest and most noninvasive method of imaging the biliary tree is an ultrasonographic examination looking for dilated bile ducts or stones in the gallbladder. Hepatobiliary (HIDA) scans are accurate in diagnosing complete cystic duct or common duct obstruction, but offer little anatomic accuracy. HIDA scans are most useful in diagnosing acute cholecystitis and identifying postoperative biliary fistulas. If dilated ducts are found, a percutaneous transhepatic cholangiogram (PTC) or endoscopic retrograde cholangiopancreatography (ERCP) can be performed, depending on local expertise, suspected cause, and therapeutic options. Both studies are highly sensitive and specific in delineating the cause of the obstruction. PTC is associated with a certain incidence of bleeding and bile leakage, particularly in patients with impaired synthetic function. Bile leakage may be minimized by leaving the catheter in for drainage. ERCP may allow for direct biopsy or brushing of a suspected neoplasm and manipulation of the distal duct with removal of stones. The purpose of both examinations is to define the anatomy and, if obstruction is present, to place a stent or decompressive tube. Antibiotics should be given before manipulation to obviate cholangitis. ERCP is the procedure of choice in patients who are jaundiced after cholecystectomy, because endoscopic sphincterotomy permits stone removal.

CT is less sensitive in detecting noncalcified gallstones, but is more reliable in identifying masses in the porta hepatis or head of the pancreas. If a Klatskin's tumor is suspected, the absence of a mass on CT suggests resectability. In carcinoma of the pancreas, a dynamic CT scan can define invasion of the portal vein. Upper gastrointestinal series may reveal partial duodenal obstruction requiring gastrojejunostomy. Partial invasion of the C- loop (E sign) is indicative of carcinoma of the pancreas.

Multiple Organ Failure Syndrome

The *multiple organ failure syndrome (MOFS)* may be associated with gastrointestinal disease. This clinical entity is characterized by the progressive but potentially reversible physiologic dysfunction of two or more organs or organ systems that arises after resuscitation from an acute life-threatening event. The classic patient who develops MOFS has overwhelming infection, multiple trauma, massive burn, or massive ischemia. Risk factors for development of this syndrome are listed in Table [22-16](#).

It is estimated that MOFS is the cause of death in at least one-half of all patients who die in the *surgical intensive care unit (SICU)*. When deaths from MOFS secondary to traumatic injury are excluded from consideration, the proportion of MOFS-related SICU deaths may be 70 percent or higher. MOFS complicates 7 to 22 percent of emergency operations, including 30 to 50 percent of emergent operations for intraabdominal sepsis. Once MOFS is established, the mortality rate exceeds 70 percent, and survival from MOFS involving four or more organ systems is unusual.

MOFS or the sepsis syndrome, high-output respiratory failure, or any of a number of synonyms has its origin in two situations that may complicate gastrointestinal disease. Although approximately 75 percent of cases of MOFS are associated with bacterial infection, systemic inflammation without active infection also may precipitate organ failure. Disease processes involving the gastrointestinal tract typically account for the bacterial source giving rise to MOFS. Typical examples include colonic perforation with fecal peritonitis, acute diverticulitis with abscess, and periappendiceal abscess. Activated host immune cells, particularly neutrophils and macrophages, cause tissue injury similar to that produced by MOFS in clinical and animal models (Table [22-17](#)). Diffuse organ injury can be induced not only by excess activation of proinflammatory mediators but also by the deficiency of counterinflammatory mediators such as transforming growth factor beta (TGF- β) and interleukin-10.

A second hypothesis for MOFS is that the gastrointestinal tract may serve as an unseen generator. This involvement of the gastrointestinal tract may result from the gut's dual role as an occult microbial reservoir and a potent immunoregulatory organ whose normal function is to maintain a tonic counterinflammatory influence on immunologic activity. The critically ill patient has rapid colonization of the oral pharynx and proximal gastrointestinal tract by the endogenous microbial species. This colonization then predisposes to nosocomial infection with the same organisms. These infections may develop as a result of subclinical aspiration in the intubated patient or as a consequence of the passage of viable bacteria through the intestinal wall, a phenomenon termed *bacterial translocation*. Although this phenomenon has been readily observed in experimental animal models in response to the same insults that predispose to MOFS, such as trauma, hemorrhage, massive burn injury, pancreatitis, intraabdominal infection, and endotoxemia, evidence in human beings is largely circumstantial, and occasionally contradictory.

The extensive immunologic activities of the gut and liver normally blunt expression of the immune response. This counterbalance may be impaired in critical illness and permit the expression of a systemic inflammatory response. Mesenteric ischemia and hypoxia cause the intestinal epithelial cells to decrease the normal dampening effect on the release of tumor necrosis factor (TNF) by macrophages in response to endotoxemia. Animal models of hemorrhagic shock and intestinal ischemia reperfusion have shown elevated TNF and interleukin-6 in portal venous blood within minutes of restoring normal gut perfusion. Patients undergoing aortic aneurysm repair have elevated portal venous levels of TNF. This portal endotoxemia with resultant Kupffer cell activation triggers a release of potent immunosuppressive activity from alveolar and splenic macrophages. This activation can be lessened by Kupffer cell blockade.

Another theory of MOFS is the “two-hit hypothesis.” Normally, after an acute insult such as infection, traumatic injury, or shock there is an initial flow phase that is a hyperdynamic hemodynamic state lasting 3 to 5 days. If convalescence continues uninterrupted, the patient's course passes into the ebb phase, in which the metabolic response and the patient's physiologic profile change from stress to downgrading catabolism and provide the basis for anabolism to complete recovery. At any point if the flow phase is again activated by even the most subtle second insult, there is a markedly exaggerated host response that is manifested as MOFS.

Seven organ systems may demonstrate dysfunction or failure as part of MOFS (Table [22-18](#)). A typical clinical course of MOFS begins with the onset of *acute respiratory distress syndrome (ARDS)*, tachypnea, tachycardia, pyrexia, progressive hypoxia, and the characteristic “fluffy whiteout” on chest x-ray. The next organ system to show signs of dysfunction or failure is the kidney. Despite an adequate urine output, laboratory tests will show elevation of the blood urea nitrogen and creatinine levels. The third organ to fail in the classic description of MOFS is the liver. Two clinical syndromes have been described: ischemic hepatitis and jaundice. The former, also called “shock liver,” characteristically follows an episode of hypotension. Biochemical laboratory studies include elevations in amino transferase level and prothrombin time and hypoglycemia. Successful resuscitation results in rapid normalization of these markers of hepatic function. Jaundice, which is more common than ischemic hepatitis, typically evolves many days after the inciting physiologic insult. Conjugated hyperbilirubinemia is a prominent feature, but elevation of amino transferase levels and prothrombin time is less pronounced. The pathogenesis is multifactorial and includes ongoing hepatic ischemia, infection, cholestasis induced by total parenteral nutrition, and drug toxicity.

At this point, if the infection or hemorrhagic shock is controlled there is an opportunity to reverse the trend of organ failure, and the mortality rate is approximately 40 percent. Once progressive hepatic and renal failure supervene, mortality rates in excess of 70 percent are observed. Cardiovascular dysfunction in MOFS is evident clinically as hypotension that is refractory to volume challenge (necessitating inotropic and vasopressor support), tachydysrhythmia, and peripheral edema. Right ventricular dysfunction is prominent and may be a consequence of increased pulmonary vascular resistance secondary to the ARDS. Seventy percent of critically ill patients will have some element of CNS dysfunction that presents as alterations in level of consciousness without localizing signs. The mechanism of this altered mentation is poorly understood. Postulated mechanisms include the direct effects of proinflammatory mediators on cerebral function, the development of vasogenic cerebral edema, areas of infarction related to hypotension, and alterations in the

blood-brain barrier that change the composition of interstitial fluid. Hematologic dysfunction includes anemia, transient leukopenia, lymphopenia, and thrombocytopenia. The most common of these is thrombocytopenia; causes include increased consumption, intravascular sequestration, and impaired thrombopoiesis secondary to suppression of bone marrow function. Heparin-induced thrombocytopenia occurs in 10 percent of patients receiving heparin. Disseminated intravascular coagulopathy (DIC) is characterized by derangements in platelet numbers and clotting times and the presence of fibrin degradation products in the plasma.

Until recently, stress gastrointestinal bleeding was a common problem occurring in up to one-quarter of all SICU admissions, but improved techniques of resuscitation and hemodynamic support, earlier diagnosis of infection, and the widespread use of stress ulcer prophylaxis all have contributed to a reduction in the frequency of this complication. Rates of clinically important bleeding in the contemporary SICU have dropped below 4 percent. Other manifestations of gastrointestinal dysfunction include ileus, intolerance of enteral feeding, pancreatitis, and acalculous cholecystitis. Splanchnic hypoperfusion with mucosal acidosis is a pathologic feature common to all of these.

Diarrhea is present in as many as 40 percent of critically ill patients. It results from a decrease of absorptive capability of the small or large intestine and happens because of one or more of the following pathophysiologic mechanisms: (1) the presence of poorly absorbed osmotically reactive solutes, (2) intestinal secretion of water and electrolytes, (3) structural mucosal damage (inflammatory or surgical), and (4) abnormal intestinal motility.

Osmotic diarrhea is typically caused by a rapid reintroduction of enteral feeding to a patient after a prolonged fast. This most likely is because of incomplete digestion of complex carbohydrate in the enteral formulas. For this reason, when beginning enteral feeding, an initial dilution of the hyperosmolar formulas to hypoosmolar is recommended.

Secretory diarrhea usually is caused by bacterial endotoxins, humoral agents, defective neural control, and bile salt fatty acids. The later is not uncommon in surgical patients undergoing resection of the terminal ileum or total abdominal colectomy. Cholestyramine is a nonabsorbable anion exchange resin that binds bile acids in the intestinal lumen. It may be of benefit if bile salts are implicated in the pathogenesis of diarrhea, particularly for short-bowel syndrome, especially if less than 100 cm of ileum has been resected.

Intestinal mucosal structural damage causes a generalized impairment of absorption and diarrhea. Crohn's disease, ischemic bowel disease, and antibiotic-associated colitis are among the primary concerns. Some series report that as many as 25 percent of hospitalized patients treated with antibiotics develop diarrhea. *C. difficile* has been established as the most important cause of colitis. Almost all antibiotics, with the possible exception of aminoglycosides and vancomycin, have been associated with *C. difficile*. It should be suspected in any patient who develops diarrhea during or within 10 weeks of antibiotic therapy, and it may develop after only a single dose. When unrecognized, complications include toxic megacolon, severe electrolyte imbalance, hypoalbuminemia, and acute migratory polyarthritis. Bedside rigid sigmoidoscopy may be diagnostic, but the preferred method of diagnosis is a tissue culture assay for the *C. difficile* toxin. Fecal leukocytes also are present. Inflammatory and ischemic bowel disease also should be considered; rectal mucosal biopsy can be used to distinguish these causes. The most widely used treatment for antibiotic-associated colitis is vancomycin, but metronidazole appears to provide comparable efficacy and is considerably less expensive. Once therapy is initiated, diarrhea resolves gradually within 4 to 5 days.

Acute pancreatitis in the critical care unit patient can be quite protean in its presentation and manifestations. Pancreatitis in the postoperative setting commonly follows surgery of the pancreas, biliary tract, stomach, or duodenum, but it may occur after nonabdominal surgery, including open- heart surgery, hypotensive shock, endoscopic retrograde cholangiopancreatography, malignant ductal obstruction, transurethral prostate resection, and transplantation. It is an uncommon problem that has a mortality rate of 25 to 40 percent. Other causes of pancreatitis in SICU patients include medications (azathioprine, 6-mercaptopurine, thiazides, sulfonamides, furosemide, estrogens, and tetracycline). Hypercalcemia and pancreatitis have been described in patients receiving total parenteral nutrition. Despite lack of specificity, the serum amylase level remains the test most frequently used for the diagnosis. It should also be determined in patients who suddenly develop shock or anuria with or without abdominal pain, exhibit fever, abdominal pain, or shocklike phenomena in the postoperative states, especially after abdominal surgery, develop diabetic coma with shock, or exhibit clinical features suggestive of a myocardial infarction. Treatment is directed at symptoms and toward preventing or treating complications of the disease. It includes aggressive fluid resuscitation for treatment of shock, nothing by mouth to avoid stimulation of the pancreas, and appropriate use of analgesics for pain relief. Quinolone antibiotics may have a role in the treatment of pancreatitis. CT-guided needle aspiration of pancreatic masses (phlegmons) and cyst/fluid collections should be performed to determine the presence of an infected process. Culture results should help in selecting appropriate antibiotic agents. An infected phlegmon or abscess requires open drainage, because CT-guided catheter drainage is ineffectual.

Acalculous cholecystitis is common after multiple trauma, massive thermal injury, and massive blood transfusions. Histologic examination confirms that mucosal ischemia is the initiating event. Treatment options include radiologically guided percutaneous drainage, open cholecystostomy, or laparoscopic cholecystectomy.

CHAPTER 23 - Esophagus and Diaphragmatic Hernia

Jeffrey H. Peters
Tom R. DeMeester

SURGICAL ANATOMY

The esophagus is a muscular tube that starts as the continuation of the pharynx and ends as the cardia of the stomach. When the head is in normal anatomic position, the transition from pharynx to esophagus occurs at the lower border of the sixth cervical vertebra. Topographically this corresponds to the cricoid cartilage anteriorly and the palpable transverse process of the sixth cervical vertebra laterally (Fig. 23-1). The esophagus is firmly attached at its upper end to the cricoid cartilage and at its lower end to the diaphragm; during swallowing, the proximal points of fixation move craniad the distance of one cervical vertebral body.

The esophagus lies in the midline, with a deviation to the left in the lower portion of the neck and upper portion of the thorax, and returns to the midline in the midportion of the thorax near the bifurcation of the trachea (Fig. 23-2). In the lower portion of the thorax, the esophagus again deviates to the left and anteriorly to pass through the diaphragmatic hiatus.

Three normal areas of esophageal narrowing are evident on the barium esophagogram or during esophagoscopy. The uppermost narrowing is located at the entrance into the esophagus and is caused by the cricopharyngeal muscle. Its luminal diameter is 1.5 cm, and it is the narrowest point of the esophagus. The middle narrowing is due to an indentation of the anterior and left lateral esophageal wall caused by the crossing of the left main stem bronchus and aortic arch. The luminal diameter at this point is 1.6 cm. The lowermost narrowing is at the hiatus of the diaphragm and is caused by the gastroesophageal sphincter mechanism. The luminal diameter at this point varies somewhat depending on the distention of the esophagus by the passage of food, but has been measured at 1.6 to 1.9 cm. These normal constrictions tend to hold up swallowed foreign objects, and the overlying mucosa is subjected to injury by swallowed corrosive liquids due to their slow passage through these areas.

Figure 23-3 shows the average distance in centimeters measured during endoscopic examination between the incisor teeth and the cricopharyngeus, aortic arch, and cardia of the stomach. Manometrically, the length of the esophagus between the lower border of the cricopharyngeus and upper border of the lower sphincter varies according to the height of the individual.

The pharyngeal musculature consists of three broad, flat, overlapping fan-shaped constrictors (Fig. 23-4). The opening of the esophagus is collared by the cricopharyngeal muscle, which arises from both sides of the cricoid cartilage of the larynx and forms a continuous transverse muscle band without an interruption by a median raphe. The fibers of this muscle blend inseparably with those of the inferior pharyngeal constrictor above and the inner circular muscle fibers of the esophagus below. Some investigators believe that the cricopharyngeus is part of the inferior constrictor; that is, that the inferior constrictor has two parts, an upper or retrothyroid portion having diagonal fibers, and a lower or retrocricoid portion having transverse fibers. Keith in 1910 showed that these two parts of the same muscle serve totally different functions. The retrocricoid portion serves as the upper sphincter of the esophagus and relaxes when the retrothyroid portion contracts to force the swallowed bolus from the pharynx into the esophagus.

The cervical portion of the esophagus is approximately 5 cm long and descends between the trachea and the vertebral column from the level of the sixth cervical vertebra to the level of the interspace between the first and second thoracic vertebrae posteriorly or the level of the suprasternal notch anteriorly. The recurrent laryngeal nerves lie in the right and left grooves between the trachea and the esophagus. The left recurrent nerve lies somewhat closer to the esophagus than the right owing to the slight deviation of the esophagus to the left and the more lateral course of the right recurrent nerve around the right subclavian artery. Laterally, on the left and right sides of the cervical esophagus are the carotid sheaths and the lobes of the thyroid gland.

The thoracic portion of the esophagus is approximately 20cm long. It starts at the thoracic inlet. In the upper portion of the thorax, it is in intimate relationship with the posterior wall of the trachea and the prevertebral fascia. Just above the tracheal bifurcation, the esophagus passes to the right of the aorta. This anatomic positioning can cause a notch indentation in its left lateral wall on a barium swallow radiogram. Immediately below this notch the esophagus crosses both the bifurcation of the trachea and the left main stem bronchus, owing to the slight deviation of the terminal portion of the trachea to the right by the aorta (Fig. 23-5). From there down the esophagus passes over the posterior surface of the subcarinal lymph nodes, and then descends over the pericardium of the left atrium to reach the diaphragmatic hiatus (Fig. 23-6). From the bifurcation of the trachea downward, both the vagal nerves and the esophageal nerve plexus lie on the muscular wall of the esophagus.

Dorsally, the thoracic esophagus follows the curvature of the spine and remains in close contact with the vertebral bodies. From the eighth thoracic vertebra downward, the esophagus moves vertically away from the spine to pass through the hiatus of the diaphragm. The thoracic duct passes through the hiatus of the diaphragm on the anterior surface of the vertebral column behind the aorta and under the right crus. In the thorax, the thoracic duct lies dorsal to the esophagus between the azygos vein on the right and the descending thoracic aorta on the left.

The abdominal portion of the esophagus is approximately 2cm long and includes a portion of the *lower esophageal sphincter (LES)* (Fig. 23-7). It starts as the esophagus passes through the diaphragmatic hiatus and is surrounded by the phrenoesophageal membrane, a fibroelastic ligament arising from the subdiaphragmatic fascia as a continuation of the transversalis fascia lining the abdomen (Fig. 23-8). The upper leaf of the membrane attaches itself in a circumferential fashion around the esophagus, about 1 to 2 cm above the level of the hiatus. These fibers blend in with the elastic-containing adventitia of the abdominal esophagus and the cardia of the stomach. This portion of the esophagus is subjected to the positive-pressure environment of the abdomen.

The musculature of the esophagus can be divided into an outer longitudinal and an inner circular layer. The upper 2 to 6cm of the esophagus contains only striated muscle fibers. From there on smooth muscle fibers gradually become more abundant. Most of the clinically significant esophageal motility disorders involve only the smooth muscle in the lower two-thirds of the esophagus. When a surgical esophageal myotomy is indicated, the incision needs to extend only this distance.

The longitudinal muscle fibers originate from a cricoesophageal tendon arising from the dorsal upper edge of the anteriorly located cricoid cartilage. The two bundles of muscle diverge and meet in the midline on the posterior wall of the esophagus about 3 cm below the cricoid (see Fig. 23-5). From this point on, the entire circumference of the esophagus is covered by a layer of longitudinal muscle fibers. This configuration of the longitudinal muscle fibers around the most proximal part of the esophagus leaves a V-shaped area in the posterior wall covered only with circular muscle fibers. Contraction of the longitudinal muscle fibers shortens the esophagus. The circular muscle layer of the esophagus is thicker than the outer longitudinal layer. In situ, the geometry of the circular muscle is helical and makes the peristalsis of the esophagus assume a wormlike drive as opposed to segmental and sequential squeezing. As a consequence, severe motor abnormalities of the esophagus assume a corkscrewlike pattern on the barium swallow radiogram.

The cervical portion of the esophagus receives its main blood supply from the inferior thyroid artery. The thoracic portion receives its blood supply from the bronchial arteries, with 75 percent of individuals having one right-sided and two left-sided branches. Two esophageal branches arise directly from the aorta. The abdominal portion of the esophagus receives its blood supply from the ascending branch of the left gastric artery and from inferior phrenic arteries (Fig. 23-9). On entering the wall of the esophagus, the arteries assume a T-shaped division to form a longitudinal plexus giving rise to an intramural vascular network in the muscular and submucosal layers. As a consequence the esophagus can be mobilized from the stomach to the level of the aortic arch without fear of devascularization and ischemic necrosis. Caution should be exercised as to the extent of esophageal mobilization in patients who have had a previous thyroidectomy with ligation of the inferior thyroid arteries proximal to the origin of the esophageal branches.

Blood from the capillaries of the esophagus flows into a submucosal venous plexus and then into a periesophageal venous plexus from which the esophageal veins originate. In the cervical region, the esophageal veins empty into the inferior thyroid vein; in the thoracic region into the bronchial, azygos, or hemiazygos veins; and in the abdominal region into the coronary vein (Fig. 23-10). The submucosal venous networks of the esophagus and stomach are in continuity with each other, and in patients with portal venous obstruction, this communication functions as a collateral pathway for portal blood to enter the superior vena cava via the azygos vein.

The parasympathetic innervation of the pharynx and esophagus is provided mainly by the vagus nerves. The constrictor muscles of the pharynx receive branches from the pharyngeal plexus, which is on the posterior lateral surface of the middle constrictor muscle and is formed by pharyngeal branches of the vagus nerves with a small contribution from the IXth and XIth cranial nerves (Fig. 23-11). The cricopharyngeal sphincter and the cervical portion of the esophagus receive branches from both recurrent laryngeal nerves, which originate from the vagus nerves—the right recurrent nerve at the lower margin of the subclavian artery, the left at the lower margin of the aortic arch. They are slung dorsally around these vessels and ascend in the groove between the esophagus and trachea, giving branches to each. Damage to these nerves interferes not only with the function of the vocal cords but also with the function of the cricopharyngeal sphincter and the motility of the cervical esophagus, predisposing the individual to pulmonary aspiration on swallowing.

Afferent visceral sensory pain fibers from the esophagus end without synapse in the first four segments of the thoracic spinal cord, using a combination of sympathetic and vagal pathways. These pathways are also occupied by afferent visceral sensory fibers from the heart; hence, both organs have similar symptomatology.

The lymphatics located in the submucosa of the esophagus are so dense and interconnected that they constitute a single plexus (Fig. 23-12). There are more lymph vessels than blood capillaries in the submucosa. Lymph flow in the submucosal plexus runs in a longitudinal direction, and on injection of a contrast medium the longitudinal spread is seen to be about six times that of the transverse spread. In the upper two-thirds of the esophagus the lymphatic flow is mostly cephalad, and in the lower third caudad. In the thoracic portion of the esophagus, the submucosal lymph plexus extends over a long distance in a longitudinal direction before penetrating the muscle layer to enter lymph vessels in the adventitia. As a consequence of this nonsegmental lymph drainage, a primary tumor can extend for a considerable length superiorly or inferiorly in the submucosal plexus. Consequently, free tumor cells can follow the submucosal lymphatic plexus in either direction for a long distance before they pass through the muscularis and on into the regional lymph nodes. The cervical esophagus has a more direct segmental lymph drainage into the regional nodes, and as a result, lesions in this portion of the esophagus have less submucosal extension and a more regionalized lymphatic spread.

The efferent lymphatics from the cervical esophagus drain into the paratracheal and deep cervical lymph nodes, and those from the upper thoracic esophagus empty mainly into the paratracheal lymph nodes. Efferent lymphatics from the lower thoracic esophagus drain into the subcarinal nodes and nodes in the inferior pulmonary ligaments. The superior gastric nodes receive lymph not only from the abdominal portion of the esophagus but also from the adjacent lower thoracic segment.

PHYSIOLOGY

Swallowing Mechanism

The act of alimentation requires the passage of food and drink from the mouth into the stomach. One-third of this distance consists of the mouth and hypopharynx, and two-thirds is made up by the esophagus. To comprehend the mechanics of alimentation, it is useful to visualize the gullet as a mechanical model in which the tongue and pharynx function as a piston pump with three valves, and the body of the esophagus and cardia function as a worm drive pump with a single valve. The three valves in the pharyngeal cylinder are the soft

pallet, the epiglottis, and the cricopharyngeus. The valve of the esophageal pump is the LES. Failure of the valves or the pumps leads to abnormalities in swallowing—that is, difficulty in food propulsion from mouth to stomach—or regurgitation of gastric contents into the esophagus or pharynx.

Food is taken into the mouth in a variety of bite sizes, where it is broken up, mixed with saliva, and lubricated. Swallowing, once initiated, is entirely a reflex. When food is ready for swallowing, the tongue, acting like a piston, moves the bolus into the posterior oropharynx and forces it into the hypopharynx (Fig. 23-13). Concomitantly with the posterior movement of the tongue, the soft palate is elevated, thereby closing the passage between the oropharynx and nasopharynx. This partitioning prevents pressure generated in the oropharynx from being dissipated through the nose. When the soft palate is paralyzed, for example, after a cerebral vascular accident, food is commonly regurgitated into the nasopharynx. During swallowing, the hyoid bone moves upward and anteriorly, elevating the larynx and opening the retrolaryngeal space, bringing the epiglottis under the tongue (see Fig. 23-13). The backward tilt of the epiglottis covers the opening of the larynx to prevent aspiration. The whole pharyngeal part of swallowing occurs within 1.5 s.

During swallowing, the pressure in the hypopharynx rises abruptly to at least 60 mmHg due to the backward movement of the tongue and contraction of the posterior pharyngeal constrictors. A sizable pressure difference develops between the hypopharyngeal pressure and the less- than-atmospheric midesophageal or intrathoracic pressure (Fig. 23-14). This pressure gradient speeds the movement of food from the hypopharynx into the esophagus when the cricopharyngeus or upper esophageal sphincter relaxes. The bolus is both propelled by peristaltic contraction of the posterior pharyngeal constrictors and sucked into the thoracic esophagus. Critical to receiving the bolus is the compliance of the cervical esophagus; when compliance is lost due to muscle pathology, dysphagia can result. The upper esophageal sphincter closes within 0.5 s of the initiation of the swallow, with the immediate closing pressure reaching approximately twice the resting level of 30 mmHg. The postrelaxation contraction continues down the esophagus as a peristaltic wave (Fig. 23-15). The high closing pressure and the initiation of the peristaltic wave prevents reflux of the bolus from the esophagus back into the pharynx. After the peristaltic wave has passed farther down the esophagus, the pressure in the upper esophageal sphincter returns to its resting level.

Swallowing can be started at will, or it can be reflexly elicited by the stimulation of areas in the mouth and pharynx, among them the anterior and posterior tonsillar pillars or the posterior lateral walls of the hypopharynx. The afferent sensory nerves of the pharynx are the glossopharyngeal nerves and the superior laryngeal branches of the vagus nerves. Once aroused by stimuli entering via these nerves, the swallowing center in the medulla coordinates the complete act of swallowing by discharging impulses through the Vth, VIIth, Xth, XIth, and XIIth cranial nerves, as well as the motor neurons of C1 to C3. Discharges through these nerves occur in a rather specific pattern and last for approximately 0.5 s. Little is known about the organization of the swallowing center except that it can trigger swallowing after a variety of different inputs, but the response is always a rigidly ordered pattern of outflow. Following a cerebral vascular accident, this coordinated outflow may be altered, causing mild-to-severe abnormalities of swallowing. In more severe injury, swallowing can be grossly disrupted, leading to repetitive aspiration.

The striated muscles of the cricopharyngeus and the upper third of the esophagus are activated by efferent motor fibers distributed through the vagus nerve and its recurrent laryngeal branches. The integrity of innervation is required for the cricopharyngeus to relax in coordination with the pharyngeal contraction and resume its resting tone once a bolus has entered the upper esophagus. Operative damage to the innervation can interfere with laryngeal, cricopharyngeal, and upper esophageal function and predispose the patient to aspiration.

The pharyngeal activity in swallowing initiates the esophageal phase. The body of the esophagus functions as a worm drive propulsive pump, due to the helical arrangement of its circular muscles, and is responsible for transmitting a bolus of food into the stomach. The esophageal phase of swallowing represents esophageal work done during alimentation in that food is moved into the stomach from a negative-pressure environment of - 6mmHg intrathoracic pressure to a positive-pressure environment of 6 mmHg intraabdominal pressure or over a gradient of 12mmHg (see Fig. 23- 14). Effective and coordinated smooth muscle function in the lower third of the esophagus is, therefore, important in pumping the food across this gradient.

The peristaltic wave generates an occlusive pressure varying from 30 to 120 mmHg (see Fig. 23-15). The wave rises to a peak in 1 s, lasts at the peak for about 0.5 s, and then subsides in about 1.5 s. The whole course of the rise and fall of occlusive pressure may occupy one point in the esophagus for 3 to 5 s. The peak of a primary peristaltic contraction initiated by a swallow (primary peristalsis) moves down the esophagus at 2 to 4cm/s and reaches the distal esophagus about 9 s after swallowing starts (see Fig. 23-15). Consecutive swallows produce similar primary peristaltic waves, but when the act of swallowing is rapidly repeated, the esophagus remains relaxed and the peristaltic wave occurs only after the last movement of the pharynx. Progress of the wave in the esophagus is caused by sequential activation of its muscles initiated by efferent vagal nerve fibers arising in the swallowing center.

Continuity of the esophageal muscle is not necessary for sequential activation if the nerves are intact. If the muscles, but not the nerves, are cut across, the pressure wave begins distally below the cut as it dies out at the proximal end above the cut. This allows a sleeve resection of the esophagus to be done without destroying its normal function. Afferent impulses from receptors within the esophageal wall are not essential for progress of the coordinated wave. Afferent nerves, however, do go to the swallowing center from the esophagus, because if the esophagus is distended at any point, a contractual wave begins with a forceful closure of the upper esophageal sphincter and sweeps down the esophagus. This secondary contraction occurs without any movements of the mouth or pharynx. Secondary peristalsis can occur as an independent local reflex to clear the esophagus of ingested material left behind after the passage of the primary wave. Current studies suggest that secondary peristalsis is not as common as once thought.

Despite the powerful occlusive pressure, the propulsive force of the esophagus is relatively feeble. If a subject attempts to swallow a bolus attached by a string to a counterweight, the maximum weight that can be overcome is 5 to 10 g. Orderly contractions of the muscular wall and anchoring of the esophagus at its inferior end are necessary for efficient aboral propulsion to occur. Loss of the inferior anchor, as occurs with a large hiatal hernia, can lead to inefficient propulsion.

The LES provides a pressure barrier between the esophagus and stomach and acts as the valve on the worm drive pump of the esophageal body. Although an anatomically distinct LES has been difficult to identify, microdissection studies show that, in humans, the sphincterlike function is related to the architecture of the muscle fibers at the junction of the esophageal tube with the gastric pouch (Fig. 23-16). The sphincter actively remains closed to prevent reflux of gastric contents into the esophagus and opens by a relaxation that coincides with a pharyngeal swallow (see Fig. 23- 15). The LES pressure returns to its resting level after the peristaltic wave has passed through the esophagus. Consequently, reflux of gastric juice that may occur through the open valve during a swallow is cleared back into the stomach.

If the pharyngeal swallow does not initiate a peristaltic contraction, then the coincident relaxation of the LES is unguarded and reflux of gastric juice can occur. This may be an explanation for the observation of spontaneous lower esophageal relaxation, thought by some to be a causative factor in gastroesophageal reflux disease. The power of the worm drive pump of the esophageal body is insufficient to force open a valve that does not relax. In dogs, a bilateral cervical parasympathetic blockade abolishes the relaxation of the LES that occurs with pharyngeal swallowing or distention of the esophagus. Consequently, vagal function appears to be important in coordinating the relaxation of the LES with esophageal contraction.

The antireflux mechanism in human beings is composed of three components: a mechanically effective LES, efficient esophageal clearance, and an adequately functioning gastric reservoir. A defect of any one of these three components can lead to increased esophageal exposure to gastric juice and the development of mucosal injury.

Physiologic Reflux

On 24-h esophageal pH monitoring, healthy individuals have occasional episodes of gastroesophageal reflux. This physiologic reflux is more common when awake and in the upright position than during sleep in the supine position. When reflux of gastric juice occurs, normal subjects rapidly clear the acid gastric juice from the esophagus regardless of their position.

There are several explanations for the observation that physiologic reflux in normal subjects is more common when they are awake and in the upright position than during sleep in the supine position. First, reflux episodes occur in healthy volunteers primarily during transient losses of the gastroesophageal barrier, which may be due to a relaxation of the LES or intragastric pressure overcoming sphincter pressure. Gastric juice can also reflux when a swallow-induced relaxation of the LES is not protected by an oncoming peristaltic wave. The average frequency of these “unguarded moments” or of transient losses of the gastroesophageal barrier is far less while asleep and in the supine position than while awake and in the upright position. Consequently, there are fewer opportunities for reflux to occur in the supine position. Second, in the upright position there is a 12-mmHg pressure gradient between the resting, positive intraabdominal pressure measured in the stomach and the most negative intrathoracic pressure measured in the esophagus at midthoracic level. This gradient favors the flow of gastric juice up into the thoracic esophagus when upright. The gradient diminishes in the supine position. Third, the LES pressure in normal subjects is significantly higher in the supine position than in the upright position. This is due to the apposition of the hydrostatic pressure of the abdomen to the abdominal portion of the sphincter when supine. In the upright position, the abdominal pressure surrounding the sphincter is negative compared with atmospheric pressure, and, as expected, the abdominal pressure gradually increases the more caudally it is measured. This pressure gradient tends to move the gastric contents toward the cardia and encourages the occurrence of reflux into the esophagus when the individual is upright. By contrast, in the supine position the gastroesophageal pressure gradient diminishes, and the abdominal hydrostatic pressure under the diaphragm increases, causing an increase in sphincter pressure and a more competent cardia.

The LES has intrinsic myogenic tone, which is modulated by neural and hormonal mechanisms. Alpha-adrenergic neurotransmitters or beta blockers stimulate the LES, and alpha blockers and beta stimulants decrease its pressure. It is not clear to what extent cholinergic nerve activity controls LES pressure. The vagus nerve carries both excitatory and inhibitory fibers to the esophagus and sphincter. The hormones gastrin and motilin have been shown to increase LES pressure; and cholecystokinin, estrogen, glucagon, progesterone, somatostatin, and secretin decrease LES pressure. The peptides bombesin, l-enkephalin, and substance P increase LES pressure; and calcitonin gene-related peptide, gastric inhibitory peptide, neuropeptide Y, and vasoactive intestinal polypeptide decrease LES pressure. Some pharmacologic agents such as antacids, cholinergics, agonists, domperidone, metoclopramide, and prostaglandin F₂ are known to increase LES pressure; and anticholinergics, barbiturates, calcium channel blockers, caffeine, diazepam, dopamine, meperidine, prostaglandin E₁ and E₂, and theophylline decrease LES pressure. Peppermint, chocolate, coffee, ethanol, and fat are all associated with decreased LES pressure and may be responsible for esophageal symptoms after a sumptuous meal.

ASSESSMENT OF ESOPHAGEAL FUNCTION

A thorough understanding of the patient's underlying anatomic and functional deficits, prior to therapeutic decisions, is fundamental to the successful treatment of esophageal disease. The diagnostic tests as presently employed may be divided into five broad groups: (1) tests to detect structural abnormalities of the esophagus; (2) tests to detect functional abnormalities of the esophagus; (3) tests to detect increased esophageal exposure to gastric juice; (4) tests to provoke esophageal symptoms; and (5) tests of duodenogastric function as they relate to esophageal disease.

Tests to Detect Structural Abnormalities

Radiographic Evaluation

The first diagnostic test in patients with suspected esophageal disease should be a barium swallow including a full assessment of the stomach and duodenum. Esophageal motility is optimally assessed by observing several individual swallows of barium traversing the entire length of the organ, with the patient in the horizontal position. Hiatal hernias are best

demonstrated with the patient prone because the increased intraabdominal pressure produced in this position promotes displacement of the esophagogastric junction above the diaphragm. To detect lower esophageal narrowing, such as rings and strictures, fully distended views of the esophagogastric region are crucial. The density of the barium used to study the esophagus can potentially affect the accuracy of the examination. Esophageal disorders shown well by a full-column technique include circumferential carcinomas, peptic strictures, large esophageal ulcers, and hiatal hernias. A small hiatal hernia is usually not associated with significant symptoms or illness; and its presence is an irrelevant finding unless the hiatal hernia is large (Fig. 23-17), the hiatal opening is narrow and interrupts the flow of barium into the stomach (Fig. 23-18), or the hernia is of the paraesophageal variety. Lesions extrinsic but adjacent to the esophagus can be reliably detected by the full-column technique if they contact the distended esophageal wall. Conversely, a number of important disorders may go undetected if this is the sole technique used to examine the esophagus. These include small esophageal neoplasms, mild esophagitis, and esophageal varices. Thus, the full-column technique should be supplemented with mucosal relief or double-contrast films to enhance detection of these smaller or more subtle lesions.

Motion-recording techniques greatly aid in evaluating functional disorders of the pharyngoesophageal and esophageal phase of swallowing. The technique and indications for cine- and videoradiography will be discussed later, as it is more useful to evaluate function and seldom used to detect structural abnormalities.

The radiographic assessment of the esophagus is not complete unless the entire stomach and duodenum have been examined. A gastric or duodenal ulcer, partially obstructing gastric neoplasm, or scarred duodenum and pylorus may contribute significantly to symptoms otherwise attributable to an esophageal abnormality.

When a patient's complaints include dysphagia and no obstructing lesion is seen on the barium swallow, it is useful to have the patient swallow a barium-impregnated marshmallow, a barium-soaked piece of bread, or a hamburger mixed with barium. This test may bring out a functional disturbance in esophageal transport that can be missed when liquid barium is used.

Endoscopic Evaluation

In any patient complaining of dysphagia, esophagoscopy is indicated, even in the face of a normal radiographic study. A barium study obtained prior to esophagoscopy is helpful to the endoscopist by directing attention to locations of subtle change and alerting the examiner to such potential danger spots as a cervical vertebral osteophyte, esophageal diverticulum, a deeply penetrating ulcer, or a carcinoma. Regardless of the radiologist's interpretation of an abnormal finding, each structural abnormality of the esophagus should be confirmed visually.

For the initial endoscopic assessment, the flexible fiberoptic esophagoscope is the instrument of choice because of its technical ease, patient acceptance, and the ability to simultaneously assess the stomach and duodenum. Rigid endoscopy may be required in specific instances and should be part of the armamentarium of the endoscopist. The rigid esophagoscope may be an essential instrument when deeper biopsies are required or the cricopharyngeus and cervical esophagus need closer assessment.

When gastroesophageal reflux disease is the suspected diagnosis, particular attention should be paid to detecting the presence of esophagitis and Barrett's columnar-lined esophagus. When endoscopic esophagitis is seen, severity and the length of esophagus involved are recorded. Grade I esophagitis is defined as reddening of the mucosa without ulceration, and its identification varies depending on the observer. Usually its presence may be confirmed by biopsy. Grade I esophagitis is an unreliable indicator of esophagitis and reflects mainly esophageal mucosal injury secondary to a variety of insults. Grade II esophagitis is defined by the presence of linear erosions lined with granulation tissue that bleeds easily when touched. Grade III esophagitis represents a more advanced stage, where the linear ulcerations coalesce, leaving islands of epithelium which on endoscopy appear as a "cobblestone" esophagus. Grade IV esophagitis is the presence of a stricture. Its severity can be assessed by the ease of passing a 36 French endoscope. When a stricture is observed, the severity of the esophagitis above it should be recorded. The absence of esophagitis above a stricture suggests a chemical-induced injury or a neoplasm as a cause. The latter should always be considered and is ruled out only by evaluation of a tissue biopsy of adequate size.

Barrett's esophagus is a condition where the tubular esophagus is lined with columnar epithelium as opposed to the normal squamous epithelium. Histologically it appears as intestinal metaplasia. It is suspected at endoscopy when there is difficulty in visualizing the squamocolumnar junction at its normal location and by the appearance of a redder, more luxuriant mucosa than is normally seen in the lower esophagus. Its presence is confirmed by biopsy. Multiple biopsies should be taken in a cephalad direction to determine the level at which the junction of Barrett's epithelium with normal squamous mucosa occurs. Barrett's esophagus is susceptible to ulceration, bleeding, stricture formation, and, most important, malignant degeneration. The earliest sign of the latter is severe dysplasia or intramucosal adenocarcinoma (Fig. 23-19). These dysplastic changes have a patchy distribution, so a minimum of four biopsy samples every 2 cm should be taken from the Barrett's-lined portion of the esophagus. Changes seen in one biopsy are significant. Nishimaki has determined that the tumors occur in an area of specialized columnar epithelium near the squamocolumnar junction in 85 percent of the patients and within 2 cm of the squamocolumnar junction in virtually all patients. Particular attention should be focused in this area in patients suspected of harboring a carcinoma.

Abnormalities of the gastroesophageal flap valve can be visualized by retroflexion of the endoscope. Hill has graded the appearance of the gastroesophageal valve from I to IV according to the degree of unfolding or deterioration of the normal valve architecture (Figure 23-20). The appearance of the valve correlates with the presence of increased esophageal acid exposure, occurring predominantly in patients with grade III and IV valves.

A hiatal hernia is endoscopically confirmed by finding a pouch lined with gastric rugal folds lying 2 cm or more above the margins of the diaphragmatic crura, identified by having the patient sniff. A prominent sliding hiatal hernia frequently is associated with increased esophageal exposure to gastric juice. When a paraesophageal hernia is observed, particular attention is taken to exclude a gastric ulcer or gastritis within the pouch. The intragastric retroflex or J maneuver is important in evaluating the full circumference of the mucosal lining of the herniated stomach.

When an esophageal diverticulum is seen, it should be carefully explored with the flexible endoscope to exclude ulceration or neoplasia. When a submucosal mass is identified, biopsies are usually not performed. Normally a submucosal leiomyoma or reduplication cyst can be easily dissected away from the intact mucosa, but if a biopsy sample is taken, the mucosa may become fixed to the underlying abnormality. This complicates the surgical dissection by increasing the risk of mucosal perforation.

Tests to Detect Functional Abnormalities

In many patients with symptoms of an esophageal disorder, standard radiographic and endoscopic evaluation fails to demonstrate a structural abnormality. In these situations, esophageal function tests are necessary to identify a functional disorder.

Stationary Manometry

Esophageal manometry is a widely used technique to examine the motor function of the esophagus and its sphincters. Manometry is indicated whenever a motor abnormality of the esophagus is suspected on the basis of complaints of dysphagia, odynophagia, or noncardiac chest pain and the barium swallow or endoscopy does not show a clear structural abnormality. Esophageal manometry is particularly necessary to confirm the diagnosis of specific primary esophageal motility disorders, i.e., achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive LES. It also identifies nonspecific esophageal motility abnormalities and motility disorders secondary to systemic disease such as scleroderma, dermatomyositis, polymyositis, or mixed connective tissue disease. In patients with symptomatic gastroesophageal reflux disease, manometry of the esophageal body can identify a mechanically defective LES and evaluate the adequacy of esophageal peristalsis and contraction amplitude. Manometry has become an essential tool in the preoperative evaluation of patients prior to antireflux surgery, allowing selection of the appropriate procedure based upon the patient's underlying esophageal function.

Esophageal manometry is performed using electronic pressure-sensitive transducers located within the catheter or water-perfused catheters with lateral side holes attached to transducers outside the body. The catheter usually consists of a train of five pressure transducers or five or more water-perfused tubes bound together. The transducers or lateral openings are placed at 5-cm intervals from the tip and oriented radially at 72° from each other around the circumference of the catheter. A special catheter assembly consisting of four lateral openings at the same level, oriented at 90° to each other, is of special use in measuring the three-dimensional vector volume of the LES. Other specially designed catheters can be used to assess the upper sphincter.

As the pressure-sensitive station is brought across the gastroesophageal junction, a rise in pressure above the gastric baseline signals the beginning of the LES. The respiratory inversion point is identified when the positive excursions that occur in the abdominal cavity with breathing change to negative deflections in the thorax. The respiratory inversion point serves as a reference point at which the amplitude of LES pressure and the length of the sphincter exposed to abdominal pressure are measured. As the pressure-sensitive station is withdrawn into the body of the esophagus, the upper border of the LES is identified by the drop in pressure to the esophageal baseline. From these measurements the pressure, abdominal length, and overall length of the sphincter are determined (Fig. 23-21). To account for the asymmetry of the sphincter (Fig. 23-22), the pressure profile is repeated with each of the five radially oriented transducers, and the average values for sphincter pressure above gastric baseline, overall sphincter length, and abdominal length of the sphincter are calculated.

Table 23-1 shows the values for these parameters in 50 normal volunteers without subjective or objective evidence of a foregut disorder. The level at which a deficiency in the mechanics of the LES occurs was defined by comparing the frequency distribution of these values in the 50 healthy volunteers with a population of similarly studied patients with symptoms of gastroesophageal reflux disease. The presence of increased esophageal exposure to gastric juice was documented by 24-h esophageal pH monitoring. Based on these studies, a mechanically defective sphincter is identified by having one or more of the following characteristics: an average LES pressure of less than 6 mmHg, an average length exposed to the positive-pressure environment in the abdomen of 1 cm or less, and an average overall sphincter length of 2 cm or less. Compared with the normal volunteers, these values are below the 2.5 percentile for sphincter pressure and overall length and for abdominal length. It has been shown that the resistance of the sphincter to reflux of gastric juice is determined by the integrated effects of radial pressures extended over the entire length, resulting in three-dimensional computerized imaging of sphincter pressures. Calculating the volume of this image reflects the sphincter's resistance and is called the *sphincter pressure vector volume (SPVV)* (Fig. 23-23). A calculated SPVV less than the 5th percentile is an indication of a mechanically defective sphincter.

In a study of 50 normal volunteers and 150 patients with increased esophageal exposure to gastric juice and various degrees of esophageal mucosal injury, the calculation of the sphincter pressure vector volume increased the ability of manometry to identify a mechanically defective sphincter compared with standard techniques (Fig. 23-24). This was particularly so in patients without mucosal injury and borderline sphincter abnormalities. Three-dimensional LES manometry and calculation of the vector volume should, therefore, become the standard technique to assess the barrier function of the LES in patients with gastroesophageal reflux disease. Patients with gastroesophageal reflux disease and an SPVV below the 5th percentile of normal or a deficiency of one, two, or all three mechanical components of a LES on standard manometry have a mechanical defect of their antireflux barrier that a surgical antireflux procedure is designed to correct.

To assess the relaxation and postrelaxation contraction of the LES, a pressure transducer is positioned within the high-pressure zone, with a distal transducer located in the stomach and the proximal transducer within the esophageal body. Ten wet swallows (5 mL water each) are performed. The normal pressure of the LES should drop to the level of gastric pressure during each wet swallow.

The function of the esophageal body is assessed with the five pressure transducers located in the esophagus. The standard procedure is to locate the most proximal pressure transducer 1 cm below the well-defined cricopharyngeal sphincter, allowing a pressure response throughout the whole esophagus to be obtained on one swallow. Ten wet swallows are recorded. Amplitude, duration, and morphology of contractions following each swallow are calculated at all recorded levels of the esophageal body. The delay between the onset or peak of esophageal contractions at the various levels of the esophagus is used to calculate the speed of wave propagation. The relationship of the esophageal contractions following a swallow is classified as peristaltic or simultaneous. The data are used to identify motor disorders of the esophagus.

The position, length, and pressure of the cricopharyngeal sphincter are assessed with a stationary pull-through technique similar to that used for the LES. The manometric catheter is withdrawn in 0.5-cm intervals from the upper esophagus through the upper esophageal sphincter region into the pharynx. The relaxation of the upper esophageal sphincter is studied by straddling the eight pressure transducers across the sphincter so that some are in the pharynx and some in the upper esophagus. High-speed graphic recordings (50 mm/s) are necessary to obtain an assessment of the coordination of cricopharyngeal relaxation with hypopharyngeal contraction. It has been difficult to consistently demonstrate a motility abnormality in patients with pharyngoesophageal disorders.

24-Hour Ambulatory Manometry

The development of miniaturized electronic pressure transducers and portable digital data recorders with large storage capacity has made ambulatory monitoring of esophageal motor function over an entire circadian cycle possible. The broad clinical application of this new technology in a large number of asymptomatic normal volunteers and patients with primary esophageal motor disorders or gastroesophageal reflux disease provides new insights into esophageal motor function in health and disease under a variety of physiologic conditions. In both normal volunteers and symptomatic patients, esophageal motor activity increases with the state of consciousness and focus on eating activity, i.e., from the supine, to the upright, to meal periods. In the normal situation, there is a higher prevalence of nonperistaltic contractions then appreciated on stationary manometry.

Compared with standard manometry, ambulatory esophageal manometry provides a more than 100 times larger database for the classification and quantification of abnormal esophageal motor function and leads to a change in the diagnosis in a substantial portion of patients with symptoms suggestive of a primary esophageal motor disorder (Fig. 23-25). In patients with nonobstructive dysphagia, the circadian esophageal motor pattern is characterized by an inability to organize the motor activity into peristaltic contraction during a meal period (Fig. 23-26). This finding can be used to provide a new classification of motility disorders on the basis of when they may give rise to dysphagia (Fig. 23-27). In patients with noncardiac chest pain, ambulatory motility monitoring can document a direct correlation of abnormal esophageal motor activity with the symptom and shows that the abnormal motor activity immediately preceding the pain episodes is characterized by an increased frequency of simultaneous double- and triple-peaked high-amplitude long contractions. Ambulatory motility monitoring of patients with gastroesophageal reflux disease shows that the contractility of the esophageal body in these patients deteriorates with increasing severity of esophageal mucosal injury, compromising the clearance function of the esophageal body. Ambulatory esophageal manometry will replace standard manometry in the assessment of esophageal body function and has the potential to improve the diagnosis and management of patients with esophageal motor abnormalities. The combination of ambulatory 24-h esophageal manometry with esophageal and gastric pH monitoring is currently the most physiologic way to assess patients with foregut motility disorders.

Esophageal Transit Scintigraphy

The esophageal transit of a 10-mL water bolus containing technetium 99m sulfur colloid can be recorded with a gamma camera. Using this technique, delayed bolus transit has been shown in patients with a variety of esophageal motor disorders, including achalasia, scleroderma, diffuse esophageal spasm, and nutcracker esophagus.

Video- and Cineradiography

High-speed cinematic or video recording of radiographic studies allows reevaluation by reviewing the studies at various speeds. This technique is more useful than manometry in the evaluation of the pharyngeal phase of swallowing. Observations suggesting oropharyngeal or cricopharyngeal dysfunction include misdirection of barium into the trachea or nasopharynx, prominence of the cricopharyngeal muscle (Fig. 23-28), a Zenker's diverticulum, a narrow pharyngoesophageal segment, and stasis of the contrast medium in the valleculae or hypopharyngeal recesses (Fig. 23-29). These findings are usually not specific, but rather common manifestations of neuromuscular disorders affecting the pharyngoesophageal area. Studies using liquid barium, barium-impregnated solids, or radiopaque pills aid the evaluation of normal and abnormal motility in the esophageal body. Loss of the normal stripping wave or segmentation of the barium column with the patient in the recumbent position correlates with abnormal motility of the esophageal body. In addition, structural abnormalities such as small diverticula, webs, and minimal extrinsic impressions of the esophagus may be recognized only with motion- recording techniques. The simultaneous computerized capture of videofluoroscopic images and manometric tracings is now available, and is referred to as manofluorography. Manofluorographic studies allow precise correlation of the anatomic events, such as opening of the upper esophageal sphincter, with manometric observations, such as sphincter relaxation. Manofluorography, while not widely available, is presently the best means available to evaluate complex functional abnormalities.

Tests to Detect Increased Exposure to Gastric Juice

24-Hour Ambulatory pH Monitoring

The most direct method of measuring increased esophageal exposure to gastric juice is by an indwelling pH electrode. Prolonged monitoring of esophageal pH is performed by placing a pH probe 5 cm above the manometrically measured upper border of the distal sphincter for 24 h. It quantifies the actual time the esophageal mucosa is exposed to gastric juice, measures the ability of the esophagus to clear refluxed acid, and correlates esophageal acid exposure with the patient's symptoms. A 24-h period is necessary so that measurements are made over one complete circadian cycle. This allows measuring the effect of physiologic activity, such as eating or sleeping, on the reflux of gastric juice into the esophagus (Fig. 23-30).

The 24-h esophageal pH monitoring should not be considered a test for reflux, but rather a measurement of the esophageal exposure to gastric juice. The measurement is expressed by the time the esophageal pH was below a given threshold during the 24-h period. This single assessment, although concise, does not reflect how the exposure has occurred: that is, did it occur in a few long episodes or several short episodes? Consequently, two other assessments are necessary: the frequency of the reflux episodes and their duration.

The units used to express esophageal exposure to gastric juice are (1) cumulative time the esophageal pH is below a chosen threshold, expressed as the percent of the total, upright, and supine monitored time; (2) frequency of reflux episodes below a chosen threshold, expressed as number of episodes per 24 h; and (3) duration of the episodes, expressed as the number of episodes greater than 5 min/24 h and the time in minutes of the longest episode recorded. Table 23-2 shows the normal values for these components of the 24-h record at the whole-number pH threshold derived from 50 normal asymptomatic subjects. The upper limits of normal were established at the 95th percentile. Most centers use pH 4 as the threshold.

To combine the result of the six components into one expression of the overall esophageal acid exposure below a pH threshold, a pH score was calculated by using the standard deviation of the mean of each of the six components measured in the 50 normal subjects as a weighting factor. By accepting an abstract zero level 2 SD below the mean, the data measured in normal subjects could be treated as though they had a normal distribution. Thus, any measured patient value could be referenced to this zero point and, in turn, be awarded points based on whether it was below or above the normal mean value for that component, according to this formula:

Component score = Point value - mean / SD + 1

The upper limits of normal for the composite score for each whole-number pH threshold are shown in Table 23-3.

The detection of increased esophageal exposure to acid gastric juice is more dependable than the detection of increased exposure to alkaline gastric juice. The latter is suggested by an increased alkaline exposure time above pH 7 or 8. Increased exposure in this pH range can be caused by abnormal calibration of the pH recorder; dental infection, which increases salivary pH; esophageal obstruction, which results in static pools of saliva with an increase in pH secondary to bacterial overgrowth; or regurgitation of alkaline gastric juice into the esophagus. Using a properly calibrated probe, in the absence of dental infections or esophageal obstruction, the percentage of time the pH is measured above 7 correlates with the concentration of bile acids continuously aspirated over a 24-h period.

When done in a test population with an equal distribution of normal healthy subjects and patients with the classical reflux symptoms and a defective sphincter, 24-h esophageal pH monitoring had a sensitivity and specificity of 96 percent. (Sensitivity is the ability to detect a disease when known to be present; specificity is the ability to exclude the disease when known to be absent.) This gave a predictive value of a positive and a negative test of 96 percent and an overall accuracy of 96 percent. Based on these studies and extensive clinical experience, 24-h esophageal pH monitoring has emerged as a gold standard for the diagnosis of gastroesophageal reflux disease.

24-Hour Ambulatory Bile Monitoring

The potentially injurious components that reflux into the esophagus include gastric secretions, such as acid and pepsin, as well as biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. The presence of duodenal content within the esophagus can now be determined via an indwelling spectrophotometric probe capable of detecting bilirubin (Fig. 23-31). Bilirubin serves as a marker for the presence of duodenal juice. Its absorbance is measured and recorded by a portable optoelectronic data logger capable of directly measuring bilirubin by spectrophotometry, based on its specific light absorption at a wavelength of 453 nm. Figure 23-32 shows the results of 24-h ambulatory bilirubin monitoring in normal subjects compared to those with esophagitis and Barrett's esophagus. Ambulatory bilirubin monitoring can be used to identify patients who are at risk for esophageal mucosal injury and are thus candidates for surgical antireflux treatment.

Standard Acid Reflux Test (SART)

The development of powerful acid reduction agents such as omeprazole has created difficulties in the measurement of esophageal acid exposure. Many patients are placed on the medications prior to study, altering normal physiology and thus complicating interpretation of ambulatory pH monitoring. The acid-reducing effects of omeprazole have been noted to be present as long as 40 days following cessation of the drug, making a prolonged period without the medication necessary before study. Standard acid reflux testing can be used to provide additional information when it is suspected that the results of ambulatory monitoring may have been altered by medications.

The test is performed following manometry by placing a pH electrode 5 cm above the upper border of the LES. The manometry catheter is then advanced temporarily into the stomach, and 300 mL of 0.1 N HCl is infused. In children the gastric acid load is reduced accordingly. The manometry catheter is flushed and then pulled back into the body of the esophagus. The pH of the esophagus is monitored while the patient rests quietly in the supine position and then while he or she performs four maneuvers: deep breathing, Valsalva, Mueller (inspiration against a closed glottis), and cough. These maneuvers are repeated in the right and left lateral decubitus position and with the head down 20°, giving 16 possibilities for acid reflux to occur. A decrease in esophageal pH to less than 4 is considered evidence of reflux. At the beginning of the test, before the patient is placed in the supine position, the distal esophagus must have a pH greater than 4. In some patients this necessitates their standing erect and swallowing repeatedly in order to clear the esophagus of acid.

Patients who fail to clear the esophagus in the erect position after 20 effective swallows monitored on a motility tracing are considered to be abnormal in all positions and maneuvers and are scored as 16. Among 90 healthy volunteers, only 2 individuals had more than two reflux episodes. Accordingly, one or two drops in pH during these challenges to the cardia are considered normal, and three or more drops in pH are taken as evidence of a mechanical incompetence of the cardia. Patients with severe reflux may be unable to clear acid from the esophagus after reflux has been documented.

When used in a test population with an equal distribution of normal healthy subjects and patients with classic symptoms of gastroesophageal reflux disease, the SART had a sensitivity of 59 percent and a specificity of 98 percent. This gave a predictive value of a positive test of 96 percent and a negative test of 75 percent, with an overall accuracy of 81 percent.

Radiographic Detection of Gastroesophageal Reflux

The definition of radiographic gastroesophageal reflux varies depending on whether reflux is spontaneous or induced by various maneuvers. In only about 40 percent of patients with classic symptoms of gastroesophageal reflux disease is spontaneous reflux—i.e., reflux of barium from the stomach into the esophagus with the patient in the upright position—observed by the radiologist. In most patients who show spontaneous reflux on radiography, the diagnosis of increased esophageal acid exposure is confirmed by 24-h esophageal pH monitoring. Therefore, the radiographic demonstration of spontaneous regurgitation of barium into the esophagus in the upright position is a reliable indicator that reflux is present. Failure to see this does not indicate the absence of disease.

Tests of Duodenogastric Function

Esophageal disorders are frequently associated with abnormalities of duodenogastric function. Abnormalities of the gastric reservoir or increased gastric acid secretion can be responsible for increased esophageal exposure to gastric juice. Reflux of alkaline duodenal juice, including bile salts, pancreatic enzymes, and bicarbonate, is thought to have a role in the pathogenesis of esophagitis and complicated Barrett's esophagus. Furthermore, functional disorders of the esophagus are often not confined to the esophagus alone, but are associated with functional disorders of the rest of the foregut, i.e., stomach and duodenum. Tests of duodenogastric function that are helpful to investigate esophageal symptoms include gastric emptying studies, gastric acid analysis, and cholescintigraphy (for the diagnosis of pathologic duodenogastric reflux). The single test of 24-h gastric pH monitoring can be used to identify gastric hypersecretion and imply the presence of duodenogastric reflux and delayed gastric emptying.

Gastric Emptying

Gastric emptying studies are performed with radionuclide-labeled meals. Emptying of solids and liquids can be assessed simultaneously when both phases are marked with different tracers. After ingestion of a labeled standard meal, gamma camera images of the stomach are obtained at 5- to 15-min intervals for 1.5 to 2 h. After correction for decay, the counts in the gastric area are plotted as percentage of total counts at the start of the imaging. The resulting emptying curve can be compared with data obtained in normal volunteers. In general, normal subjects will empty 59 percent of a meal within 90 min.

24-Hour Ambulatory Gastric Emptying

Although a variety of different gamma camera scanning techniques exist, none permits the continuous measurement of gastric emptying under physiologic conditions. Ambulatory assessment of gastric emptying using an intraluminal cadmium-telluride gamma detector has become available (Fig. 23-33). This technique allows continuous measurements without the need for supervision by skilled personnel, and allows the subject to engage in normal activities with assessment of gastric emptying in different postures.

Barostat

Because the stomach is a hollow viscus, filled with air and fluid, direct measurement of the contractions of the gastric wall is difficult, particularly in the proximal stomach. Malagelada and others have introduced an electronic “barostat” to record the volume changes of the proximal stomach in response to a meal, thus providing a direct measure of proximal gastric motility. The barostat consists of a highly compliant low- pressure bag that is introduced into the proximal stomach and filled with air. The system is maintained at a constant pressure via an electronic circuit. Changes in gastric tone are reflected in the increase or decrease in volume of the air-filled bag necessary to maintain a constant pressure (Fig. 23-34). Although its precise role in clinical decision making remains to be determined, it has been shown to be a sensitive and useful technique to measure gastric relaxation following meals in patients.

Gastric Acid Analysis

The gastric secretory state is usually evaluated by determination of the titratable gastric acid in aspirated gastric juice. Interdigestive or basal gastric acid secretion is measured in the fasting state and varies between 0 and 5 mmol/h in normal volunteers. The maximal acid secretory capacity of the stomach, which reflects the available parietal cell mass, is calculated following stimulation of gastric acid secretion with pentagastrin or histamine. Acid hypersecretors have a basal gastric acid secretory capacity of greater than 5 mmol/h and a maximal acid secretory capacity of over 30 mmol/h.

Cholescintigraphy

Scintigraphic hepatobiliary imaging is performed after intravenous injection of 5 mCi of technetium 99m iminodiacetic acid derivatives such as disofenin (99mTc-DISIDA). Gamma camera images of the upper abdomen including the gallbladder and stomach are obtained at 5-min intervals for 60 min. Imaging is continued for an additional 30 min after stimulation of gallbladder contraction with 20 mg/kg of synthetic C-terminal octapeptide of *cholecystokinin* (*CCK*). Duodenogastric reflux is demonstrated as an increase of radioactivity in the stomach in the sequential images. The clinical value of this test is limited due to its short duration and a relatively high false-positive rate in normal volunteers.

24-Hour Gastric pH Monitoring

Monitoring is performed over a complete circadian cycle with a pH electrode placed 5cm below the manometrically located LES. The patient is fully ambulatory during the test and is encouraged to perform normal daily activity. The gastric pH profile is assessed separately for the meal, postprandial period, and fasting period. The latter is divided into the time spent upright and supine.

The interpretation of continuous gastric pH recordings is more difficult than that of esophageal pH recordings. This is because the gastric pH environment is determined by a complex interplay of acid secretion, mucous secretion, ingested food, swallowed saliva, regurgitated duodenal, pancreatic, and biliary secretions, and the effectiveness of the mixing and evacuation of the chyme. Using 24-h gastric pH monitoring to evaluate the gastric secretory state is based on studies that have shown that a good correlation exists between increased basal acid output on standard gastric acid analysis and a left shift on the frequency distribution graph of gastric pH recordings during the supine fasting period. The evaluation of gastric emptying by 24-h gastric pH monitoring is based on studies demonstrating a good correlation between the emptying of a solid meal and the duration of the postprandial plateau and decline phase of the gastric pH record.

Using 24-h gastric pH monitoring to evaluate duodenogastric reflux is based on the observation that reflux of alkaline duodenal juice into the stomach can alkalize the gastric pH environment. The measurement is not straightforward because of the effect of meals, and reduction in acid secretion can result in changes in gastric pH that mimic alkaline reflux episodes. To overcome this problem, computerized measurements of the number and height of alkalizing peaks, the baseline pH, the postprandial pH plateau, and the pattern of pH decline from the plateau can be used to identify the probability of duodenogastric reflux. The results are presented as an overall score that indicates the likelihood of pathologic duodenogastric reflux. Initial data indicate that this approach has a higher sensitivity and specificity for the diagnosis of pathologic duodenogastric reflux than scintigraphic methods do.

Combined 24-h esophageal and gastric pH monitoring can identify excessive alkaline duodenogastric and alkaline gastroesophageal reflux in symptomatic patients. The combined tracings can often identify simultaneous gastric and esophageal alkalization, suggesting a duodenal origin for the esophageal alkaline exposure (Fig. 23-35).

24-Hour Gastric Bilirubin Monitoring

Ambulatory gastric bilirubin monitoring using the Bilitech 2000 spectrophotometric probe is now available, for the detection of duodenogastric reflux, and the test may be superior to gastric pH monitoring as it allows direct measurement of duodenal content, rather than its inference via an alkaline pH. The probe is placed 5 cm below the LES and connected to a portable data logger, and a 24-h ambulatory study is performed on an outpatient basis. The patient is allowed a solid diet consisting of food that does not interfere with the absorbance spectrum of bilirubin. Studies have suggested that duodenal juice is detected in the stomach of both normal subjects and patients most commonly during the supine period and that duodenogastric reflux may be aggravated by previous cholecystectomy.

GASTROESOPHAGEAL REFLUX DISEASE

Definition

Gastroesophageal reflux is a common disease that accounts for approximately 75 percent of esophageal pathology. Despite its high prevalence, it can be one of the most challenging diagnostic and therapeutic problems in benign esophageal disease. A contributing factor to this is the lack of a universally accepted definition of the disease.

The simplest approach is to define the disease by its symptoms. However, symptoms thought to be indicative of gastroesophageal reflux disease, such as heartburn or acid regurgitation, are very common in the general population, and many individuals consider them to be normal and do not seek medical attention. Even when excessive, these symptoms are not specific for gastroesophageal reflux and can be caused by other diseases such as achalasia, diffuse spasm, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease. In addition, patients with gastroesophageal reflux disease can present with atypical symptoms, such as nausea, vomiting, postprandial fullness, chest pain, choking, chronic cough, wheezing, and hoarseness. Further, bronchiolitis, recurrent pneumonia, idiopathic pulmonary fibrosis, and asthma can be primarily due to gastroesophageal reflux disease. To confuse the issue more, gastroesophageal reflux disease can coexist with cardiac and pulmonary disease. Thus using clinical symptoms to define gastroesophageal reflux disease lacks sensitivity and specificity.

An alternative definition for gastroesophageal reflux disease is the presence of endoscopic esophagitis. Using this criterion for diagnosis assumes that all patients who have esophagitis have excessive regurgitation of gastric juice into their esophagus. This is true in 90 percent of patients, but in 10 percent the esophagitis has other causes, the most common being unrecognized chemical injury from drug ingestion. In addition, the definition leaves undiagnosed those patients who have symptoms of gastroesophageal reflux but do not have endoscopic esophagitis.

A third approach to define gastroesophageal reflux disease is to measure the basic pathophysiologic abnormality of the disease, that is, increased exposure of the esophagus to gastric juice. In the past this was inferred by the presence of a hiatal hernia, later by endoscopic esophagitis, and more recently by a hypotensive LES pressure. The development of miniaturized pH electrodes and data recorders allowed measurement of esophageal exposure to gastric juice by calculating the percentage of time the pH was less than 4 over a 24-h period. This provided an opportunity to objectively identify the presence of the disease and stimulated a rational stepwise approach to determining the cause for the abnormal

esophageal exposure to gastric juice.

The Human Antireflux Mechanism and the Pathophysiology of Gastroesophageal Reflux

The human antireflux mechanism consists of a pump, the esophageal body, and a valve, the LES. The common denominator for virtually all episodes of gastroesophageal reflux in both patients and normal subjects is the loss of the normal gastroesophageal barrier to reflux. This is usually secondary to low or reduced LES resistance. The loss of this resistance may be either permanent or transient. A structurally defective sphincter results in a permanent loss of LES resistance and permits unhampered reflux of gastric contents into the esophagus, throughout the circadian cycle. Transient loss of the gastroesophageal barrier may occur secondary to gastric abnormalities including gastric distention with air or food, increased intragastric or intraabdominal pressure, and delayed gastric emptying. These transient losses of sphincter resistance occur in the early stages of gastroesophageal reflux disease and are likely the mechanism for both physiologic and pathophysiologic postprandial reflux. Thus, gastroesophageal reflux disease may begin in the stomach.

Data have shown that transient loss of sphincter resistance is due to gastric distention. This results in shortening of the LES, upright reflux, and inflammatory changes at the gastroesophageal junction secondary to prolapse of esophageal squamous mucosa into the gastric environment (Fig. 23-36). Over time, persistent inflammation and the development of a hiatal hernia result in the permanent loss of LES function. Reflux in the supine position, erosive esophagitis, and Barrett's esophagus follow.

Several studies support the biomechanical effects of a distended stomach in the pathogenesis of gastroesophageal reflux disease and provide a mechanical explanation for why patients with a structurally normal LES may have increased esophageal acid exposure. In vitro bench studies have shown that increasing the diameter of the cardia, as occurs with gastric distention, results in incompetency of the gastroesophageal sphincter by reducing its overall length (Fig. 23-37). Further, as the sphincter length decreases, its resting pressure, as measured by a perfused catheter, also decreases. The decrease usually occurs suddenly when an inefficient length of sphincter is reached. This phenomenon may explain how transient LES relaxations (TLESRs) are caused by gastric distention. When the stomach is distended, gastric wall tension vectors play on the gastroesophageal junction; the resulting forces pull the sphincter open, thereby reducing sphincter length. When a critical length is reached, usually between 1 to 2 cm, the sphincter pressure drops precipitously. As gastric volume or distention increases, sphincter length decreases. If mechanical forces, set in play by gastric distention, are important in pulling open the sphincter and shortening its length, then the anatomic structure of the cardia, i.e., the presence of an acute angle of His or the dome architecture of a hiatal hernia, should influence the ease at which the sphincter was pulled open. Reflux episodes in this situation are more common after meals, when the stomach is distended.

The mechanism by which gastric distention contributes to shortening of sphincter length so that its resistance drops and reflux occurs provides a mechanical explanation for "transient relaxations" of the LES without invoking a neuromuscular reflex. Rather than a "spontaneous" muscular relaxation, there is a mechanical shortening of the sphincter length, as a consequence of gastric distention, to the point where it becomes incompetent. After gastric venting, sphincter length is restored and competence returns until distention again shortens the sphincter and encourages further venting and reflux. This sequence results in the common complaints of repetitive belching and bloating heard from patients with gastroesophageal reflux disease. Gastric distention may initially occur due to overeating, stress aerophagia, or delayed gastric emptying, secondary to fatty diet or a systemic disorder. The distention is subsequently augmented by an increased swallowing frequency that occurs in patients as they repetitively swallow their saliva in an effort to neutralize the acid refluxed into their esophagus.

The consequence of fundic distention, with the LES being "taken up" into the stretched fundus, is that the squamous epithelium of the sphincter is exposed to gastric juice and mucosal injury. This initial step in the pathogenesis of gastroesophageal reflux disease explains why mild esophagitis is usually limited to the very distal esophagus. Erosions in the terminal squamous epithelium caused by this mechanism may also explain the complaint of epigastric pain so often registered by patients with early disease. It may also be the stimulus to increase the swallowing of saliva to bathe the erosions in order to alleviate the discomfort induced by exposure to gastric acid. With increased swallowing come aerophagia, gastric distention, bloating, and repetitive belching. During this process there is repeated exposure of the squamous epithelium to gastric juice, due to the sphincter being "taken up" into the stretched fundus, which may cause erosion, ulceration, fibrosis (ring formation), and metaplasia of the terminal squamous mucosa.

This mechanism is supported by the finding that as the severity of gastroesophageal reflux disease progresses, the length of columnar lining above the anatomic gastroesophageal junction is increased. This suggests that the presence and extent of columnar epithelium lining the distal esophageal sphincter result from a metaplastic process associated with a loss of sphincter function and increased esophageal acid exposure (Fig. 23-38). To interrupt the progression from early to late disease requires preventing gastric distention and the resultant unfolding of the sphincter. Currently, this can only be achieved with an antireflux operative procedure.

In summary, gastroesophageal reflux diseases starts in the stomach (Fig. 23-39). It is caused by gastric distention due to overeating or ingestion of fried foods, typical of the Western diet, which delays gastric emptying. Gastric distention causes unfolding of the sphincter as it is taken up by the distended fundus and exposure of the terminal squamous epithelium within the sphincter to noxious gastric juice. Signs of injury to the exposed squamous epithelium are erosions, ulceration, fibrosis, and columnar metaplasia with an inflammatory infiltrate or foveolar hyperplasia. Intestinal metaplasia within the sphincter may result, as in Barrett's metaplasia of the esophageal body. This process results in the loss of muscle function and the sphincter becomes mechanically defective, allowing free reflux with progressively higher degrees of mucosal injury.

Structural damage to the components of the LES, such as loss of pressure, inadequate overall length, or the loss of abdominal length—i.e., the portion exposed to the positive-pressure environment of the abdomen as measured by manometry—results in permanent failure of sphincter function. The probability of increased exposure to gastric juice is 73 percent if one component of the sphincter is abnormal, 74 percent if two components are abnormal, and 92 percent if all three are abnormal. This indicates that the failure of one or two of the components of the sphincter may be compensated for by the clearance of the esophageal body. Failure of all three sphincter components inevitably leads to increased esophageal exposure to gastric juice.

The most common cause of a structurally defective LES is inadequate sphincter pressure. The reduced pressure is most likely due to an abnormality of myogenic function. This is supported by two observations. First, the location of the LES, in either the abdomen or the chest, is not a major factor in the genesis of the sphincter pressure, since it can still be measured when the chest and abdomen are surgically opened and the distal esophagus is held free in the surgeon's hand. Second, Biancani and co-workers have shown that the distal esophageal sphincter's muscle response to stretch is reduced in patients with an incompetent cardia. This suggests that sphincter pressure depends on the length and tension properties of the sphincter's smooth muscle. Surgical fundoplication has been shown to restore the mechanical efficiency of the sphincter to normal by correcting the abnormal length-tension characteristics.

Although an inadequate pressure is the most common cause of a structurally defective sphincter, the efficiency of a sphincter with normal pressure can be nullified by an inadequate abdominal length or an abnormally short overall resting length. An adequate abdominal length is important in preventing reflux caused by increases in intraabdominal pressure, and an adequate overall length is important in providing the resistance to reflux caused by gastric distention independent of intraabdominal pressure. Therefore, patients with a low sphincter pressure or those with a normal pressure but a short abdominal length are unable to protect against reflux caused by fluctuations of intraabdominal pressure that occur with daily activities or changes in body position. Patients with a low sphincter pressure or those with a normal pressure but short overall length are unable to protect against reflux related to gastric distention caused by outlet obstruction, aerophagia, gluttony, delayed gastric emptying associated with a fatty diet, or various gastropathies. Persons who have a short overall length on a resting motility study are at a disadvantage in protecting against excessive gastric distention secondary to eating, and suffer postprandial reflux. This is because with normal dilatation of the stomach, sphincter length becomes shorter, and if already shortened in the resting state, there is very little tolerance for further shortening before incompetency occurs.

The combined effects of pressure, overall length, and abdominal length on the resistance of the sphincter to the reflux of gastric juice can be determined by integrating the effects of radial pressures extended over the entire length of the sphincter. This can be quantified by three-dimensional computerized imaging of pressures throughout the sphincter length and calculating the volume of this image. This is referred to as the sphincter pressure vector volume. Figure 23-40 shows the three-dimensional sphincter representations for a normal volunteer and a patient with Barrett's esophagus before and after Nissen fundoplication. The marked improvement in the sphincter is apparent.

The second portion of the human antireflux mechanism is an effective esophageal pump which clears the esophagus of physiologic reflux episodes. Ineffective esophageal clearance can result in an abnormal esophageal exposure to gastric juice in individuals who have a normal LES and gastric function but fail to clear physiologic reflux episodes. This situation is relatively rare, and ineffectual clearance is more apt to be seen in association with a structurally defective sphincter, which augments the esophageal exposure to gastric juice by prolonging the duration of each reflux episode.

Four factors important in esophageal clearance are gravity, esophageal motor activity, salivation, and anchoring of the distal esophagus in the abdomen. The loss of any one can augment esophageal exposure to gastric juice by contributing to ineffective clearance. This explains why, in the absence of peristalsis, reflux episodes are prolonged in the supine position. The bulk of refluxed gastric juice is cleared from the esophagus by a primary peristaltic wave initiated by a pharyngeal swallow. Secondary peristaltic waves are initiated by either distention of the lower esophagus or a drop in the intraesophageal pH. Ambulatory motility studies indicate that secondary waves are less common and play less of a role in clearance than previously thought. The esophageal contractions initiated by a drop in esophageal pH rarely have a normal peristaltic pattern; they commonly have a broad-based, powerful synchronous pattern, which reduces the efficiency of esophageal clearance and encourages the regurgitation of refluxed material into the pharynx, predisposing the patient to aspiration.

Manometry of the esophageal body can detect failure of esophageal clearance by analysis of the pressure amplitude and speed of wave progression through the esophagus. The work of Kahrilas and Dodds has shown that the amplitude of an esophageal contraction required to clear the esophagus of liquid barium varies according to the level. Lower segments require a greater amplitude than upper segments. Inadequate amplitude results in ineffective clearance.

Salivation contributes to esophageal clearance by neutralizing the minute amount of acid that is left following a peristaltic wave. Return of esophageal pH to normal takes significantly longer if salivary flow is reduced, such as after radiotherapy, and is shorter if saliva is stimulated by sucking lozenges. Saliva production may also be increased by the presence of acid in the lower esophagus. The patient experiences excessive mucus in the throat. Clinically, this is referred to as "water brash."

A hiatal hernia can also contribute to an esophageal propulsion defect due to loss of anchorage of the esophagus in the abdomen. This results in a reduction in the efficiency of acid clearance (Fig. 23-41). Kahrilas has shown that complete esophageal emptying without retrograde flow was achieved in 86 percent of test swallows in control subjects without a hiatal hernia, 66 percent in patients with a reducing hiatal hernia, and only 32 percent of patients with a nonreducing hiatal hernia. Impaired clearance in patients with nonreducing hiatal hernias suggests that the presence of a hiatal hernia contributes to the pathogenesis of gastroesophageal reflux disease.

Gastric Reservoir

The third component of the human antireflux mechanism is the gastric reservoir. Abnormalities of the gastric reservoir that increase esophageal exposure to gastric juice include gastric dilatation, increased intragastric pressure, persistent gastric reservoir, and increased gastric acid secretion. The effects of gastric dilatation on reflux are discussed above. Increased intragastric pressure may be the result of outlet obstruction due to a scarred pylorus or duodenum, or the result of a vagotomy; it can also be found in the diabetic patient

with gastroparesis. The latter two conditions are secondary to abnormalities of the normal adaptive relaxation of the stomach. The increase in intragastric pressure due to alteration in the pressure-volume relationship in these abnormalities can overcome the sphincter resistance and results in reflux.

A persistent gastric reservoir results from delayed gastric emptying and increases the exposure of the esophagus to gastric juice by accentuating physiologic reflux. It is caused by myogenic abnormalities such as gastric atony in advanced diabetes, diffuse neuromuscular disorders, anticholinergic medications, and postviral infections. Nonmyogenic causes are vagotomy, antropyloric dysfunction, and duodenal dysmotility. Delayed gastric emptying can result in increased exposure of the gastric mucosa to bile and pancreatic juice refluxed from the duodenum into the stomach, with the development of gastritis.

Gastric hypersecretion can increase esophageal exposure to gastric acid juice by the physiologic reflux of concentrated gastric acid. Barlow has shown that 28 percent of patients with increased esophageal exposure to gastric juice measured by 24-h pH monitoring have gastric hypersecretion. A mechanically defective sphincter seems to be more important than gastric hypersecretion in the development of complications of reflux disease. In this respect, gastroesophageal reflux disease differs from duodenal ulcer disease, as the latter is specifically related to gastric hypersecretion.

Complications of Gastroesophageal Reflux

The complications of gastroesophageal reflux result from the damage inflicted by gastric juice on the esophageal mucosa or respiratory epithelium and changes caused by their subsequent repair and fibrosis. Complications due to repetitive reflux are esophagitis, stricture, and Barrett's esophagus; repetitive aspiration may lead to progressive pulmonary fibrosis. The severity of the complications is directly related to the prevalence of a structurally defective sphincter (Table 23-4). The observation that a structurally defective sphincter occurs in 42 percent of patients without complications (most of whom have one or two components failed) suggests that disease may be confined to the sphincter due to compensation by a vigorously contracting esophageal body. Eventually all three components of the sphincter fail, allowing unrestricted reflux of gastric juice into the esophagus and overwhelming its normal clearance mechanisms. This leads to esophageal mucosal injury with progressive deterioration of esophageal contractility, as is commonly seen in patients with strictures and Barrett's esophagus. The loss of esophageal clearance increases the potential for regurgitation into the pharynx with aspiration.

The potential injurious components that reflux into the esophagus include gastric secretions such as acid and pepsin, as well as biliary and pancreatic secretions that regurgitate from the duodenum into the stomach. There is a considerable body of experimental evidence to indicate that maximal epithelial injury occurs during exposure to bile salts combined with acid and pepsin. These studies have shown that acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, while the combination of duodenal juice and gastric acid is particularly noxious (Table 23-5).

Experimental animal studies have shown that the reflux of duodenal contents into the esophagus enhances inflammation, increases the prevalence of Barrett's esophagus, and results in the development of esophageal adenocarcinoma. The component of duodenal juice thought to be most damaging are the bile acids. In order for bile acids to injure mucosal cells, it is necessary that they be both soluble and unionized, so that the unionized nonpolar form may enter mucosal cells. Before the entry of bile into the gastrointestinal tract, 98 percent of bile acids are conjugated with either taurine or glycine in a ratio of about 3:1. Conjugation increases the solubility and ionization of bile acids by lowering their pKa. At the normal duodenal pH of approximately 7, over 90 percent of bile salts are in solution and completely ionized. At pH ranges from 2 to 7, there is a mixture of the ionized salt and the lipophilic, nonionized acid. Acidification of bile to below pH 2 results in an irreversible bile acid precipitation. Consequently, under normal physiologic conditions, bile acids precipitate and are of minimal consequence when an acid gastric environment exists. On the other hand, in a more alkaline gastric environment, such as occurs with excessive duodenogastric reflux and after acid suppression therapy or vagotomy and partial or total gastrectomy, bile salts remain in solution, are partially dissociated, and when refluxed into the esophagus can cause severe mucosal injury by crossing the cell membrane and damaging the mitochondria.

Complications of gastroesophageal reflux such as esophagitis, stricture, and Barrett's metaplasia occur in the presence of two predisposing factors: a mechanically defective LES and an increased esophageal exposure to fluid with a pH of <4 and >7 (Fig. 23-42). The duodenal origin of esophageal contents in patients with an increased exposure to a pH >7 has been confirmed by esophageal aspiration studies (Fig. 23-43). Studies have clarified and expanded these observations by measuring esophageal bilirubin exposure over a 24-h period as a marker for the presence of duodenal juice. Direct measurement of esophageal bilirubin exposure as a marker for duodenal juice has shown that 58 percent of patients with gastroesophageal reflux disease have increased esophageal exposure to duodenal juice and that this exposure occurs most commonly when the esophageal pH is between 4 and 7 (Fig. 23-44). Further, it is associated with a more severe mucosal injury (Fig. 23-45).

The fact that the combination of refluxed gastric and duodenal juice is more noxious to the esophageal mucosa than gastric juice alone may explain the repeated observation that 25 percent of patients with reflux esophagitis develop recurrent and progressive mucosal damage, often despite medical therapy. A potential reason is that acid suppression therapy is unable to consistently maintain the pH of refluxed gastric and duodenal juice above 6. Lapses into pH ranges from 2 to 6 encourage the formation of undissociated, nonpolarized, soluble bile acids, which are capable of penetrating the cell wall and injuring mucosal cells. To assure that bile acids remain completely ionized in their polarized form, and thus unable to penetrate the cell, requires that the pH of the refluxed material be maintained above 7, 24 h a day, 7 days a week, for the patient's lifetime. In practice this would not only be impractical but likely impossible, unless very high doses of medications were used. The use of lesser doses would allow esophageal mucosal damage to occur while the patient was relatively asymptomatic. Antireflux operative procedures reestablish the barrier between stomach and esophagus, protecting the esophagus from damage in patients with mixed gastroesophageal reflux. If reflux of gastric juice is allowed to persist and sustained or repetitive esophageal injury occurs, two sequelae can result. First, a luminal stricture can develop from submucosal and eventually intramural fibrosis. Second, the tubular esophagus may become replaced with columnar epithelium. The columnar epithelium is resistant to acid and is associated with the alleviation of the complaint of heartburn. This columnar epithelium often becomes intestinalized, identified histologically by the presence of goblet cells. This specialized intestinal metaplasia is currently required for the diagnosis of Barrett's esophagus. Endoscopically, Barrett's esophagus can be quiescent or associated with complications of esophagitis, stricture, Barrett's ulceration, and dysplasia. The complications associated with Barrett's esophagus may be due to the continuous irritation from refluxed duodenogastric juice. This continued injury is pH-dependent and may be modified by medical therapy. The incidence of metaplastic Barrett's epithelium becoming dysplastic and progressing to adenocarcinoma is approximately 1 percent per year.

An esophageal stricture can be associated with severe esophagitis or Barrett's esophagus. In the latter situation, it occurs at the site of maximal inflammatory injury, i.e., the columnar-squamous epithelial interface. As the columnar epithelium advances into the area of inflammation, the inflammation extends higher into the proximal esophagus and the site of the stricture moves progressively up the esophagus. Patients who have a stricture in the absence of Barrett's esophagus should have the presence of gastroesophageal reflux documented before the presence of the stricture is ascribed to reflux esophagitis. In patients with normal acid exposure, the stricture may be due to cancer or a drug-induced chemical injury, the latter resulting from the lodgment of a capsule or tablet in the distal esophagus. In such patients, dilation usually corrects the problem of dysphagia. Heartburn, which may have occurred only because of the chemical injury, need not be treated. It is also possible for drug-induced injuries to occur in patients who have underlying esophagitis and a distal esophageal stricture secondary to gastroesophageal reflux. In this situation, a long stringlike stricture progressively develops as a result of repetitive caustic injury from capsule or tablet lodgment on top of an initial reflux stricture. These strictures are often resistant to dilation.

When the refluxed gastric juice is of sufficient quantity, it can reach the pharynx, with the potential for pharyngeal tracheal aspiration, causing symptoms of repetitive cough, choking, hoarseness, and recurrent pneumonia. This is often an unrecognized complication of gastroesophageal reflux disease, since either the pulmonary or the gastrointestinal symptoms may predominate in the clinical situation and focus the physician's attention on one to the exclusion of the other. Three factors are important in these patients. First, it may take up to 7 days for the loss of respiratory epithelium secondary to the aspiration of gastric contents to be recovered, and a chronic cough may develop, between episodes of aspiration, that is not related to a reflux episode. Second, the presence of an esophageal motility disorder is observed in 75 percent of patients with reflux-induced aspiration and is believed to promote the aboral movement of the refluxate toward the pharynx. Third, if the pH in the cervical esophagus in patients with increased esophageal acid exposure is below 4 for less than 1 percent of the time, there is a high probability that the respiratory symptoms have been caused by aspiration. Increasingly, benign pulmonary pathology is recognized as secondary to gastroesophageal reflux disease including asthma, idiopathic pulmonary fibrosis, and bronchiectases.

Medical Therapy

Gastroesophageal reflux disease is such a common condition that most patients with mild symptoms carry out self-medication. Patients when first seen with symptoms of heartburn without obvious complications can reasonably be placed on 8 to 12 weeks of simple antacids before extensive investigations are carried out. In many situations, this successfully aborts the attacks. Patients should be advised to elevate the head of the bed, avoid tight clothing, eat small, frequent meals, avoid eating their nighttime meal shortly before retiring, lose weight, and avoid alcohol, coffee, chocolate, and peppermints, which may aggravate the symptoms.

Alginic acid, used in combination with simple antacids, may augment the relief of symptoms by creating a physical barrier to reflux as well as by acid reduction. Alginic acid reacts with sodium bicarbonate in the presence of saliva to form a highly viscous solution that floats like a raft on the surface of the gastric contents. When reflux occurs, this protective layer is refluxed into the esophagus and acts as a protective barrier against the noxious gastric contents. Medications to promote gastric emptying such as metoclopramide, domperidone, or cisapride are beneficial in early disease but of little value in more severe disease.

In patients with persistent symptoms, the mainstay of medical therapy is acid suppression. High dosage regimens of hydrogen potassium proton pump inhibitors, such as omeprazole (up to 40mg/day) can reduce gastric acidity by as much as 80 to 90 percent. This usually heals mild esophagitis. In severe esophagitis, healing may occur in only half of the patients. In patients who reflux a combination of gastric and duodenal juice, acid suppression therapy may give relieve symptoms while still allowing mixed reflux to occur. This can allow persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for gastroesophageal reflux disease, 80 percent of patients have a recurrence of symptoms.

Suggested Therapeutic Approach

The traditional stepwise approach to the therapy of gastroesophageal reflux disease should be reexamined in view of a more complete understanding of the pathophysiology of gastroesophageal reflux, the rising incidence of Barrett's esophagus, and the increasing mortality rates associated with end-stage reflux disease. The approach should be to identify risk factors for persistent and progressive disease early in the course of the disease and encourage surgical treatment when these factors are present. The following approach is suggested.

Patients presenting for the first time with symptoms suggestive of gastroesophageal reflux may be given initial therapy with H₂ blockers. In view of the availability of these as over-the-counter medication, many patients will have already self-medicated their symptoms. Failure of H₂ blockers to control the symptoms, or immediate return of symptoms after stopping treatment, suggests either that the diagnosis is incorrect or that the patient has relatively severe disease. Endoscopic examination at this stage of the patient's evaluation provides the opportunity for assessing the severity of mucosal damage and the presence of Barrett's esophagus. Both of these findings on initial endoscopy are associated with a high probability that medical treatment will fail. A measurement of the degree and pattern of esophageal exposure to gastric and duodenal juice, via 24-h pH and bilirubin monitoring, should be obtained at this point. The status of the LES and the function of the esophageal body should also be measured. These studies identify features such as the following, which are predictive of a poor response to medical therapy, frequent relapses, and the development of complications: supine reflux, poor esophageal contractility, erosive esophagitis (or a columnar-lined esophagus at initial presentation), bile in the refluxate, and a structurally defective sphincter. Patients who have these risk factors should be given

the option of surgery as a primary therapy with the expectation of long-term control of symptoms and complications.

Selection of Patients for Surgery

Studies on the natural history of gastroesophageal reflux disease indicate that most patients have a relatively benign form of the disease that is responsive to lifestyle changes and dietary and medical therapy, and do not need surgical treatment. Approximately 25 to 50 percent of the patients with gastroesophageal reflux disease have persistent or progressive disease, and it is this patient population that is best suited to surgical therapy. These patients are identified by the same risk factors that predict a poor response to medical therapy. In the past, the presence of esophagitis and a structurally defective LES were the primary indications for surgical treatment, and many internists and surgeons were reluctant to recommend operative procedures in their absence. However, one should not be deterred from considering antireflux surgery in a symptomatic patient with or without esophagitis or a defective sphincter, provided the disease process has been objectively documented by 24-h pH monitoring. This is particularly true in patients who have become dependent upon therapy with proton pump inhibitors, or require increasing doses to control their symptoms. It is important to note that a good response to medical therapy in this group of patients predicts an excellent outcome following antireflux surgery.

A structurally defective LES is the most important factor predicting failure of medical therapy. While patients with normal sphincter pressures tend to remain well controlled with medical therapy, patients with a structurally defective LES do not respond well to medical therapy, usually developing recurrent symptoms within 1 to 2 years of the onset of therapy, and these patients should be considered for an antireflux operation, regardless of the presence or absence of endoscopic esophagitis.

Young patients with documented reflux disease and a defective LES are also excellent candidates for antireflux surgery. They will invariably require long-term medical therapy for control of their symptoms and many will go on to develop complications of the disease. An analysis of the cost of therapy based upon data from the Veterans Administration Cooperative trial indicates that surgery has a cost advantage over medical therapy in patients less than 49 years of age.

Severe endoscopic esophagitis in a symptomatic patient with a structurally defective LES is also an indication for early surgical therapy. These patients are prone to breakthrough of their symptoms while receiving medical therapy. Symptoms and mucosal injury can be controlled in such patients, but careful monitoring is required, and increasing dosages of proton pump inhibitors are necessary. In everyday clinical practice, however, such treatment can be both difficult and impractical, and in such cases, antireflux surgery should be considered early as a therapeutic option.

The development of a stricture in a patient represents a failure of medical therapy, and is also an indication for a surgical antireflux procedure. In addition, strictures are often associated with a structurally defective sphincter and loss of esophageal contractility. Before proceeding with surgical treatment, malignancy and a drug etiology of the stricture should be excluded, and the stricture progressively dilated up to a 60 French bougie. When the stricture is fully dilated, the relief of dysphagia is evaluated and esophageal manometry is performed to determine the adequacy of peristalsis in the distal esophagus. If dysphagia is relieved and the amplitude of esophageal contractions is adequate, an antireflux procedure should be performed; if there is a global loss of esophageal contractility, caution should be exercised in performing an antireflux procedure with a complete fundoplication and a partial fundoplication should be considered.

Barrett's columnar-lined esophagus is commonly associated with a severe structural defect of the LES and often poor contractility of the esophageal body. Patients with Barrett's esophagus are at risk of progression of the mucosal abnormality up the esophagus, formation of a stricture, hemorrhage from a Barrett's ulcer, and the development of an adenocarcinoma. An antireflux procedure may arrest the progression of the disease, heal ulceration, and resolve strictures. Evidence is accumulating that surgical treatment also reduces the risk of progression to cancer. If severe dysplasia or intramucosal carcinoma is found on mucosal biopsy specimens, an esophageal resection should be done.

The ideal therapy of gastroesophageal reflux disease can be viewed conceptually along the continuum depicted in Fig. 23-46. The majority of patients requiring treatment have a relatively mild form of disease and will respond to antisecretory medications. Patients with more severe forms of disease, particularly those with risk factors predictive of medical failure and those who develop persistent or progressive disease, should be considered for early definitive therapy. Laparoscopic Nissen fundoplication will provide a long-term cure in the majority of these patients, with minimal discomfort, and an early return to normal activity. Patients who present with long-standing disease associated with poor esophageal function or a short esophagus should undergo an open antireflux procedure tailored to their underlying anatomic and physiologic abnormalities. Finally, if the disease has resulted in global failure of esophageal contractility, Barrett's metaplasia with high-grade dysplasia, or esophageal adenocarcinoma, an esophagectomy is required.

Surgical Therapy

Preoperative Evaluation

Before proceeding with an antireflux operation, several factors should be evaluated. First, the propulsive force of the body of the esophagus should be evaluated by esophageal manometry to determine if it has sufficient power to propel a bolus of food through a newly reconstructed valve. Patients with normal peristaltic contractions do well with a 360° Nissen fundoplication. When peristalsis is absent or severely disordered or the amplitude of the contraction is below 20 mmHg throughout the lower esophagus, the Belsey two-thirds partial fundoplication is the procedure of choice.

Second, anatomic shortening of the esophagus can compromise the ability to do an adequate repair without tension and lead to an increased incidence of breakdown or thoracic displacement of the repair. Esophageal shortening is identified on a barium swallow roentgenogram by a sliding hiatal hernia that will not reduce in the upright position or that measures larger than 5 cm between the diaphragmatic crura and gastroesophageal junction on endoscopy. When esophageal shortening is present, the motility of the esophageal body must be carefully evaluated and, if inadequate, a gastroplasty should be performed. In patients who have a global absence of contractility, more than 50 percent interrupted or dropped contractions, or a history of several failed previous antireflux procedures, esophageal resection should be considered as an alternative.

Third, the surgeon should specifically query the patient for complaints of nausea, vomiting, and loss of appetite. In the past, these symptoms were accepted as part of the reflux syndrome, but we now realize that they can be due to excessive duodenogastric reflux or gastric pathology. This problem is most pronounced in patients who have had previous upper gastrointestinal surgery, particularly cholecystectomy, although this is not always the case. In such patients, these symptoms may persist after an antireflux procedure, and patients should be given this information before the operation. In these patients, 24-h bilirubin monitoring and gastric emptying studies can be performed to detect and quantify duodenogastric abnormalities. Antireflux surgery alone may influence these symptoms by improving the efficiency of gastric emptying.

Fourth, approximately 30 percent of patients with proven gastroesophageal reflux on 24-h pH monitoring will have hypersecretion on gastric analysis, and 2 to 3 percent of patients who have an antireflux operation will develop a gastric or duodenal ulcer. The presence of *Helicobacter pylori* should be assessed in these patients and treated if present.

Principles of Surgical Therapy

The primary goal of antireflux surgery is to safely restore the structure of the sphincter or to prevent its shortening with gastric distention, while preserving the patient's ability to swallow normally, to belch to relieve gaseous distention, and to vomit when necessary. Regardless of the choice of the procedure, this goal can be achieved if attention is paid to five principles in reconstructing the cardia. First, the operation should restore the pressure of the distal esophageal sphincter to a level twice resting gastric pressure—i.e., 12 mmHg for a gastric pressure of 6 mmHg—and its length to at least 3 cm. This not only augments sphincter characteristics in patients in which they are reduced prior to surgery but prevents unfolding of a normal sphincter in response to gastric distention (Fig. 23-47). Preoperative and postoperative esophageal manometry measurements have shown that the resting sphincter pressure and the overall sphincter length can be surgically augmented over preoperative values, and that the change in the former is a function of the degree of gastric wrap around the esophagus (Fig. 23-48).

Second, the operation should place an adequate length of the distal esophageal sphincter in the positive-pressure environment of the abdomen by a method that ensures its response to changes in intraabdominal pressure. The permanent restoration of 1.5 to 2 cm of abdominal esophagus in a patient whose sphincter pressure has been augmented to twice resting gastric pressure will maintain the competency of the cardia over various challenges of intraabdominal pressure. All three of the popular antireflux procedures increase the length of the sphincter exposed to abdominal pressure by an average of 1 cm. When poorly performed, however, an operation may result in a reduction of the length of abdominal sphincter. Increasing the length of sphincter exposed to abdominal pressure will improve competency only if it is acted on by challenges of intraabdominal pressure. The creation of a conduit that will ensure the transmission of intraabdominal pressure changes around the abdominal portion of the sphincter is a necessary aspect of surgical repair. The fundoplication in the Nissen and Belsey repairs serves this purpose.

Third, the operation should allow the reconstructed cardia to relax on deglutition. In normal swallowing a vagally mediated relaxation of the distal esophageal sphincter and the gastric fundus occurs. The relaxation lasts for approximately 10 s and is followed by a rapid recovery to the former tonicity. To ensure relaxation of the sphincter, three factors are important: (1) only the fundus of the stomach should be used to buttress the sphincter, since it is known to relax in concert with the sphincter; (2) the gastric wrap should be properly placed around the sphincter and not incorporate a portion of the stomach or be placed around the stomach itself, since the body of the stomach does not relax with swallowing; and (3) damage to the vagal nerves during dissection of the thoracic esophagus should be avoided because it may result in failure of the sphincter to relax.

Fourth, the fundoplication should not increase the resistance of the relaxed sphincter to a level that exceeds the peristaltic power of the body of the esophagus. The resistance of the relaxed sphincter depends on the degree, length, and diameter of the gastric fundic wrap and on the variation in intraabdominal pressure. A 360° gastric wrap should be no longer than 2 cm and constructed over a 60 French bougie. This will ensure that the relaxed sphincter will have an adequate diameter with minimal resistance. This is not necessary when constructing a partial wrap.

Fifth, the operation should ensure that the fundoplication can be placed in the abdomen without undue tension and maintained there by approximating the crura of the diaphragm above the repair. Leaving the fundoplication in the thorax converts a sliding hernia into a paraesophageal hernia with all the complications associated with that condition. Maintaining the repair in the abdomen under tension predisposes to an increased incidence of recurrence. This can occur in patients who have a stricture or Barrett's esophagus and is due to shortening of the esophagus from the inflammatory process. This problem can be resolved by lengthening the esophagus by gastroplasty and constructing a partial fundoplication.

Procedure Selection

Selection of the surgical procedure and approach is based upon an assessment of esophageal contractility and length (Fig. 23-49). A transabdominal approach is used in patients with normal esophageal contractility and length. Patients with poor contractility or questionable esophageal length are approached transthoracically. Those with weak esophageal contractions and/or abnormal wave progression are treated with a partial fundoplication in order to avoid the increased outflow resistance associated with a complete fundoplication. If the esophagus is short after it is mobilized from diaphragm to aortic arch, a Collis gastroplasty is done to provide additional length and avoid placing the repair under tension. In the majority of patients who have good esophageal contractility and normal esophageal length the laparoscopic Nissen fundoplication is the procedure of choice for a primary antireflux repair. Experience and randomized studies have shown that the Nissen fundoplication is an effective and durable antireflux repair with minimal side effects that provides long-lasting relief of reflux symptoms in over 90 percent of patients.

Primary Antireflux Repairs Nissen Fundoplication

The most common antireflux procedure is the Nissen fundoplication. The procedure can be performed through an abdominal or a chest incision, and more recently through a laparoscope. Rudolph Nissen described the procedure as a 360° fundoplication around the lower esophagus for a distance of 4 to 5 cm. Although this provided good control of reflux, it was associated with a number of side effects which have encouraged modifications of the procedure as originally described. These include using only the gastric fundus to envelope the esophagus in fashion analogous to a Witzel jejunostomy, sizing the fundoplication with a 60 French bougie, and limiting the length of the fundoplication to 1 to 2 cm. The essential elements necessary for the performance of a transabdominal fundoplication are common to both the laparoscopic and open procedures and include the following:

- (1) Crural dissection, identification, and preservation of both vagi, and the anterior hepatic branch
- (2) Circumferential dissection of the esophagus
- (3) Crural closure
- (4) Fundic mobilization by division of short gastric vessels
- (5) Creation of a short, loose fundoplication by placing the posterior fundic wall posterior, and the anterior fundus anterior, to the esophagus, meeting at the right lateral position.

The Laparoscopic Approach

Laparoscopic fundoplication has become commonplace and has replaced the open abdominal Nissen fundoplication as the procedure of choice. Five 10-mm ports are utilized (Fig. 23-50). Dissection is begun by an incision of the portion of the gastrohepatic omentum above the hepatic branch of the anterior vagal nerve. The circumference of the diaphragmatic crura is dissected and the esophagus is mobilized by careful dissection of the anterior and posterior soft tissues within the hiatus. The esophagus is held anterior and to the left and the crura approximated with three to four interrupted 0 silk sutures, starting just above the aortic decussation and working anterior. Complete fundic mobilization allows construction of a tension-free fundoplication. Short gastric vessels along the upper third of the greater curvature are sequentially dissected and divided. Following complete mobilization, the posterior wall of the fundus is gently brought behind the esophagus to the right side. The anterior wall of the fundus is brought anterior to the esophagus and the fundic lips are manipulated to allow the fundus to envelope the esophagus without twisting (Fig. 23-51). A 60 French bougie is passed to properly size the fundoplication, and it is sutured utilizing a single U stitch of 2-0 Prolene buttressed with felt pledgets.

Transthoracic Nissen Fundoplication

The indications for performing an antireflux procedure by a transthoracic approach are as follows:

- (1) A patient who has had a previous hiatal hernia repair. In this situation, a peripheral circumferential incision in the diaphragm is made to provide simultaneous exposure of the upper abdomen. This allows safe dissection of the previous repair from both the abdominal and thoracic sides of the diaphragm.
- (2) A patient who requires a concomitant esophageal myotomy for achalasia or diffuse spasm.
- (3) A patient who has a short esophagus. This is usually associated with a stricture or Barrett's esophagus. In this situation, the thoracic approach is preferred to allow maximum mobilization of the esophagus and to perform a Collis gastroplasty in order to place the repair without tension below the diaphragm.
- (4) A patient with a sliding hiatal hernia that does not reduce below the diaphragm during a roentgenographic barium study in the upright position. This can indicate esophageal shortening, and, again, a thoracic approach is preferred for maximum mobilization of the esophagus and, if necessary, the performance of a Collis gastroplasty.
- (5) A patient who has associated pulmonary pathology. In this situation, the nature of the pulmonary pathology can be evaluated and the proper pulmonary surgery, in addition to the antireflux repair, can be performed.
- (6) An obese patient. In this situation, the abdominal repair is difficult because of poor exposure, particularly in men in whom the intraabdominal fat is more abundant.

In the thoracic approach the hiatus is exposed through a left posterior lateral thoracotomy incision in the sixth intercostal space, i.e., over the upper border of the seventh rib. When necessary, the diaphragm is incised circumferentially 2 to 3 cm from the lateral chest wall for a distance of approximately 10 to 15cm. The esophagus is mobilized from the level of the diaphragm to underneath the aortic arch. Mobilization up to the aortic arch is usually necessary to place the repair in a patient with a shortened esophagus into the abdomen without undue tension. Failure to do this is one of the major causes for subsequent breakdown of a repair and return of symptoms. The cardia is then freed from the diaphragm. When all the attachments between the cardia and diaphragmatic hiatus are divided, the fundus and part of the body of the stomach are drawn up through the hiatus into the chest. The vascular fat pad that lies at the gastroesophageal junction is excised. Crural sutures are then placed to close the hiatus and the fundoplication constructed by enveloping the fundus around the distal esophagus in a manner similar to that described for the abdominal approach. When complete, the fundoplication is placed into the abdomen by compressing the fundic ball with the hand and manually maneuvering it through the hiatus.

Belsey Mark IV Partial Fundoplication

In the presence of altered esophageal motility, where the propulsive force of the esophagus is not sufficient to overcome the outflow obstruction of a complete fundoplication, a partial fundoplication is indicated. Although a partial fundoplication may be performed laparoscopically (Toupet fundoplication), the Belsey Mark IV repair is the prototype of partial fundoplications. It consists of a 270° gastric fundoplication around the distal 4 cm of esophagus performed through a left chest incision (Fig. 23-52). The dissection of the Belsey Mark IV and the transthoracic Nissen operations are the same, differing only in the technique of constructing the fundoplication.

To perform the Belsey Mark IV partial fundoplication, the esophagus is mobilized up to the aortic arch, the cardia is dissected free of the hiatus, and the fundus of the stomach is brought up through the hiatus as described for the transthoracic Nissen procedure. The partial fundoplication is held in place by two rows of three horizontal mattress sutures placed equidistantly between the seromuscular layers of the stomach and the muscular layers of the esophagus. A second row of sutures is placed 1.5 to 2.0 cm above the first row, using the position of the previously placed sutures in the first row as a guide. The diaphragmatic sutures are placed at the 4, 8, and 12 o'clock positions on a clock face, oriented with the 6 o'clock position placed posteriorly between the right and left crus just anterior to the aorta. The reconstructed cardia is gently pushed through the hiatus and placed in the abdomen. Once in the abdomen, the cardia should remain there without tension. The diaphragmatic and crural sutures are then tied, anchoring the wrap in the abdomen.

In patients with a short esophagus secondary to a stricture, Barrett's esophagus, or a large hiatal hernia, the esophagus is lengthened with a Collis gastroplasty (Fig. 23-53). The esophagus is lengthened by constructing a gastric tube along the lesser curvature. This allows a tension-free constriction of a Belsey Mark IV or Nissen fundoplication around the newly formed gastric tube, with placement of the repair in the abdomen. Because a short esophagus is commonly associated with a reduction in esophageal contraction amplitude and the gastric tube is inert, most surgeons prefer to combine the gastroplasty procedure with a 280° Belsey Mark IV fundoplication rather than a 360° Nissen fundoplication.

Outcome after Fundoplication

Nearly all published reports of laparoscopic fundoplication show that this procedure relieves the typical symptoms of gastroesophageal reflux—heartburn, regurgitation, and dysphagia—in greater than 90 percent of the patients. Overall, there is a 4.2 percent conversion rate to open surgery, and a 0.5 percent rate of early reoperation. Persistent postoperative dysphagia occurred in approximately 9 percent of patients in the early series, a rate 2 to 3 times higher than what is accepted for open fundoplication. The incidence of dysphagia has decreased to the 3 to 5 percent range with increasing experience and attention to the technical details in constructing the fundoplication. Resting LES characteristics and esophageal acid exposure return to normal in nearly all patients (Fig. 23-54). Morbidity after laparoscopic fundoplication is similar to that after open fundoplication, averaging 10 to 15 percent. A pitfall unique to the laparoscopic approach is that 1 to 2 percent of patients develop a pneumothorax and surgical emphysema. This is related to excessive hiatal dissection and has decreased as surgeons' experience has increased. Unrecognized perforation of the esophagus or stomach is the most life-threatening complication. Perforations occur most often during hiatal and circumferential dissection of the esophagus, and their incidence is also related to the surgeon's experience. Intraoperative recognition and repair are the keys to preventing a life-threatening complication.

It is recommended that the surgical approach to patients with gastroesophageal reflux disease be selective, that is, that the specific antireflux procedure for any patient be based upon the patient's existing esophageal function. The benefit of a selective approach is shown in our experience with 85 consecutive patients with different spectra of the disease (Table 23-6). In approximately 75 to 80 percent of the patients a transabdominal Nissen fundoplication was the most suitable treatment. The remaining 20 to 25 percent were best treated by tailoring the antireflux procedure to their existing amplitude of esophageal contractility and esophageal length. Of interest, patients selected for a Belsey partial fundoplication because of poor motility but normal esophageal length benefited the least. This suggests that in these patients the motility disorder may be a primary abnormality rather than secondary to reflux-induced injury.

BARRETT'S ESOPHAGUS

The condition whereby the tubular esophagus is lined with columnar epithelium rather than squamous epithelium was first described by Norman Barrett in 1950. He incorrectly believed it to be congenital in origin. It is now realized that it is an acquired abnormality, occurs in 7 to 10 percent of patients with gastroesophageal reflux disease, and represents the end stage of the natural history of this disease. It is also distinctly different from the congenital condition in which islands of gastric fundic epithelium are found in the upper half of the esophagus.

The definition of Barrett's esophagus has evolved considerably over the past decade. Traditionally, Barrett's esophagus was identified by the presence of columnar mucosa extending at least 3 cm into the esophagus. It is now recognized that the specialized intestinal type epithelium found in the Barrett's mucosa is the only tissue predisposed to malignant degeneration. Consequently, the diagnosis of Barrett's esophagus is presently made given any length of endoscopically identifiable columnar mucosa that proves on biopsy to show intestinal metaplasia. While long segments of columnar mucosa without intestinal metaplasia do occur, they are uncommon and are probably congenital in origin.

The hallmark of intestinal metaplasia is the presence of intestinal goblet cells. There is a high prevalence of biopsy-demonstrated intestinal metaplasia at the cardia, on the gastric side of the squamocolumnar junction, in the absence of endoscopic evidence of a columnar-lined esophagus. Evidence is accumulating that these patches of what appears to be

Barrett's in the cardia have a similar malignant potential as the longer segments and are precursors for carcinoma of the cardia.

The long-term relief of symptoms remains the primary reason for performing antireflux surgery in patients with Barrett's esophagus. Healing of esophageal mucosal injury and the prevention of disease progression are important secondary goals. In this regard, patients with Barrett's esophagus are no different than the broader population of patients with gastroesophageal reflux. They should be considered for antireflux surgery when patient data suggest severe disease or predict the need for long-term medical management. Most patients with Barrett's esophagus are symptomatic. Although it has been argued that some patients with Barrett's esophagus may not have symptoms, careful history taking will reveal the presence of symptoms in most, if not all, patients.

Patients with Barrett's esophagus have a spectrum of disease ranging from visually identifiable but short segments to long segments of classic Barrett's esophagus. In general, however, they represent a relatively severe stage of gastroesophageal reflux, usually with markedly increased esophageal acid exposure, deficient LES characteristics, poor esophageal body function, and a high prevalence of duodenogastroesophageal reflux. Gastric hypersecretion occurs in 44 percent of patients. Most will require long-term proton pump inhibitor therapy for relief of symptoms and control of coexistent esophageal mucosal injury. Given such profound deficits in esophageal physiology, antireflux surgery is an excellent means of long-term control for most patients with Barrett's esophagus. In years past, referral for antireflux surgery was reserved for patients with associated complications such as stricture, ulceration, or progression of the metaplastic segment. The advent of laparoscopic fundoplication and its successful control of gastroesophageal reflux in over 90 percent of patients has lowered the threshold for referral. Patients with quiescent, uncomplicated Barrett's esophagus, particularly young patients, are now considered by many to be excellent candidates for antireflux surgery.

The typical complications in Barrett's esophagus include ulceration in the columnar-lined segment, stricture formation, and a dysplasia-cancer sequence. Barrett's ulceration is unlike the erosive ulceration of reflux esophagitis in that it more closely resembles peptic ulceration in the stomach or duodenum and has the same propensity to bleed, penetrate, or perforate. The strictures found in Barrett's esophagus occur at the squamocolumnar junction and are typically higher than peptic strictures in the absence of Barrett's esophagus. Ulceration and stricture in association with Barrett's esophagus were commonly reported prior to 1975, but with the advent of potent acid suppression medication they have become less common. In contrast, the complication of adenocarcinoma developing in Barrett's mucosa has become more common. Adenocarcinoma developing in Barrett's mucosa was considered a rare tumor prior to 1975. Today it occurs in approximately 1 in every 100 patient years of follow-up, which represents a risk 40 times that of the general population. Most, if not all, cases of adenocarcinoma of the esophagus arise in Barrett's epithelium (Fig. 23-55). About one-third of all patients with Barrett's esophagus present with malignancy.

The long-term risk of progression to dysplasia and adenocarcinoma, while not the driving force behind the decision to perform antireflux surgery, is a significant concern for both patient and physician. Although to date there have been no prospective randomized studies documenting that antireflux surgery has an effect on the risk of progression to dysplasia and carcinoma, complete control of reflux of gastric juice into the esophagus is clearly a desirable goal. As data accumulate regarding the relative impact of medical and surgical therapy on the natural history of Barrett's metaplasia, the risk of progression may play a larger role in therapeutic decisions.

Outcome of Antireflux Surgery in Patients with Barrett's Esophagus

Few studies have focused on the alleviation of symptoms after antireflux surgery in patients with Barrett's esophagus (Table 23-7). Those that are available document excellent to good results in 72 to 95 percent of patients at 5 years following surgery.

Several studies have compared medical and surgical therapy. Attwood et al., in a prospective but nonrandomized study, reported upon 45 patients undergoing either medical (26) or surgical (19) treatment of Barrett's esophagus. The groups were similar in age, length of Barrett's segment, the percentage of time during which pH was less than 4, and length of follow-up. Improvement of symptoms was dramatic after antireflux surgery. Symptoms of heartburn or dysphagia recurred in 88 percent of patients treated with medical therapy alone, and 21 percent after antireflux surgery. Complications, largely the development of an esophageal stricture, occurred in 38 percent of medically treated and 16 percent of surgically treated patients ($p < 0.05$) over the 3-year follow-up period. One patient in each group developed esophageal adenocarcinoma. They concluded that antireflux surgery was superior to acid suppression for both the control of symptoms and the prevention of complications in patients with Barrett's esophagus. Other nonrandomized comparisons of medical and surgical therapy have reported similar results.

Ortiz et al. have published a prospective randomized comparison of medical and surgical therapy in 59 patients with Barrett's esophagus. Twenty-seven patients were treated medically and thirty-two with antireflux surgery. Medical therapy consisted of either H2 blockade or proton pump inhibitors. All patients in the medical group were treated with omeprazole beginning in 1992. Symptomatic improvement occurred in the majority of patients in both groups, 85 percent of those receiving medical therapy and 89 percent of those who underwent antireflux surgery. There was a marked difference in the prevalence of persistent esophagitis and strictures between the medical and surgical groups. In the group receiving medical therapy 53 and 45 percent of patients had persistent esophagitis or stricture, compared to 5 and 15 percent of patients having antireflux surgery. The authors concluded that the "systematic" nonsurgical approach to Barrett's esophagus should be questioned. Taken together these studies document the ability of antireflux surgery to provide long-term symptomatic relief in patients with Barrett's esophagus.

Long-Term Results

Three relevant questions arise concerning the fate, over time, of the metaplastic tissue found in Barrett's esophagus: (1) Does antireflux surgery cause regression of Barrett's epithelium? (2) Does it prevent progression? (3) Can the development of Barrett's metaplasia be prevented by early antireflux surgery in patients with reflux disease?

Evidence suggests that neither medical nor surgical therapy reliably results in complete regression of Barrett's epithelium. Considerable enthusiasm followed the initial report of Brand and Pope in which Barrett's epithelium in 4 of 10 patients appeared to regress following antireflux surgery. Most subsequent studies have shown no consistent regression. In one of the most recent studies, Sagar et al. evaluated the effect of antireflux surgery on 56 patients with Barrett's esophagus. The majority of patients (31) had a partial fundoplication in which a higher incidence of persistent reflux was well documented. Of the 56 patients, 24 had partial or complete regression of the Barrett's segment at a median follow-up of 5.5 years. Complete regression occurred in only five patients. Nine patients showed progression of the length of Barrett's mucosa, and adenocarcinoma developed in one patient with persistent symptoms 9 years after surgery. All patients in which the Barrett's segment regressed were asymptomatic. The authors concluded that both regression and progression of columnar-lined esophagus occur, although the relief of symptoms and effective prevention of reflux favored regression.

Current data indicate that patients with Barrett's esophagus should remain in an endoscopic surveillance program following antireflux surgery since there is no reliable evidence to indicate that the Barrett's mucosa will regress. Biopsy specimens should be reviewed by a pathologist with expertise in the field. If low-grade dysplasia is confirmed, biopsies should be repeated after 12 weeks of high-dose acid suppression therapy. If high-grade dysplasia is evident on more than one biopsy specimen, esophageal resection is advisable because of the greater than 50 percent probability that an invasive cancer is already present. Early detection and resection have been shown to decrease the mortality rate from esophageal cancer in these patients.

Since Barrett's esophagus results from chronic uncontrolled gastroesophageal reflux, and esophageal adenocarcinoma is virtually always associated with intestinal metaplasia, there are strong theoretical grounds for halting the progression toward malignancy by permanently and effectively stopping reflux of gastric contents. Thus prevention of progression, not regression, becomes the central issue. Although some cancers have developed after antireflux surgery, the absence of preexistent dysplasia prior to surgery or the efficacy of the operative procedure in reducing 24-h esophageal acid exposure to normal has not been documented. If the dysplasia is reported as lower grade or indeterminant, then inflammatory change often confused with dysplasia should be suppressed by a course of acid suppression therapy in high doses for 2 to 3 weeks followed by rebiopsy of the Barrett's segment.

There is a growing body of evidence to attest to the ability of fundoplication to protect against dysplasia and invasive malignancy. Three studies suggest that an effective antireflux procedure can impact the natural history of Barrett's esophagus in this regard. McCallum and co-workers analyzed the longitudinal follow-up of patients with Barrett's esophagus in the registry of the American College of Gastroenterologists. All patients had nondysplastic quiescent Barrett's esophagus at initial endoscopy; 152 received medical treatment and 29 underwent antireflux surgery. Surveillance endoscopy was performed annually. Of patients in the medically treated group 19 percent developed dysplasia while on medical therapy while only 3.4 percent did after antireflux surgery. A single adenocarcinoma was identified in a patient undergoing medical treatment.

In the prospective randomized study of Ortiz et al., dysplasia developed in 6 of 27 patients (22 percent) while on medical treatment. It was low-grade in five patients and high-grade in one. A single patient developed dysplasia following antireflux surgery; 24-h pH monitoring showed that the fundoplication procedure in this patient had been ineffective. The small number of patients developing dysplasia prevented these data from being statistically significant, but the trend is clear and is similar to that identified by McCallum.

Data from the Mayo clinic strongly suggest that antireflux surgery impacts the development of adenocarcinoma in patients with Barrett's esophagus. The authors reviewed the outcome of 118 patients with Barrett's esophagus undergoing antireflux surgery between 1960 and 1990. Three cancers occurred over an 18.5 year follow-up period, all within the first 3 years after surgery (Fig. 23-56). The fact that the development of adenocarcinoma was clustered in the early years after antireflux surgery and not randomly dispersed throughout the follow-up period suggests that antireflux surgery altered the natural history of the disease. Hammeetman has shown that once dysplasia has developed, carcinoma ensues in an average of 3 years. The occurrence of all observed cancers in the first few years suggests that the point of no return in the dysplasia-cancer sequence had already occurred prior to the time of antireflux surgery.

A more fundamental issue, but one that is less often addressed, is that of preventing Barrett's esophagus. It is likely that an aggressive diagnostic approach coupled with early and complete elimination of gastroesophageal reflux in patients free of Barrett's esophagus would dramatically reduce its incidence. While it is theoretically possible to eliminate gastroesophageal reflux with high doses of proton pump inhibitors, the requirement to do so 24 h a day, 7 days a week, 365 days a year for the patient's lifetime makes it impractical. Rather, carefully performed antireflux surgery in carefully selected patients is likely to be a more expedient choice. The effect of reliable and complete control of gastroesophageal reflux on the natural history of Barrett's metaplasia once it has developed, and on its prevention in symptomatic patients free of complications, is one of the most important areas of study over the next decade.

Atypical Reflux Symptoms (Fig. 23-57)

Chronic respiratory symptoms, such as chronic cough, recurrent pneumonias, episodes of nocturnal choking, waking up with gastric contents in the mouth, or soilage of the bed pillow, may also indicate the need for surgical therapy. The chest radiogram in patients suffering from repetitive pulmonary aspiration secondary to gastroesophageal reflux often shows signs of pleural thickening, bronchiectasis, and chronic interstitial pulmonary fibrosis. If 24-h pH monitoring confirms the presence of increased esophageal acid exposure and manometry shows normal esophageal body motility, an antireflux procedure can be done with an expected good result. Usually these patients have, however, a nonspecific motor abnormality of the esophageal body which tends to propel the refluxed material toward the pharynx. In some of these patients, the motor abnormality will disappear after a surgical antireflux procedure. In others, the motor disorder will persist and contribute to postoperative aspiration of swallowed saliva and food. Consequently, the results of an antireflux procedure in patients with a motor disorder of the esophageal body are variable.

Chest pain may be an atypical symptom of gastroesophageal reflux and is often confused with coronary artery disease. Fifty percent of patients in whom a cardiac cause of the

chest pain has been excluded will have increased esophageal acid exposure as a cause of the episode of pain. An antireflux procedure provides relief of the chest pain with greater constancy than will occur with medical therapy.

Dysphagia, regurgitation, or chest pain on eating in a patient with normal endoscopy and esophageal function studies can be an indication for an antireflux procedure. These symptoms are usually related to the presence of a large paraesophageal hernia, intrathoracic stomach, or a small hiatal hernia with a narrow diaphragmatic hiatus. A Schatzki ring may be present with the latter. All these conditions are easily identified with an upper gastrointestinal radiographic barium examination done by a knowledgeable radiologist. These patients may have no heartburn, since the LES is usually normal and reflux of gastric acid into the esophagus does not occur. The surgical repair of the hernia usually includes an antireflux procedure because of the potential of destroying the competency of the cardia during the surgical dissection.

Reoperation for Failed Antireflux Repairs

Failure of an antireflux procedure occurs when the patient, after the repair, is unable to swallow normally, experiences upper abdominal discomfort during and after meals, or has recurrence or persistence of reflux symptoms. The assessment of these symptoms and the selection of patients who need further surgery are challenging problems. Functional assessment of patients who have recurrent, persistent, or emergent new symptoms following a primary antireflux repair is critical to identify the cause of failure. Analysis of patients requiring reoperation after a previous antireflux procedures shows that placement of the wrap around the stomach is the most frequent cause for failure after open procedures, while herniation of the repair into the chest is the most frequent cause of failure after a laparoscopic procedure. This is probably due, in both instances, to an unrecognized short esophagus. In the laparoscopic approach the elevated diaphragm allows the repair to be properly placed but the tension from the short esophagus pulls the repair above the diaphragm when the crura are relaxed. Partial or complete breakdown of the fundoplication and construction of a too-tight or too-long wrap of a fundoplication occurs with both open and closed procedures. The fact that 10 percent of these patients had an undiagnosed underlying esophageal motor disorder underlines the critical role of preoperative esophageal function tests before the initial procedure.

The preferred surgical approach to a patient who has had a previously failed antireflux procedure is through a left thoracotomy with a peripheral circumferential incision in the diaphragm to provide for simultaneous exposure of the upper abdomen and safe dissection of the previous repair from both abdominal and thoracic sides of the diaphragm. Patients who have recurrence of heartburn and regurgitation without dysphagia and have good esophageal motility are most amenable to reoperation and can be expected to have an excellent outcome. When dysphagia is the cause of failure, the situation is more difficult to manage. If the dysphagia occurred immediately following the repair, it is usually due to a technical failure, most commonly a misplaced fundoplication around the upper stomach, and rerepair is usually satisfactory. When dysphagia is associated with poor motility and multiple previous repairs, serious consideration should be given to esophageal resection and replacement. With each reoperation the esophagus is damaged further and the chances of preserving function become less. Also, blood supply is reduced and ischemic necrosis of the esophagus can occur after several previous mobilizations.

MOTILITY DISORDERS OF THE PHARYNX AND ESOPHAGUS

Clinical Manifestations

Dysphagia, i.e., difficulty in swallowing, is the primary symptom of esophageal motor disorders. Its perception by the patient is a balance between the severity of the underlying abnormality causing the dysphagia and the adjustment made by the patient in altering eating habits. Consequently, any complaint of dysphagia must include an assessment of the patient's dietary history. It must be known whether the patient experiences pain, chokes, or vomits with eating; whether the patient requires liquids with the meal, is the last to finish, or is forced to interrupt a social meal; and whether he or she has been admitted to the hospital for food impaction. These assessments, plus an evaluation of the patient's nutritional status, help to determine how severe the dysphagia is and evaluate the indications for surgical therapy.

A surgical myotomy is designed to improve the symptoms of dysphagia caused by a motility disorder. The results can profoundly improve the patient's ability to ingest food, but rarely return the function of the foregut to normal. The principle of the procedure is to destroy esophageal contractility in order to correct a defect in esophageal motility, resulting in improvement but never a return to normal function. To use a surgical myotomy to treat the problem of dysphagia, the surgeon needs to know the precise functional abnormality causing the symptom. This usually entails a complete esophageal motility evaluation. A clear understanding of the physiologic mechanism of swallowing and determination of the motility abnormality giving rise to the dysphagia are essential for determining if surgery is indicated and the extent of the myotomy to be performed. Endoscopy is necessary only to exclude the presence of tumor or inflammatory changes as the cause of dysphagia.

Motility Disorders of the Pharyngoesophageal Segment

Disorders of the pharyngoesophageal phase of swallowing result from a discoordination of the neuromuscular events involved in chewing, initiation of swallowing, and propulsion of the material from the oropharynx into the cervical esophagus. They can be categorized into one or a combination of the following abnormalities: (1) inadequate oropharyngeal bolus transport; (2)inability to pressurize the pharynx; (3) inability to elevate the larynx; (4) discoordination of pharyngeal contraction and cricopharyngeal relaxation; and (5) decreased compliance of the pharyngoesophageal segment secondary to muscle pathology. The latter results in incomplete anatomic relaxation of the cricopharyngeus and cervical esophagus.

Pharyngoesophageal swallowing disorders are usually congenital or due to acquired disease involving the central and peripheral nervous system. This includes cerebrovascular accidents, brainstem tumors, poliomyelitis, multiple sclerosis, Parkinson's disease, pseudobulbar palsy, peripheral neuropathy, and operative damage to the cranial nerves involved in swallowing. Muscular diseases such as radiation-induced myopathy, dermatomyositis, myotonic dystrophy, and myasthenia gravis are less common causes. Rarely, extrinsic compression by thyromegaly, cervical lymphadenopathy, or hyperostosis of the cervical spine can cause pharyngoesophageal dysphagia.

Diagnostic Assessment of the Cricopharyngeal Segment

Abnormalities of pharyngoesophageal swallowing are difficult to assess with standard manometric techniques because of the rapidity of the oropharyngeal phase of swallowing, the movement of the gullet, and the asymmetry of the cricopharyngeus. Video- or cineradiography is currently the most objective test to evaluate oropharyngeal bolus transport, pharyngeal compression, relaxation of the pharyngoesophageal segment, and the dynamics of airway protection during swallowing. It readily identifies a diverticulum (Fig. 23-58), stasis of the contrast medium in the valleculae, a cricopharyngeal bar, and/or narrowing of the pharyngoesophageal segment. These are anatomic manifestations of neuromuscular disease, and result from the loss of muscle compliance in portions of the pharynx and esophagus composed of skeletal muscle.

Careful analysis of video- or cineradiographic studies combined with manometry using specially designed catheters can identify the cause of a pharyngoesophageal dysfunction in most situations (Fig. 23-59). Motility studies may demonstrate inadequate pharyngeal pressurization, insufficient or lack of cricopharyngeal relaxation, marked discoordination of pharyngeal pressurization, cricopharyngeal relaxation and cervical esophageal contraction, or a hypopharyngeal bolus pressure suggesting decreased compliance of the skeletal portion of the cervical esophagus (Fig. 23-60).

In many patients with cricopharyngeal dysfunction, including those with Zenker's diverticulum, it has been difficult to consistently demonstrate a motility abnormality or discoordination of pharyngoesophageal events. The abnormality most apt to be present is a loss of compliance in the pharyngoesophageal segment manifested by an increased bolus pressure. Cook and colleagues have demonstrated an increased resistance to the movement of a bolus through what appears on manometry to be a completely relaxed cricopharyngeal sphincter. Using simultaneous manometry and videofluoroscopy they showed that in these patients the cricopharyngeus is only partially relaxed; that is, the sphincter is relaxed enough to allow a drop of its pressure to esophageal baseline on manometry, but insufficiently relaxed to allow unimpaired passage of the bolus into the esophagus (Fig. 23-61). This incomplete relaxation is due to a loss of compliance of the muscle in the pharyngoesophageal segment and may be associated with a cricopharyngeal bar or Zenker's diverticulum. This decreased compliance of the cricopharyngeal sphincter can be recognized on esophageal manometry by a "shoulder" on the pharyngeal pressure wave, the amplitude of which correlates directly with the degree of outflow obstruction (Fig. 23-62). Increasing the diameter of this noncompliant segment reduces the resistance imposed to the passage of a bolus. Consequently, patients with low pharyngeal pressure, that is, poor piston function of the pharynx, or patients with increased resistance of the pharyngocervical esophageal segment from loss of skeletal muscle compliance are improved by a pharyngocricocervical esophageal myotomy. This enlarges the pharyngoesophageal segment and reduces outflow resistance. Esophageal muscle biopsy specimens from patients with Zenker's diverticulum have shown histologic evidence of the restrictive myopathy in the pharyngoesophageal segment. These findings correlate well with the observation of a decreased compliance of the upper esophagus demonstrated by videoradiography and the findings on detailed manometric studies of the pharynx and cervical esophagus. They suggest that the diverticulum develops as a consequence of the outflow resistance to bolus transport through the noncompliant muscle of the pharyngoesophageal segment.

The requirements for a successful pharyngoesophageal myotomy are (1) adequate oropharyngeal bolus transport; (2) the presence of an intact swallowing reflux; (3) reasonable coordination of pharyngeal pressurization with cricopharyngeal relaxation; (4) a cricopharyngeal bar, Zenker's diverticulum, or a narrowed pharyngoesophageal segment on videosophagogram and/or the presence of excessive pharyngoesophageal shoulder pressure on motility study.

Zenker's Diverticulum

In the past, the most common recognized sign of pharyngoesophageal dysfunction was the presence of a Zenker's diverticulum, originally described by Ludlow in 1769. The eponym resulted from Zenker's classic clinicopathologic descriptions of 34 cases published in 1878. Pharyngoesophageal diverticula have been reported to occur in 0.1 percent of 20,000 routine barium examinations and classically occur in elderly white males. Zenker's diverticula tend to enlarge progressively with time due to the decreased compliance of the skeletal portion of the cervical esophagus that occurs with aging.

Presenting symptoms include dysphagia associated with the spontaneous regurgitation of undigested, bland material, often interrupting eating or drinking. The symptom of dysphagia is due initially to the loss of muscle compliance in the pharyngoesophageal segment, later augmented by the presence of an enlarging diverticulum. On occasion, the dysphagia can be severe enough to cause debilitation and significant weight loss. Chronic aspiration and repetitive respiratory infection are common associated complaints. The diagnosis, once suspected, is established by a barium swallow. Endoscopy is usually difficult in the presence of a cricopharyngeal diverticulum, and potentially dangerous, owing to obstruction of the true esophageal lumen by the diverticulum and the attendant risk of diverticular perforation.

Pharyngocricoesophageal Myotomy

The low morbidity and mortality associated with cricopharyngeal and upper esophageal myotomy have encouraged a liberal approach toward its use for almost any problem in the oropharyngeal phase of swallowing. This attitude has resulted in an overall success rate in the relief of symptoms of only 64 percent. When patients are selected using radiographic or motility markers of disease as outlined above, it is unusual for patients not to be benefited.

The myotomy can be performed under local or general anesthesia through an incision along the anterior border of the left sternocleidomastoid muscle. The pharynx and cervical esophagus are exposed by retracting the sternocleidomastoid muscle and carotid sheath laterally and the thyroid, trachea, and larynx medially (Fig. 23-63). When a pharyngoesophageal diverticulum is present, localization of the pharyngoesophageal segment is easy. The diverticulum is carefully freed from the overlying areolar tissue to expose its neck, just below the inferior pharyngeal constrictor and above the cricopharyngeus muscle. It can be difficult to identify the cricopharyngeus muscle in the absence of a

diverticulum. A benefit of local anesthesia is that the patient can swallow and demonstrate an area of persistent narrowing at the pharyngoesophageal junction. Further, before closing the incision, gelatin can be fed to the patient to ascertain whether the symptoms have been relieved and to inspect the opening of the previously narrowed pharyngoesophageal segment. Under general anesthesia, and in the absence of a diverticulum, the placement of a nasogastric tube to the level of the manometrically determined cricopharyngeal sphincter helps in localization of the structures. The myotomy is extended cephalad by dividing 1 to 2 cm of inferior constrictor muscle of the pharynx and caudad by dividing the cricopharyngeal muscle and the cervical esophagus for a length of 4 to 5 cm. The cervical wound is closed only when all oozing of blood has ceased since a hematoma after this procedure is common and is often associated with temporary dysphagia while the hematoma absorbs. Oral alimentation is started the day after surgery. The patient is usually discharged on the first or second postoperative day.

If a diverticulum is present and is large enough to persist after a myotomy, it may be sutured in the inverted position to the prevertebral fascia using a permanent suture, i.e., diverticulopexy (Fig. 23-64). If the diverticulum is excessively large so that it would be redundant if suspended, or its walls are thickened, a diverticulectomy should be performed.

Postoperative complications include fistula formation, abscess, hematoma, recurrent nerve paralysis, difficulties in phonation, and Horner's syndrome. The incidence of the first two can be reduced by performing a diverticulopexy. Recurrence of a Zenker's diverticulum occurs late, and is more common after diverticulectomy without myotomy, presumably due to persistence of the underlying loss of compliance of the cervical esophagus when a myotomy is not performed.

Postoperative motility studies have shown that the peak pharyngeal pressure generated on swallowing is not affected, the resting cricopharyngeal pressure is reduced but not eliminated and the cricopharyngeal sphincter length is shortened. Consequently, after myotomy there is protection against esophagopharyngeal regurgitation.

Motility Disorders of the Esophageal Body and LES

Disorders of the esophageal phase of swallowing result from abnormalities in the propulsive pump action of the esophageal body or the relaxation of the LES. These disorders result from either primary esophageal abnormalities or from generalized neural, muscular, or collagen vascular disease (Table 23-8). The use of standard esophageal manometry techniques has allowed specific primary esophageal motility disorders to be identified out of a pool of nonspecific motility abnormalities. These include achalasia, diffuse esophageal spasm, the so-called nutcracker esophagus, and the hypertensive LES. The manometric characteristics of these disorders are shown in Table 23-9.

The boundaries between the primary esophageal motor disorders are, however, vague, and intermediate types exist. This is because their diagnosis usually is based on the analysis of 10 wet swallows performed in a laboratory setting. The technique of ambulatory 24-h monitoring of esophageal motor activity allows the classification of esophageal motor disorders to be performed on the basis of more than 1000 contractions recorded during different physiologic states, that is, normal daily activity, eating, and sleeping. There are significant differences in the classification of esophageal motor disorders based on standard manometry and classification based on ambulatory monitoring (see Fig. 23-25). The degree of reclassification that occurs when analysis of esophageal motor function is done on the basis of ambulatory manometry indicates that the classic categories of esophageal motor disorders are inappropriate. These findings indicate that esophageal motility disorders should be looked at as a spectrum of abnormalities which reflects various stages of destruction of esophageal motor function.

Achalasia

The best-known and best-understood primary motility disorder of the esophagus is achalasia, with an incidence of 6 per 100,000 population per year. Although complete absence of peristalsis in the esophageal body has been proposed as the major abnormality, present evidence indicates achalasia is a primary disorder of the LES. This is based on 24-h outpatient esophageal motility monitoring, which shows that even in advanced disease up to 5 percent of contractions can be peristaltic. Simultaneous esophageal waves develop as a result of the increased resistance to esophageal emptying caused by the nonrelaxing LES. This is supported by experimental studies in which a Gore-Tex band placed loosely around the gastroesophageal junction in cats did not change sphincter pressures, but resulted in impaired relaxation of the LES and outflow resistance. This led to a marked increased frequency of simultaneous waveforms and a decrease in contraction amplitude. The changes were associated with radiographic dilation of the esophagus and were reversible after removal of the band. Observations in patients with pseudoachalasia due to tumor infiltration, a tight stricture in the distal esophagus, or an antireflux procedure that is too tight also provide evidence that dysfunction of the esophageal body can be caused by the increased outflow obstruction of a nonrelaxing LES. The observation that esophageal peristalsis can return in patients with classic achalasia following dilation or myotomy provides further support that achalasia is a primary disease of the LES.

The pathogenesis of achalasia is presumed to be a neurogenic degeneration, which is either idiopathic or due to infection. In experimental animals, the disease has been reproduced by destruction of the nucleus ambiguus and the dorsal motor nucleus of the vagus nerve. In patients with the disease, degenerative changes have been shown in the vagus nerve and in the ganglia in the Auerbach plexus of the esophagus itself. This degeneration results in hypertension of the LES, a failure of the sphincter to relax on deglutition, elevation of intraluminal esophageal pressure, esophageal dilatation, and a subsequent loss of progressive peristalsis in the body of the esophagus. The esophageal dilatation results from the combination of a nonrelaxing sphincter, which causes a functional holdup of ingested material in the esophagus, and elevation of intraluminal pressure from repetitive pharyngeal air swallowing (Fig. 23-65). With time, the functional disorder results in anatomic alterations seen on radiographic studies, such as a dilated esophagus with a tapering, beaklike narrowing of the distal end (Fig. 23-66). There is usually an air-fluid level in the esophagus from the retained food and saliva, the height of which reflects the degree of resistance imposed by the nonrelaxing sphincter. As the disease progresses, the esophagus becomes massively dilated and tortuous.

A subgroup of patients with otherwise typical features of classic achalasia have simultaneous contractions of their esophageal body which can be of high amplitude. This manometric pattern has been termed "vigorous achalasia," and chest pain episodes are a common finding in these patients. Differentiation of vigorous achalasia from diffuse esophageal spasm can be difficult. In both diseases videoradiographic examination can show a corkscrew deformity of the esophagus and diverticulum formation.

Diffuse and Segmental Esophageal Spasm

Diffuse esophageal spasm is characterized by substernal chest pain and/or dysphagia. Diffuse esophageal spasm differs from classic achalasia in that it is primarily a disease of the esophageal body, produces a lesser degree of dysphagia, causes more chest pain, and has less effect on the patient's general condition. True symptomatic diffuse esophageal spasm is a rare condition, occurring about five times less frequently than achalasia.

The causation and neuromuscular pathophysiology of diffuse esophageal spasm are unclear. The basic motor abnormality is rapid wave progression down the esophagus secondary to an abnormality in the latency gradient. Hypertrophy of the muscular layer of the esophageal wall and degeneration of the esophageal branches of the vagus nerve have been observed in this disease, although these are not constant findings. Manometric abnormalities in diffuse esophageal spasm may be present over the total length of the esophageal body, but usually are confined to the distal two-thirds. In *segmental esophageal spasm* the manometric abnormalities are confined to a short segment of the esophagus.

The classic manometric findings in these patients are characterized by the frequent occurrence of simultaneous wave forms and multi peaked esophageal contractions, which may be of abnormally high amplitude or long duration. Key to the diagnosis of diffuse esophageal spasm is that there remain some peristaltic waveforms in excess of those seen in achalasia. A criterion of 20 percent or more simultaneous waveforms out of 10 wet swallows has been used to diagnose diffuse esophageal spasm. This figure is, however, arbitrary and often debated. Discriminate analysis has identified a series of abnormalities on the ambulatory motility record of patients with classic diffuse esophageal spasm. A composite score based on these parameters of the ambulatory motility record has allowed diagnosis of the disease with a sensitivity of 90 percent and a specificity of 100 percent. When applied prospectively, this scoring system identified severely deteriorated esophageal motor function in symptomatic patients despite the absence of the classic motility abnormalities of diffuse spasm on standard manometry.

The LES in patients with diffuse esophageal spasm usually shows a normal resting pressure and relaxation on deglutition. A hypertensive sphincter with poor relaxation may also be present. In patients with advanced disease, the radiographic appearance of tertiary contractions appears helical and has been termed *corkscrew esophagus* or *pseudodiverticulosis* (Fig. 23-67). Patients with segmental or diffuse esophageal spasm can compartmentalize the esophagus and develop an epiphrenic or midesophageal diverticulum (Fig. 23-68).

Nutcracker Esophagus

The disorder termed "nutcracker" or "supersqueezer" esophagus was recognized in the late 1970s. Other terms used to describe this entity are "hypertensive peristalsis" or "high-amplitude peristaltic contractions." It is the most frequent of the primary esophageal motility disorders. By definition the so-called nutcracker esophagus is a manometric abnormality in patients with chest pain characterized by peristaltic esophageal contractions with peak amplitudes greater than 2 SDs above the normal values in individual laboratories. Contraction amplitudes in these patients can easily be above 400 mmHg. Ambulatory 24-h monitoring of esophageal motor function in patients diagnosed as having nutcracker esophagus has identified a subgroup of patients with a motor pattern characteristic of diffuse esophageal spasm. These patients usually complain of dysphagia in addition to chest pain and probably are misclassified on the basis of standard manometric findings. The identification of these patients is important, since esophageal myotomy is a therapeutic option for patients with dysphagia and diffuse esophageal spasm but is of questionable value in patients with chest pain secondary to nutcracker esophagus.

Hypertensive Lower Esophageal Sphincter

Hypertensive LES in patients with chest pain or dysphagia was first described as a separate entity by Code et al. This disorder is characterized by an elevated basal pressure of the LES with normal relaxation and normal propulsion in the esophageal body. About half of these patients, however, have associated motility disorders of the esophageal body, particularly hypertensive peristalsis and simultaneous waveforms. In the remainder, the disorder exists as an isolated abnormality. Dysphagia in these patients may be caused by a lack of compliance of the sphincter even in its relaxed state. Myotomy of the LES may be indicated in patients not responding to medical therapy or dilation.

Nonspecific Esophageal Motor Disorders

Many patients complaining of dysphagia or chest pain of noncardiac origin demonstrate a variety of wave patterns and contraction amplitudes on esophageal manometry that are clearly out of the normal range but do not meet the criteria of a primary esophageal motility disorder. Esophageal manometry in these patients frequently shows an increased number of multi peaked or repetitive contractions, contractions of prolonged duration, nontransmitted contractions, an interruption of a peristaltic wave at various levels of the esophagus, or contractions of low amplitude. These motility abnormalities have been termed nonspecific esophageal motility disorders. Their significance in the causation of chest pain or dysphagia is still unclear. Surgery plays no role in the treatment of these disorders unless there is an associated diverticulum.

A clear distinction between primary esophageal motility disorders and nonspecific esophageal motility disorders is often not possible. Patients diagnosed as having nonspecific esophageal motility abnormalities on repeated studies will occasionally show abnormalities consistent with nutcracker esophagus. Similarly, progression from a nonspecific esophageal motility disorder to classic diffuse esophageal spasm has been demonstrated. The finding of a nonspecific esophageal motility disorder, therefore, may represent only a manometric marker of an intermittent more severe esophageal motor abnormality. Combined ambulatory 24-h esophageal pH and motility monitoring has shown that an increased esophageal exposure to gastric juice is common in patients diagnosed as having a nonspecific esophageal motility disorder. In some situations, the motor abnormalities may be induced by the irritation of refluxed gastric juice; in other situations it may be a primary event unrelated to the presence of reflux.

Diverticula of the Esophageal Body

Radiographic abnormalities such as segmental spasm, corkscrewing, compartmentalization, and diverticulum are the anatomic results of disordered motility function. Of these, the most persistent and easiest to demonstrate is an esophageal diverticulum. Diverticula occur most commonly with nonspecific motility disorders but can occur with all of the primary motility disorders. In the latter situation, the motility disorder is usually diagnosed before the development of the diverticulum. When present, a diverticulum may temporarily alleviate the symptom of dysphagia by becoming a receptacle for ingested food, and substitute the symptoms of postprandial pain and the regurgitation of undigested food. If a motility abnormality of the esophageal body or LES cannot be identified, a traction or congenital cause for the diverticulum should be considered. Because development in radiology preceded development in motility monitoring, diverticula of the esophagus were considered historically to be a primary abnormality, the cause, rather than the consequence, of motility disorders. Consequently, earlier texts focused on them as specific entities based upon their location.

Epiphrenic diverticula arise from the terminal third of the thoracic esophagus and are usually found adjacent to the diaphragm. They have been associated with distal esophageal muscular hypertrophy, esophageal motility abnormalities, and increased luminal pressure. They are “pulsion” diverticula, and have been associated with diffuse spasm, achalasia, or nonspecific motor abnormalities in the body of the esophagus.

Whether the diverticulum should be surgically resected or suspended depends upon its size and proximity to the vertebral body. When diverticula are associated with esophageal motility disorders, esophageal myotomy from the distal extent of the diverticulum to the stomach is indicated; otherwise, one can expect a high incidence of suture line rupture due to the same intraluminal pressure that initially gave rise to the diverticulum. If the diverticulum is suspended to the prevertebral fascia of the thoracic vertebra, a myotomy is begun at the neck of the diverticulum and extended across the LES. If the diverticulum is excised by dividing the neck, the muscle is closed over the excision site and a myotomy is performed on the opposite esophageal wall, starting at the level of diverticulum. When a large diverticulum is associated with a hiatal hernia, the diverticulum is excised, a myotomy is performed if there is an associated esophageal motility abnormality, and the hernia is repaired because of the high incidence of postoperative reflux when it is omitted.

Midesophageal or traction diverticula were first described in the nineteenth century (Fig. 23-69). At that time they were frequently noted in patients who had mediastinal lymph node involvement with tuberculosis. It was theorized that adhesions form between the inflamed mediastinal nodes and the esophagus. By contraction, the adhesions exerted “traction” on the esophageal wall and led to a localized diverticulum (Fig. 23-70). This theory was based on the findings of early dissections, where adhesions between diverticula and lymph nodes were commonly found. It is now believed that some diverticula in the midesophagus may also be caused by motility abnormalities.

Most midesophageal diverticula are asymptomatic and incidentally discovered during investigation for nonesophageal complaints. In such patients, the radiologic abnormality may be ignored. Patients with symptoms of dysphagia, regurgitation, chest pain, or aspiration in whom a diverticulum is discovered should be thoroughly investigated for an esophageal motor abnormality and treated appropriately. Occasionally, a patient will present with a bronchoesophageal fistula manifested by a chronic cough on ingestion of meals. The diverticulum in such patients is most likely to have an inflammatory etiology.

The indication for surgical intervention is the degree of symptomatic disability. Usually midesophageal diverticula can be suspended due to their proximity to the spine. If motor abnormality is documented, a myotomy should be performed similar to that described for an epiphrenic diverticulum.

Operations Long Esophageal Myotomy for Motor Disorders of the Esophageal Body

A long esophageal myotomy is indicated for dysphagia caused by any motor disorder characterized by segmental or generalized simultaneous waveforms in a patient whose symptoms are not relieved by medical therapy. Such disorders include diffuse and segmental esophageal spasm, vigorous achalasia, and nonspecific motility disorders associated with a mid or epiphrenic esophageal diverticulum. However, the decision to operate must be made by a balanced evaluation of the patient's symptoms, diet, lifestyle adjustments, and nutritional status, with the most important factor being the possibility of improving the patient's swallowing disability. The symptom of chest pain alone is not an indication for a surgical procedure.

Twenty-four-hour ambulatory motility monitoring has greatly aided in the identification of patients with symptoms of dysphagia and chest pain who might benefit from a surgical myotomy. Ambulatory motility studies have shown that when the prevalence of “effective contractions,” that is, peristaltic waveforms consisting of contractions with an amplitude above 30 mmHg, drops below 50 percent during meals, the patient is likely to experience dysphagia (Fig. 23-71). This would suggest that relief from the symptom can be expected with an improvement of esophageal contraction amplitude or amelioration of nonperistaltic waveforms. Prokinetic agents may increase esophageal contraction amplitude but do not alter the prevalence of simultaneous waveforms. Patients in whom the efficacy of esophageal propulsion is severely compromised because of a high prevalence of simultaneous waveforms usually receive little benefit from medical therapy. In these patients, a surgical myotomy of the esophageal body can improve the patients' dysphagia provided the loss of contraction amplitude in the remaining peristaltic waveforms, caused by the myotomy, has less effect on swallowing function than the presence of the excessive simultaneous contractions. This situation is reached when the prevalence of effective waveforms during meals drops below 30 percent.

In patients selected for surgery, preoperative manometry is essential to determine the proximal extent of the esophageal myotomy. Most surgeons extend the myotomy distally across the LES to reduce outflow resistance. Consequently, some form of antireflux protection is needed to avoid gastroesophageal reflux if there has been extensive dissection of the cardia. In this situation, most authors prefer a partial, rather than a full, fundoplication in order not to add back-resistance that will further interfere with the ability of the myotomized esophagus to empty (Fig. 23-72). If the symptoms of reflux are present preoperatively, 24-h pH monitoring is required to confirm its presence.

The procedure may be performed either open or via thoracoscopy. The open technique is performed through a left thoracotomy in the sixth intercostal space (Fig. 23-73). An incision is made in the posterior mediastinal pleura over the esophagus, and the left lateral wall of the esophagus is exposed. The esophagus is not circumferentially dissected unless necessary. A 2-cm incision is made into the abdomen through the parietal peritoneum at the midportion of the left crus. A tongue of gastric fundus is pulled into the chest. This exposes the gastroesophageal junction and its associated fat pad. The latter is excised to give a clear view of the junction. A myotomy is performed through all muscle layers, extending distally over the stomach 1 to 2 cm below the gastroesophageal junction and proximally on the esophagus over the distance of the manometric abnormality. The muscle layer is dissected from the mucosa laterally for a distance of 1 cm. Care is taken to divide all minute muscle bands, particularly in the area of the junction. The gastric fundic tongue is sutured to the margins of the myotomy over a distance of 3 to 4 cm and replaced into the abdomen. This maintains separation of the muscle and acts as a partial fundoplication to prevent reflux.

If an epiphrenic diverticulum is present, it is excised by dividing the neck and closing the muscle. The myotomy is then performed on the opposite esophageal wall. If a midesophageal diverticulum is present, the myotomy is made so that it includes the muscle around the neck, and the diverticulum is inverted and suspended by attaching it to the paravertebral fascia of the thoracic vertebra.

The results of myotomy for motor disorders of the esophageal body have improved in parallel with the improved preoperative diagnosis afforded by manometry. Previous published series report between 40 and 92 percent improvement of symptoms, but interpretation is difficult due to the small number of patients involved and the varying criteria for diagnosis of the primary motor abnormality. When myotomy is accurately done, 93 percent of the patients have effective palliation of dysphagia after a mean follow-up of 5 years, and 89 percent would have the procedure again if it was necessary. Most patients gain or maintain rather than lose weight after the operation. Postoperative motility studies show that the myotomy reduces the amplitude of esophageal contractions to near zero and eliminates simultaneous and peristaltic waves. If the benefit of obliterating the simultaneous waves exceeds the adverse effect on bolus propulsion caused by the loss of peristaltic waveforms, the patient's dysphagia is likely to be improved by the procedure. If not, the patient is likely to continue to complain of dysphagia and to have little improvement as a result of the operation. Preoperative motility studies are thus crucial in deciding which patients are most likely to benefit from a long esophageal myotomy.

The thoracoscopic technique is complicated by the fact that it requires complete retraction of the lung anteriorly to expose the esophagus. Proper positioning of the patient is critical to achieving this exposure. A prone position is ideal, allowing the left lung to fall forward away from the esophagus. Because of the possibility of open thoracotomy, however, it is best to place the patient in the right lateral decubitus position with the left thorax up, and then roll the patient anteriorly 45° toward prone. A beanbag secured to the table is used to hold the patient. The table can be rotated a further 30 to 40° so that the patient ends up nearly prone. Should thoracotomy be necessary, the table can be rotated back to the horizontal position and a thoracotomy performed without difficulty. Prone positioning is the key element in providing exposure for long myotomy. Four thoracoscopic ports in the left chest are utilized. With suitable lung retraction the myotomy is performed through all esophageal muscle layers extending distally to the endoscopic gastroesophageal junction and proximally over the distance of the manometric abnormality.

Few reports exist concerning the minimally invasive technique for performing long esophageal myotomy. Cuschieri has reported a preliminary experience with a thoracoscopically performed long esophageal myotomy for the treatment of nutcracker esophagus. Three patients with symptoms of chest pain and high-amplitude esophageal contractions and peristaltic waves forms were operated upon. No major morbidity was encountered. Nasogastric tubes were removed the first postoperative day and oral feeding was started on the second postoperative day. Two patients were discharged on postoperative day 4 and one patient on day 5. All had symptomatic relief on short follow-up.

Myotomy of the Lower Esophageal Sphincter

Secondary to reflux disease, achalasia is the most common functional disorder of the esophagus to require surgical intervention. The goal of treatment is to relieve the functional outflow obstruction secondary to the loss of relaxation and compliance of the LES. This requires disrupting the LES muscle. When performed adequately, that is, reducing sphincter pressure below 10 mmHg, and done early in the disease, LES myotomy results in symptomatic improvement with the occasional return of esophageal peristalsis. Reduction in LES resistance can be accomplished intraluminally by hydrostatic balloon dilation, which ruptures the sphincter muscle, or by a surgical myotomy that cuts the sphincter. The difference between these two methods appears to be the greater likelihood of reducing sphincter pressure to less than 10 mmHg by surgical myotomy as compared with hydrostatic balloon dilation. However, patients whose sphincter pressure has been reduced by hydrostatic balloon dilation to less than 10 mmHg have an outcome similar to those after surgical myotomy (Fig. 23-74). In performing a surgical myotomy of the LES, there are four important principles: (1) minimal dissection of the cardia, (2) adequate distal myotomy to reduce outflow resistance, (3) prevention of postoperative reflux, and (4) preventing rehealing of the myotomy site. In the past, the drawback of a surgical myotomy was the need for an open procedure. With the advent of limited-access technology, the myotomy can now be performed without a thoracotomy, either thoracoscopically or laparoscopically. The benefit of a thoracoscopic approach is that a myotomy can be done with no more disruption of the cardia than occurs with a balloon rupture of the sphincter muscle. A laparoscopic approach requires more extensive dissection of the cardia and the addition of an antireflux procedure to prevent postmyotomy gastroesophageal reflux.

The therapeutic decisions regarding the treatment of patients with achalasia center around four issues. The first issue is, should newly diagnosed patients be treated with pneumatic dilation or a surgical myotomy? Long-term follow up studies have shown that pneumatic dilation achieves adequate relief of dysphagia and pharyngeal regurgitation in 50 to 60 percent of patients (Fig. 23-75). Close follow-up is required and, if dilation fails, myotomy is indicated. For those patients who have a dilated and tortuous esophagus or an associated hiatal hernia, balloon dilation is dangerous and surgery is the better option. Whether it is better to treat a newly diagnosed esophageal achalasia patient by forceful dilation or by operative cardiomyotomy remains undecided. The outcome of the one controlled randomized study (38 patients) comparing the two modes of therapy suggests that surgical myotomy as a primary treatment gives better long-term results. There are several large retrospective series which report the outcome obtained with the two modes of

treatment (Table [23- 10](#)). Despite objections regarding variations in surgical and dilation techniques and the number of physicians performing the procedures, these collective data would appear to support operative myotomy as the initial treatment of choice when performed by a surgeon of average skill and experience. This view is confirmed by the large series of 899 patients reported by the Mayo Clinic spanning a 27-year period, and by the series of Csendes et al. on 100 patients followed for 5 to 7 years after surgery. Although it has been reported that a myotomy after previous balloon dilation is more difficult, this has not been our experience unless the cardia has been ruptured in a sawtooth manner. In this situation, operative intervention either immediately or after healing has occurred can be difficult.

The second issue is, should a surgical myotomy be performed through the abdomen or the chest? Myotomy of the LES can be accomplished via either an abdominal or thoracic approach. Advantages of the thoracic approach are (1) the myotomy can be achieved with minimal dissection of the esophageal hiatus, thereby preserving normal antireflux mechanisms and avoiding postoperative gastroesophageal reflux, (2) it allows easy extension of the myotomy cephalad, which may be necessary to encompass the full extent of abnormal motor function in patients with vigorous achalasia, and (3) associated pathology such as esophageal diverticula can be readily managed. The abdominal approach has the advantages of (1) better access to the gastroesophageal junction and (2) the ease of then performing an antireflux procedure, if so desired.

The third issue—one that has been long debated—is, should an antireflux procedure be added to a surgical myotomy? Excellent results have been reported following meticulously performed myotomy without an antireflux component. Complicating the controversy is the virtual absence of studies including objective documentation of the presence or absence of pathologic reflux following myotomy. The results of published studies are mixed, although the majority support the need for antireflux protection, particularly if there is extensive dissection of the hiatus as occurs when a transabdominal myotomy is performed. Further support for an antireflux procedure is that the development of a reflux-induced stricture after an esophageal myotomy is a serious problem and usually necessitates esophagectomy for relief of symptoms. On the other hand, the complications of gastroesophageal reflux are paradoxically more common in patients who had a myotomy plus an antireflux procedure than those who had only a transthoracic myotomy. This indicates that the addition of an antireflux procedure does not protect against the complications of reflux. Consequently, there is little reason to accept the degree of dissection required for the performance of an antireflux procedure if less dissection is beneficial in maintaining the competency of the cardia; similarly, there is little reason to accept the resistance an antireflux procedure imposes to esophageal emptying when the elimination of this resistance is the purpose for performing a myotomy in the first place. If an antireflux procedure is used as an adjunct to esophageal myotomy, a complete 360° fundoplication should be avoided. Rather, a 270° Belsey fundoplication or a Dor hemifundoplication should be used to avoid long-term esophageal dysfunction secondary to the outflow obstruction afforded by the fundoplication itself (see Fig. [23-72](#)).

The fourth issue centers upon whether or not a cure of this disease is achievable. Long-term follow-up studies after surgical myotomy have shown that late deterioration in results occurs after this procedure regardless of whether an antireflux procedure is done, and also after balloon dilation even when the sphincter pressure is reduced to below 10mmHg. It may be that even though a myotomy or balloon rupture of the LES muscle reduces the outflow obstruction at the cardia, the underlying motor disorder in the body of the esophagus persists and deteriorates further with the passage of time, leading to increased impairment of esophageal emptying. The earlier an effective reduction in outflow resistance can be accomplished the better the outcome will be and the more likely some esophageal body function can be restored.

Open Esophageal Myotomy

A modified Heller myotomy is performed through a left thoracotomy in the sixth intercostal space along the upper border of the seventh rib. The esophagus, and a tongue of gastric fundus, are exposed as described for a long myotomy. A myotomy through all muscle layers is performed, extending distally over the stomach to 1 to 2 cm below the junction and proximally on the esophagus for 4 to 5 cm. The cardia is reconstructed by suturing the tongue of gastric fundus to the margins of the myotomy to prevent rehealing of the myotomy site and to provide reflux protection in the area of the divided sphincter. If an extensive dissection of the cardia has been done, a more formal Belsey repair is performed. The tongue of gastric fundus is allowed to retract into the abdomen. Postoperatively, nasogastric drainage is maintained for 6 days to prevent distention of the stomach during healing. An oral diet is resumed on the seventh day, after a barium swallow study shows unobstructed passage of the bolus into the stomach without extravasation.

In a randomized long-term follow-up by Csendes et al. of 81 patients treated for achalasia either by forceful dilation or by surgical myotomy, myotomy was associated with a significant increase in the diameter at the gastroesophageal junction and a decrease in the diameter at the middle third of the esophagus on follow-up radiographic studies. There was a greater reduction in sphincter pressure and improvement in the amplitude of esophageal contractions after myotomy. Thirteen percent of patients regained some peristalsis after dilation compared with twenty-eight percent after surgery. These findings were shown to persist over a 5-year follow-up period, at which time 95 percent of those treated with surgical myotomy were doing well. Of those who were treated with dilation, only 54 percent were doing well, while 16 percent required redilation and 22 percent eventually required surgical myotomy to obtain relief.

If simultaneous esophageal contractions are associated with the sphincter abnormality, the so-called vigorous achalasia, then the myotomy should extend over the distance of the abnormal motility as mapped by the preoperative motility study. Failure to do this will result in continuing dysphagia and a dissatisfied patient. The best objective evaluation of improvement in the patient following either balloon dilation or myotomy is a scintigraphic measurement of esophageal emptying time. A good therapeutic response improves esophageal emptying toward normal. Some degree of dysphagia may, however, persist despite improved esophageal emptying due to disturbances in esophageal body function. When an antireflux procedure is added to the myotomy it should be a partial fundoplication. A 360° fundoplication is associated with progressive retention of swallowed food, regurgitation, and aspiration to a degree that exceeds the patient's preoperative symptoms.

Endosurgical Esophageal Myotomy

Video-assisted endosurgical myotomy can be accomplished safely either laparoscopically or thoracoscopically. The thoracoscopic procedure is performed with the patient in the left lateral decubitus position. A double-lumen endotracheal tube is used to allow selective ventilation of the right lung. A seven-port technique is used: three are placed along the left costal margin for depressing the dome of the diaphragm and retracting the right and left crura, one is placed in the right axilla to retract the lung, one is placed behind the tip of the scapula for the camera, and two are operating ports. In contrast to laparoscopic surgery, the thoracoscopic ports are in close proximity to one another. With selective ventilation of the right lung, it is not necessary to insufflate the left hemithorax. Angled-viewing telescopes are preferable to the zero-degree scopes.

Identification and dissection of the esophagus are aided by the concomitant use of an endoscope within the esophageal lumen. The mediastinal pleura overlying the terminal esophagus is divided sharply with scissors. The myotomy is performed with a hook-type electrocautery probe (Fig. [23-76](#)). Having an endoscope within the esophagus helps prevent mucosal injury. Once the esophageal mucosa is clearly identified, the myotomy is carried distally with either the electrocautery probe or scissors. The inferior extent of the myotomy is identified by the presence of the junctional fat pad and the change from esophageal to gastric mucosa as observed externally and intraluminally with the endoscope. The myotomy is ended when the spasm of the valve commonly associated with achalasia is alleviated and a pull-through with an intraoperative motility probe shows loss of the gastroesophageal gradient.

The laparoscopic approach is similar to the Nissen fundoplication in terms of the trocar placement and exposure and dissection of the esophageal hiatus. Once the esophagus is mobilized, the myotomy is performed in a fashion analogous to the thoracoscopic approach. After the myotomy, the fundus of the stomach is brought posterior to the esophagus and sutured to both margins of the myotomy.

Outcome Assessment of the Therapy for Achalasia

Critical analysis of the results of therapy for motor disorders of the esophagus requires objective measurement. The use of symptoms alone as an endpoint to evaluate therapy for achalasia may be misleading. The propensity for patients to unconsciously modify their diet to avoid difficulty swallowing is underestimated, making an assessment of results based upon symptoms unreliable. Insufficient reduction in outflow resistance may allow progressive esophageal dilatation to develop slowly, giving the impression of improvement because the volume of food able to be ingested with comfort increases. A variety of objective measurements may be used to assess success, including LES pressure, esophageal baseline pressure, and scintigraphic assessment of esophageal emptying time. Esophageal baseline pressure is usually negative when compared to gastric pressure. Given that the goal of therapy is to eliminate the outflow resistance of a nonrelaxing sphincter, measurement of improvements in esophageal baseline pressure and scintigraphic transit time may be better indicators of success, but are rarely reported.

Eckardt et al. investigated whether the outcome of pneumatic dilation in patients with achalasia could be predicted on the basis of objective measurements. Postdilation LES pressure was the most valuable measurement for predicting long-term clinical response. A postdilatation sphincter pressure less than 10 mmHg predicted a good response. Fifty percent of the patients studied had postdilation sphincter pressures between 10 and 20 mmHg, with a 2-year remission rate of 71 percent. Importantly, 16 of 46 patients were left with a postdilation sphincter pressure of greater than 20 mmHg and had an unacceptable outcome. Overall, only 30 percent of patients dilated remain in symptomatic remission at 5 years.

Bonavina et al. reported good to excellent results with transabdominal myotomy and Dor fundoplication in 94 percent of patients after a mean follow-up of 5.4 years. No operative mortality occurred in either of these series, attesting to the safety of the procedure. Malthaner and Pearson reported the long-term clinical results in 35 patients with achalasia having a minimum follow up of 10 years (Table [23-11](#)). Twenty-two of these patients underwent primary esophageal myotomy and Belsey hemifundoplication at the Toronto General Hospital. Excellent to good results were noted in 95 percent of patients at 1 year, declining to 68, 69, and 67 percent at 10, 15, and 20 years, respectively. Two patients underwent early reoperation for an incomplete myotomy and three underwent an esophagectomy for progressive disease. They concluded that there was a deterioration of the initially good results after surgical myotomy and hiatal repair for achalasia, which is due to late complications of gastroesophageal reflux.

Ellis reported his lifetime experience with transthoracic short esophageal myotomy without an antireflux procedure. One hundred seventy-nine patients were analyzed at a mean follow-up of 9 years, ranging from 6 months to 20 years. Overall 89 percent of patients were improved at the 9-year mark. He also observed that the level of improvement deteriorated with time, with excellent results (patients continuing to be symptom-free) decreasing from 54 percent at 10 years to 32 percent at 20 years. He concluded that a short transthoracic myotomy without an antireflux procedure provides excellent long-term relief of dysphagia and, contrary to Malthaner and Pearson's experience, does not result in complications of gastroesophageal reflux. Both studies document nearly identical results 10 to 15 years following the procedure, and both report deterioration over time probably due to progression of the underlying disease. The addition of an antireflux procedure if the operation is performed transthoracically has no significant effect on the outcome.

Early experience with endosurgical esophageal myotomy is encouraging (Fig. [23-77](#)). Pellegrini reported on 17 patients, 15 of whom were treated thoracoscopically and 2 of whom were treated laparoscopically. Postoperatively, the mean LES pressure was 10 mmHG. The relief of dysphagia was graded as excellent in 12 patients, good in 2 patients, fair in 2 patients, and poor in one patient.

Esophageal Resection for End-Stage Motor Disorders of the Esophagus

Patients with dysphagia and long-standing benign disease whose esophageal function has been destroyed by the disease process or multiple previous surgical procedures are best managed by esophagectomy. Fibrosis of the esophagus and cardia can result in weak contractions and failure of the distal esophageal sphincter to relax. The loss of esophageal contractions can result in the stasis of food, esophageal dilatation, regurgitation, and aspiration. The presence of these abnormalities signals end-stage motor disease. In these situations esophageal replacement is usually required to establish normal alimentation. Before proceeding with esophageal resection for patients with end-stage benign disease,

the choice of the organ to substitute for the esophagus, that is,, stomach, jejunum, or colon, should be considered. The choice of replacement is affected by a number of factors, as described later in the section on techniques of esophageal reconstruction.

CARCINOMA OF THE ESOPHAGUS

Squamous carcinoma accounts for the majority of esophageal carcinomas. Its incidence is highly variable, ranging from approximately 20 per 100,000 in the United States and Britain to 160 per 100,000 in certain parts of South Africa and the Honan province of China, and even 540 per 100,000 in the Guriev district of Kazakhstan. The environmental factors responsible for these localized high-incidence areas have not been conclusively identified, though additives to local foodstuffs (nitroso compounds in pickled vegetables and smoked meats) and mineral deficiencies (zinc and molybdenum) have been suggested. In Western societies, smoking and alcohol consumption are strongly linked with squamous carcinoma. Other definite associations link squamous carcinoma with long-standing achalasia, lye strictures, tylosis (an autosomal dominant disorder characterized by hyperkeratosis of the palms and soles), and human papillomavirus.

Adenocarcinoma of the esophagus, once an unusual malignancy, is diagnosed with increasing frequency (Fig. [23-78](#)) and now accounts for over 50 percent of esophageal cancer in some Western countries. The gross appearance resembles that of squamous cell carcinoma. Microscopically, adenocarcinoma almost always originates in metaplastic Barrett's mucosa, and resembles gastric cancer. Rarely it arises in the submucosal glands and forms intramural growths which resemble the mucoepidermal and adenoid cystic carcinomas of the salivary glands. The most important etiologic factor in the development of primary adenocarcinoma of the esophagus is a metaplastic columnar-lined or Barrett's esophagus, which occurs as a complication in approximately 10 percent of patients with gastroesophageal reflux disease. The incidence of adenocarcinoma in a patient with Barrett's esophagus when studied prospectively is 1 in 100 patient years of follow-up; that is, for every 100 patients with Barrett's esophagus followed for 1 year, one will develop adenocarcinoma. Although this risk appears to be small, it is at least 30 to 40 times that expected for a similar population without Barrett's esophagus. This risk is similar to the risk for developing lung cancer in a person with a 20 pack per year history of smoking. Endoscopic surveillance for patients with Barrett's esophagus is recommended for two reasons: (1) at present there is no reliable evidence that medical therapy removes the risk of neoplastic transformation; and (2) malignancy in Barrett's esophagus is curable if detected at an early stage.

Clinical Manifestations

Esophageal cancer is a disease affecting patients of advancing age, with dysphagia and weight loss being by far the most common symptoms at the time of diagnosis. In a few patients, dysphagia does not occur and symptoms arise from invasion of the primary tumor into adjacent structures or from metastases. Extension of the primary tumor into the tracheobronchial tree can cause stridor, and if a tracheoesophageal fistula develops, coughing, choking, and aspiration pneumonia result. Rarely, severe bleeding from erosion into the aorta or pulmonary vessels occurs. Either vocal cord may be invaded, causing paralysis, but most commonly, paralysis is caused by invasion of the left recurrent laryngeal nerve by the primary tumor or lymph node metastasis. Systemic organ metastases are usually manifested by jaundice or bone pain. The situation is different in high-incidence areas where screening is practiced. In these communities, the most prominent early symptom is pain on swallowing rough or dry food.

Dysphagia usually presents late in the natural history of the disease because the lack of a serosal layer on the esophagus allows the smooth muscle to dilate with ease. As a result, the dysphagia becomes severe enough to for the patient to seek medical advice only when more than 60 percent of the esophageal circumference is infiltrated with cancer. Consequently, the disease is usually far advanced if symptoms herald its presence. Tracheoesophageal fistula may be present in some patients on their first visit to the hospital, and more than 40 percent will have evidence of distant metastases. With tumors of the cardia, anorexia and weight loss usually precede the onset of dysphagia. The physical signs of esophageal tumors are those associated with the presence of distant metastases.

Staging of Esophageal Carcinoma

At the initial encounter with a patient diagnosed as having carcinoma of the esophagus, a decision must be made as to whether he or she is a candidate for curative surgical therapy, palliative surgical therapy, or nonsurgical palliation. Making this decision is difficult, because evaluating the pretreatment disease stage of esophageal carcinoma is imprecise due to the difficulty of measuring the depth of tumor penetration of the esophageal wall and the inaccessibility of the organ's widespread lymphatic drainage.

The introduction of endoscopic ultrasound has made it possible to identify patients who are potentially curable prior to surgical therapy. Using an endoscope, the depth of the wall penetration by the tumor and the presence of five or more lymph node metastases can be determined with an 80 percent accuracy. A curative resection should be encouraged if endoscopic ultrasound indicates that the tumor has not penetrated the esophageal wall and/or fewer than five enlarged lymph nodes are imaged. Thoracoscopic and laparoscopic staging of esophageal cancer have been recommended; preliminary results indicate that correct staging of esophageal carcinomas, using these techniques, approaches 90 percent. If these results are confirmed and the cost is not prohibitive, then thoracoscopic and laparoscopic staging are likely to become valuable tools to determine the extent of disease prior to therapy. At the present time, despite the modern techniques of computed tomography, magnetic resonance imaging, endoscopic ultrasound, and laparoscopic and thoracoscopic technology, pretreatment staging still remains imprecise. This underscores the need for an intraoperative assessment of the potential for cure in each individual patient.

Experience with esophageal resections in patients with early disease has identified characteristics of esophageal cancer that are associated with improved survival. A number of studies suggest that only metastasis to lymph nodes and tumor penetration of the esophageal wall have a significant and independent influence on prognosis. The beneficial effects of the absence of one factor persists even when the other is present. Factors known to be important in the survival of patients with advanced disease, such as cell type, degree of cellular differentiation, or location of tumor in the esophagus, have no effect on survival of patients who have undergone resection for early disease. Studies also showed that patients having five or less lymph node metastases have a better outcome. Using these data, Skinner developed the wall penetration, lymph node, and distant organ metastases (WNM) system for staging.

The WNM system differed somewhat from the previous efforts to develop a satisfactory staging criteria for carcinoma of the esophagus. Most surgeons agreed that the 1983 TMN system left much to be desired. In the third edition of the manual for staging of cancer of the American Joint Committee on Cancer (1988), an effort was made to provide a finer discrimination between stages than had been contained in the previous edition, in 1983. Table [23-12](#) shows the definitions for the primary tumor, regional lymph nodes, and distant metastasis as listed in the 1988 manual. Recently, Ellis, in a study comparing different staging criteria, showed that the new staging criteria of the American Joint Committee provide no better discrimination of stages as they relate to survival than the earlier version had. The 5-year survival of stage IIA patients was similar to that of stage IIB patients, and the survival of stage IIB patients was similar to that of stage III patients. Similarly, there was no difference between the 5-year survival of patients with T1 and T2 disease, nor was there a survival difference between those with T3 and T4 disease. He did confirm the observation that the depth of wall penetration and extent of lymph node involvement were reliable independent predictors of survival.

Ellis proposed adoption of Skinner's WNM staging system with some modifications (Table [23-13](#)). In Ellis's proposal, tumors limited to above the muscularis mucosa would be equivalent to Skinner's W0 designation, T1 and T2 tumors would equate with the W1 classification, and T3 and T4 tumors to the W2 classification. These classifications are illustrated in Fig. [23-79](#). He further reported a clear distinction between the 5-year survival of patients with negative nodes and those with fewer than five nodes involved, and a highly significant difference between the latter group and those with five or more nodes involved. Table 23-13 shows the definitions for the primary tumor, regional lymph nodes, and distant metastasis for the Skinner WNM staging system as modified by Ellis.

Using an expanded base of 408 resected patients, Ellis compared the 1988 staging criteria with his modification of the Skinner WNM system and produced evidence that a modified WNM staging system was more useful from a prognostic standpoint (see Tables 23-12 and 23-13) than the 1988 criteria. Not only is the number of patients more evenly divided among the four stages in the modified Skinner system, but the comparison of the 5- year survival rates between stages is highly significant, with almost a 50 percent reduction in survival rates for each increasing stage. The major difference in the staging criteria of the proposed modification to the Skinner WNM system is the recognition that the number of nodes involved has a profound effect on prognosis. Ellis has been a proponent of a limited resection and lymph node dissection. The data used to validate the modified staging system represent what the outcome would be for simple tumor removal. Consequently, it serves as an excellent basis for comparison with the results for more extensive en bloc resections or preoperative chemotherapy programs.

Clinical Approach to Carcinoma of the Esophagus and Cardia

The selection of a curative versus a palliative operation for cancer of the esophagus is based on the location of the tumor, the patient's age and health, the extent of the disease, and intraoperative staging. Figure [23-80](#) shows an algorithm of the clinical decisions important in the selection for curative or palliative therapy.

Tumor Location

The selection of surgical therapy for patients with carcinoma of the esophagus depends not only on the anatomic stage of the disease and an assessment of the swallowing capacity of the patient, but also on the location of the primary tumor.

It is estimated that 8 percent of the primary malignant tumors of the esophagus occur in the cervical portion (Fig. [23-81](#)). They are almost always squamous cell lesions, with a rare adenocarcinoma arising from a congenital inlet patch of columnar lining. These tumors, particularly those in the postcricoid area, represent a separate pathologic entity for a number of reasons: (1) they are more common in females and appear to be a unique entity in this regard; and (2) the efferent lymphatics from the cervical esophagus drain completely differently from those of the thoracic esophagus. The latter drain directly into the paratracheal and deep cervical or internal jugular lymph nodes with minimal flow in a longitudinal direction. Except in advanced disease, it is unusual for intrathoracic lymph nodes to be involved.

Low cervical lesions that reach the level of the thoracic inlet are usually unresectable due to early invasion of the great vessels and trachea. The length of the esophagus below the cricopharyngeus is insufficient to allow intubation or construction of a proximal anastomosis for a bypass procedure. Consequently, palliation of these tumors is very difficult, and patients afflicted with disease at this site have a poor prognosis. Upper airway obstruction or the development of tracheoesophageal fistulas in such tumors may require surgical intervention for palliation. If possible, these tumors should be resected after a preoperative course of chemotherapy has reduced their size.

Tumors that arise within the middle or upper third of the thoracic esophagus lie too close to the trachea and aorta to allow an en bloc resection without removal of these vital structures. Consequently, in this location only tumors that have not penetrated through the esophageal wall and have not metastasized to the regional lymph nodes are potentially curable. The resection for a tumor at this level is done similarly whether for palliation or cure, and long-term survival is a chance phenomenon. This does not mean that when resecting such tumors, efforts to remove the adjacent lymph nodes should be abandoned. To do so may inadvertently leave unrecognized metastatic disease behind and compromise the patient's overall survival, because of recurrent local disease and compression of the trachea. It is recommended that a course of preoperative chemoradiotherapy should be given before resection to shrink the size of the tumor. It is recommended that the radiotherapy be limited to 3.5 Gy to allow for tissue healing.

Tumors of the lower esophagus and cardia are usually adenocarcinomas. Squamous cell carcinoma of the lower esophagus, however, does occur. Both types of tumor are amenable to en bloc resection. Unless preoperative and intraoperative staging clearly demonstrate an incurable lesion, an en bloc resection in continuity with a lymph node

dissection should be performed. Because of the propensity of gastrointestinal tumors to spread for long distances submucosally, long lengths of grossly normal gastrointestinal tract should be resected. The longitudinal lymph flow in the esophagus can result in skip areas, with small foci of tumor above the primary lesion, which underscores the importance of a wide resection of esophageal tumors. Wong has shown that local recurrence at the anastomosis can be prevented by obtaining a 10-cm margin of normal esophagus above the tumor. Anatomic studies have also shown that there is no submucosal lymphatic barrier between the esophagus and the stomach at the cardia, and Wong has shown that 50 percent of the local recurrences in patients with esophageal cancer who are resected for cure occur in the intrathoracic stomach along the line of the gastric resection. Considering that the length of the esophagus ranges from 17 to 25 cm, and the length of the lesser curve of the stomach is approximately 12 cm, a curative resection requires a cervical division of the esophagus and a greater than 50 percent proximal gastrectomy in most patients with carcinoma of the distal esophagus or cardia. This compromises the length of the stomach and esophagus remaining to reestablish gastrointestinal continuity and necessitates a colon interposition.

Age

An en bloc resection for cure of carcinoma of the esophagus in a patient older than 75 is rarely indicated, because of the additional operative risk and the shorter life expectancy. Regardless of how favorable the staging criteria, a palliative resection is performed in these patients. This approach provides relief of symptoms with less extensive surgical procedures, and cure is still a chance possibility.

Cardiopulmonary Reserve

Patients undergoing esophageal resection should have sufficient cardiopulmonary reserve to tolerate the proposed procedure. The respiratory function is best assessed with the FEV1, which ideally should be 2 L or more. Any patient with an FEV1 of less than 1.25 L is a poor candidate for surgery because he or she has a 40 percent risk of dying from respiratory insufficiency within 4 years. In such a patient, the chances of long-term survival, even if cured from the disease, do not justify an extensive en bloc resection. Clinical evaluation and electrocardiogram are not sufficient indicators of cardiac reserve. Echocardiography and dipyridamole thallium imaging provide accurate information on wall motion, ejection fraction, and myocardial blood flow. A defect on thallium imaging may require further evaluation with preoperative coronary angiography. A resting ejection fraction of less than 40 percent, particularly if there is no increase with exercise, is an ominous sign. We prefer to perform a palliative resection in such a patient, regardless of how favorable the other criteria are.

Clinical Stage

Clinical factors that indicate an advanced stage of carcinoma and exclude surgery with curative intent are recurrent nerve paralysis, Horner's syndrome, persistent spinal pain, paralysis of the diaphragm, fistula formation, and malignant pleural effusion. Factors that make surgical cure unlikely include a tumor greater than 8 cm in length, abnormal axis of the esophagus on a barium radiogram, enlarged lymph nodes on CT, a weight loss more than 20 percent, and loss of appetite. In patients where these findings are not present, staging depends primarily on the length of the tumor as measured with endoscopy and the degree of wall penetration and lymph node metastasis seen with endoscopic ultrasound. Studies indicate that there are a high number of favorable parameters associated with tumors less than 4 cm in length; there are fewer with tumors between 4 and 8 cm, and favorable criteria for tumors greater than 8 cm in length are absent. Consequently, the finding of a tumor over 8 cm in length should exclude curative resection; the finding of a smaller tumor should encourage an aggressive approach, and the smaller the tumor the more aggressive the approach should be. Endoscopic ultrasound imaging of esophageal tumors has recently become available, and provides further information regarding the size, wall penetration, and lymph node status of the lesion (Fig. [23-82](#)).

Intraoperative Staging

Intraoperative staging allows selection of favorable candidates for a curative en bloc resection. It is based on the fact that there is a low survival rate for patients with a tumor that penetrates through the esophageal wall, or has multiple or distant lymph node metastasis, and requires an approach that allows switching from an en bloc curative dissection to a palliative resection if during the course of an operation one of the following features is revealed: an unresectable primary tumor, cavitory spread of the tumor, distant organ metastasis, extension of the tumor through the mediastinal pleura, multiple gross lymph node metastases, or microscopic evidence of lymph node involvement at the margins of an en bloc resection, i.e., low paratracheal, portal triad, subpancreatic, or periaortic lymph nodes. Figure [23-83](#) is an algorithm for intraoperative decision making. For cancers of the distal esophagus and cardia, patients with a favorable stage of disease can be identified by a combination of preoperative and intraoperative assessment with an 86 percent accuracy. The overall 5-year survival of these selected patients after a curative en bloc resection is between 40 and 55 percent. If the tumor does not extend through the esophageal wall and there are less than five positive lymph nodes, the 5-year survival is 75 percent. These results support a clinical approach in which an en bloc resection of the esophagus and stomach is advocated only for patients most likely to benefit.

Management of Patients Excluded from Curative Resection

If the patient is considered incurable on preoperative or intraoperative evaluation, the severity of dysphagia or other incapacitating symptoms is assessed. Dysphagia of grade IV or higher (Table [23-14](#)) is an indication for a palliative resection. If the patient is physiologically fit, simple esophageal resection and reconstruction with a cervical esophagogastrostomy offer the best palliation. This procedure allows the patient to eat without dysphagia and prevents the local complications of perforation, hemorrhage, fistula formation, and incapacitating pain. Occasionally a patient will be cured by a palliative resection, but this should not be used as justification for a palliative resection in the absence of dysphagia. Malignant pleural effusion, obvious mediastinal spread, or distant organ metastases are usually contraindications for a palliative resection. In this setting, if dysphagia is not a problem, nothing more need be done.

If an obstructing tumor cannot be resected due to invasion of the trachea, aorta, or heart, or the patient's general condition precludes an operative procedure, relief of dysphagia by reestablishing the esophageal lumen is the focus of therapy. In this situation, the objective is to provide relief of dysphagia with the lowest mortality and the shortest hospital stay. A variety of techniques including bouginage, intubation, laser ablation, and electrical coagulation are available and can be used alone or in combination. Most centers prefer intubation of the esophagus.

Figure [23-84](#) shows the correlation between grade of dysphagia and a patient's score on the Linear Analogue Self Assessment test (LASA), which assesses the patient's physical and psychological well-being and symptom control, including dysphagia. There is a significant negative correlation between dysphagia grade and quality of life as measured by the LASA.

Surgical Treatment

A patient's nutritional status before surgery has a profound effect on the outcome of an esophageal resection. Low serum protein levels have a deleterious effect on the cardiovascular system, and a poor nutritional status affects the host resistance to infection and the rate of anastomotic and wound healing. A serum albumin level of less than 3.4 g/dL on admission indicates poor caloric intake and an increased risk of surgical complications, including anastomotic breakdown. A feeding jejunostomy tube provides the most reliable and safest method for nutritional support in patients who cannot consume an oral diet and have a functionally normal small bowel. In severely malnourished patients, the jejunostomy is performed as a separate procedure to allow for preoperative nutritional support. In these patients the abdomen is entered through a small supraumbilical midline incision. Otherwise, the jejunostomy tube is placed at the time of esophageal resection, and feeding is begun on the third postoperative day.

In an analysis of 43 patients undergoing curative en bloc resection for adenocarcinoma of the distal esophagus, lymph node metastasis were present in 76 percent. Tumor depth was a good indicator of nodal involvement (Fig. [23-85](#)). At the time of resection 89 percent of transmural tumors, 60 percent of intramural tumors, and 33 percent of intramucosal lesions had lymph node metastasis. This is in agreement with the findings of Japanese investigators who reported nodal involvement in 30 percent of 40 patients with intramucosal squamous cell carcinoma. This finding has implications in the management of patients with high-grade dysplasia, where the prevalence of unexpected adenocarcinoma is up to 50 percent.

In the same series, adenocarcinomas of the lower esophagus and cardia spread widely to regional nodes, most commonly to nodes along the lesser curvature, celiac axis, and parahiatal regions (Table [23-15](#)). Ten percent had subcarinal nodes and eighteen percent had involved nodes of the splenic hilum, along the splenic artery, or along the greater curvature of the stomach; subcarinal and splenic nodes would remain following transhiatal resection. The involved nodes along the greater curve of the stomach would, by necessity, be transposed into the chest if the stomach was used to reestablish gastrointestinal continuity. In addition, over 20 percent of patients had positive celiac axis nodes, an area not dissected by most during transhiatal esophagectomy.

Control of the local and regional disease forms the basis for the classical en bloc resection. In our experience, the site of nodal recurrence following en bloc resection was outside the limits of the resection in 80 percent of patients with recurrent disease (Fig. [23-86](#)). All patients with thoracic nodal recurrence had disease in their upper mediastinum or aortopulmonary window, suggesting that these recurrences arose from nodes lying along the recurrent laryngeal nerve chains, which are not routinely removed by the en bloc dissection. Performing a more extended mediastinal dissection combined with a radical neck dissection has been advocated by some authors in the treatment of esophageal squamous cell carcinoma. The increased morbidity and the possibility of permanent hoarseness associated with this approach have discouraged its widespread application. It has been reported that the finding of metastatic disease involving the celiac nodes precludes survival beyond 2 years. By contrast, we have reported prolonged survival in patients with celiac axis involvement.

Cervical and Upper Thoracic Esophageal Cancer

When considering resection, tumors of the esophagus are best divided into those above and below the carina. Czerny reported the first successful resection of a carcinoma of the cervical esophagus in 1877. It was hoped that the prognosis for patients with this disease might be better than for those with carcinoma of the thoracic esophagus; this has not proved to be the case. Early experience with resection of the cervical esophagus resulted in a high mortality rate, and reconstruction by neck flaps often required multiple operations. Because of these complexities and the generally disappointing results, radiotherapy frequently was elected. Immediate mortality decreased, but control of the tumor was not satisfactory.

The difference between the two forms of therapy is the manner in which the disease recurs. Tumors treated with radiation therapy initially tend to recur locally as well as systemically, and cause unmanageable local disease with eventual erosion into neck vessels and trachea, causing hemorrhage and dyspnea. Patients who undergo surgical therapy have few local recurrences of the tumor provided total excision was possible, but they succumb to metastatic disease. Colin has reported a local failure rate of 80 percent after definitive radiation therapy, and 20 percent of these patients required palliative surgery in order to control the disease locally. Improvements in the techniques of immediate esophageal reconstruction have reduced the complications of the surgical treatment of this disease and encouraged a more aggressive surgical approach. The data reported by Colin suggest that an initial aggressive surgical resection yields longer survival than radiation therapy (Fig. [23-87](#)). Positive surgical margins, tracheal invasion that cannot be removed, and vocal cord paralysis correlate with a significantly shorter survival following surgery. Palliation was better achieved in patients who underwent esophagectomy with immediate gastric pull-up than in those who underwent primary radiation therapy or chemotherapy.

Lesions that are not fixed to the spine, do not invade the vessels or trachea, and do not have fixed cervical lymph node metastases should be resected. If lymph node metastases are present or the tumor comes in close proximity to the cricopharyngeus muscle, a course of preoperative chemo- and radiotherapy should be given before surgical resection. This usually consist of 2 to 3 cycles of chemotherapy and no more than 3.5 Gy of radiation therapy. Neoadjuvant therapy is given in an attempt to salvage the larynx, since the larynx is

often invaded by microscopic tumors, and, in the past, a total laryngectomy in combination with esophagectomy was usually necessary. A simultaneous en bloc dissection of the superior mediastinum and cervical lymph nodes is done, sparing the jugular veins on both sides.

The thoracic esophagus is removed via a right posterolateral thoracotomy with a corresponding en bloc lymphadenectomy. The continuity of the gastrointestinal tract is reestablished by pulling the stomach up through the esophageal bed. If removing the larynx is necessary, a permanent tracheostomy stoma is constructed in the lower flap of the cervical incision. The division of the trachea in some patients may preclude the possibility of a permanent cervical standard tracheostomy, since the remaining tracheal stump distal to the tumor will not reach the suprasternal notch. Removal of the medial head of the clavicles and the manubrium down to the sternal angle of Louis provides excellent exposure and allows the construction of a mediastinal tracheostomy. A bipedicle skin flap over the pectoralis muscle can be advanced upward, or a single-pedicle musculocutaneous flap including the pectoralis muscle and its overlying skin can be rotated to cover the defect. A circular incision in the flap can be used as a port through which the tracheal remnant is brought out to the skin.

Tumors of the Thoracic Esophagus and Cardia

For tumors that arise below the carina, we prefer either an en bloc resection for cure or a transhiatal removal for palliation. A curative procedure is performed according to the principles of an en bloc resection in continuity with the regional lymph nodes (Fig. 23-88). It is attempted in a patient whose preresection physical condition and tumor characteristics have the potential for long-term survival. The en bloc resection is done through three incisions in the following order: right posterolateral thoracotomy, en bloc dissection of the distal esophagus, mobilization of the esophagus above the aortic arch, closure of the thoracotomy, repositioning of the patient in the recumbent position; upper midline abdominal incision, en bloc dissection of the stomach and associated lymph nodes; left neck incision and proximal division of the esophagus. The specimen is removed transhiatally and the stomach is divided at the angulus, preserving the antrum. Gastrointestinal continuity is reestablished with a left colon interposition. During the thoracic and abdominal dissection, intraoperative staging is done. If during the course of the operation an incurable situation is identified, the en bloc resection is abandoned and a palliative resection is performed in a manner similar to that described for tumors of the middle and upper thoracic esophagus. The hospital mortality for the group undergoing a curative en bloc resection is similar to those undergoing a palliative transhiatal resection. If preoperative staging has shown that the patient is a candidate for palliative resection, a transhiatal esophagectomy is performed (Fig. 23-89). A standard left thoracotomy with intrathoracic anastomosis for lower lesions or an Ivor Lewis combined approach for higher lesions is not advocated because of (1) the proven need to resect long lengths of the esophagus to eradicate submucosal spread, (2) the higher morbidity associated with a thoracic anastomotic leak, and (3) the high incidence of esophagitis secondary to reflux following an intrathoracic anastomosis.

En Bloc Esophagogastrectomy Versus Transhiatal Resection for Carcinoma of the Lower Esophagus and Cardia

Strategies for treatment of esophageal carcinoma limit the role of surgery to removing the primary tumor, with the hope that adjuvant therapy will increase cure rates by destroying systemic disease. This approach emphasizes the concept of biological determinism, i.e., the outcome of treatment in esophageal cancer is determined at the time of diagnosis and that surgical therapy aimed at removing more than the primary tumor is not helpful. Lymph node metastases are considered simply markers of systemic disease; the systematic removal of involved nodes is not considered beneficial. The belief that removal of the primary tumor by transhiatal esophagogastrectomy results in the same survival rates as a more extensive en bloc resection is based on the same kind of reasoning.

In the transhiatal procedure there is no specific attempt made to remove lymph node-bearing tissue in the posterior mediastinum. By contrast, the en bloc esophagectomy removes the tumor covered on all surfaces with a layer of normal tissue (see Fig. 23-88). A long length of foregut above and below the lesion is resected to incorporate submucosal spread of the tumor. Consistent with this is resection of the proximal two-thirds of the stomach in patients with a tumor in the lower third of the thoracic esophagus or cardia. Appropriate cervical mediastinal and abdominal lymph node dissections are included using an en bloc technique to remove potentially involved regional nodes. Arguments to support the more extensive esophagectomy, gastrectomy, and lymph node dissection are listed in Table 23-16.

Data collected by Hagen et al. showed that en bloc esophagogastrectomy resulted in significantly better 5-year survival than transhiatal esophagogastrectomy despite the fact that postoperative pathologic classification of the removed specimens from the patients who underwent transhiatal esophagogastrectomy showed that these patients tended to have been in an earlier disease stage (Fig. 23-90). Comparison of the actuarial survival following en bloc esophagogastrectomy and transhiatal esophagogastrectomy based on pathologic classification and stage of disease is shown in Figs. 23-91, 23-92, and 23-93. A clear survival advantage is observed in patients with early lesions following en bloc esophagogastrectomy, where the 5-year survival was 75 percent. This was less so for intermediate and late lesions. Of interest is the fact that the results after transhiatal esophagogastrectomy were similar for early and intermediate disease, 19.8 percent and 21.0 percent at 2 years, respectively, and not much better than the 8.6 percent for late disease.

These studies showed that for early cancers of the lower esophagus and cardia, en bloc esophagogastrectomy results in significantly better survival rates than transhiatal esophagogastrectomy. This finding cannot be explained by a bias in the stage of disease resected, a difference in operative mortality, or death from nontumor causes. Rather, it appears to be due to the type of operation performed. The results in patients with intermediate and advanced disease are less clear; a survival advantage was present in advanced disease but not in intermediate disease. We suspect that the explanation for this outcome is the imprecision in assigning a stage of esophageal cancer to patients or the evaluation of too few patients with intermediate disease. Ideally, the question as to which procedure is the best should be resolved by a prospective randomized study.

Extent of Resection to Cure Disease Confined to the Mucosa

The development of surveillance programs for the detection of early squamous cell carcinoma in endemic areas and for early adenocarcinoma in patients with Barrett's esophagus has given rise to controversy over how to manage tumors confined to the mucosa. Some authors have endoscopically resected squamous carcinomas after using endoscopic ultrasound to determine that the depth of the tumor was limited to the mucosa. Surprisingly, large areas of squamous mucosa can be resected without perforation or bleeding, leaving the smooth surface of the muscularis mucosa intact. Reepithelization of the large artificially induced ulcer is usually complete in 3 weeks. In order not to miss a squamous cancer that has invaded deeper than expected, it is important to examine the deep margins of the resected specimen carefully and to perform periodic endoscopic follow-up examinations with vital staining techniques. This technique is not appropriate for multiple and widespread or circumferential squamous lesions because of the risk of developing a stricture during the healing process. In this situation, those acquainted with endoscopic resection would advocate an esophagectomy.

Several studies have shown that intraepithelial carcinoma, i.e., carcinoma in situ or high-grade dysplasia, and intramucosal tumors, i.e., invasive cancer limited by the muscular mucosa, are quite different in their biological behavior from submucosal tumors regardless of their histologic characteristics, that is, regardless of whether they are squamous cell carcinoma or adenocarcinoma arising in Barrett's mucosa. Vessel invasion and lymph node metastasis do not occur in severe dysplasia, are uncommon in the intramucosal tumors, but are the rule in submucosal tumors. Consequently, the 5-year survival for intramucosal tumors is significantly better than for submucosal tumors. These findings indicate that both severe dysplasia and intramucosal cancers represent early malignant lesions of the esophagus. A critical issue to be resolved is whether an intramucosal tumor can be correctly discriminated from a submucosal tumor before surgery. The results of using endoscopic ultrasound for determining the depth of tumors confined to the esophageal wall are of questionable accuracy. The resolution of present-day endoscopic ultrasonographic systems is not sufficient to predictably differentiate the fine detail of tumor infiltration when it is limited to the esophageal wall. Currently there is no dependable way, before surgery, of determining whether a tumor extends beyond the muscularis mucosa.

Another complicating factor is that up to 30 percent of patients with intramucosal tumors have lymph node metastases, although the number of involved nodes per patient is usually five or less. Akiyama and others have reported that even though the number of involved nodes may be small, they can spread to distant nodal regions including cervical and abdominal nodes.

For these reasons—the difficulty of determining preoperatively the depth to which a tumor has penetrated into the esophageal wall, the knowledge that tumors which invade through the muscularis mucosa into the submucosa have a 60 percent or more incidence of lymph node metastasis—as well as the fact that the distance from the epithelium to the muscularis mucosa is only 1 to 2 mm less than to the submucosa, it seems prudent to perform an en bloc esophagectomy for the treatment of intramucosal tumors. This also holds true for patients with Barrett's esophagus and high-grade dysplasia, since 50 percent of these patients will harbor an unknown intramucosal tumor. In both situations, a mediastinal and abdominal lymph node dissection is performed as well, but the proximal stomach and spleen is not resected since the possibility of extensive submucosal spread and splenic node metastases is minimal. Gastrointestinal continuity is reestablished by pulling the stomach up into the neck and performing an esophagogastrostomy. This approach, however, is not universally accepted.

As the understanding of the pathology of esophageal cancer improves and experience with its resection increases, evidence is accumulating that the best chance for cure of patients with an intramural tumor in the distal esophagus or cardia is an en bloc esophagectomy and proximal gastrectomy with gastrointestinal continuity reestablished with a colon interposition. For patients with a tumor in the upper or cervical esophagus, the best chance for cure is an en bloc esophagectomy and a cervical lymph node dissection with gastrointestinal continuity reestablished with a gastric pull-up. Table 23-17 presents a summary of the extent of resection for tumors extending various depths into the esophageal wall.

Alternative Therapies

Radiation Therapy

Primary treatment with radiation therapy does not produce results comparable with those obtained with surgery. Currently, the use of radiotherapy is restricted to patients who are not candidates for surgery. Palliation of dysphagia is short-term, generally lasting only 2 to 3 months. Furthermore, the length and course of treatment are difficult to justify in patients with a limited life expectancy. Consequently there is a reluctance to treat patients with advanced disease.

Adjuvant Chemotherapy

The proposal to use adjuvant chemotherapy in the treatment of esophageal cancer began when it became evident that most patients develop postoperative systemic metastasis without local recurrence. This observation led to the hypothesis that undetected systemic micrometastasis had been present at the time of diagnosis and if effective systemic therapy was added to local regional therapy, survival should improve.

Recently this hypothesis has been supported by the observation of epithelial tumor cells in the bone marrow in 37 percent of patients with esophageal cancer who were resected for cure. These patients had a greater prevalence of relapse at 9 months after surgery compared to those patients without such cells. Such studies emphasize that hematogenous dissemination of viable malignant cells occurs early in the disease and that systemic chemotherapy may be helpful if the cells are sensitive to the agent. On the other hand, systemic chemotherapy may be a hindrance, because of its immunosuppressive properties, if the cells are resistant. Unfortunately, current technology is not able to test tumor cell sensitivity to chemotherapeutic drugs. This requires that the choice of drugs be made solely on the basis of their clinical effectiveness against grossly similar tumors.

The decision to use preoperative rather than postoperative chemotherapy was based on the ineffectiveness of chemotherapeutic agents when used after surgery and animal studies suggesting that agents given before surgery were more effective. The claim that patients who receive chemotherapy before resection are less likely to develop resistance to the drugs is unsupported by hard evidence. The claim that drug delivery is enhanced because blood flow is more robust before patients undergo surgical dissection is similarly

flawed, since if enough blood reaches the operative site to heal the wound or anastomosis, then the flow should be sufficient to deliver chemotherapeutic drugs. There are, however, data supporting the claim that preoperative chemotherapy in patients with esophageal carcinoma can, if effective, facilitate surgical resection by reducing the size of the tumor. This is particularly beneficial in the case of squamous cell tumors above the level of the carina. Reducing the size of the tumor may provide a safer margin between the tumor and the trachea and allow an anastomosis to a tumor-free cervical esophagus just below the cricopharyngeus. Involved margin at this level usually requires a laryngectomy to prevent subsequent local recurrence.

Preoperative Chemotherapy

Three randomized prospective studies with squamous cell carcinoma have shown no survival benefit with preoperative chemotherapy over surgery alone (Table [23-18](#)). Similar studies for adenocarcinoma have not been done. For squamous cell tumors a complete response to chemotherapy occurred only in 6 percent of patients.

With the exception of the potential to improve resectability of tumors located above the carina, the benefits cited by those in favor of preoperative chemotherapy are questionable. Preoperative chemotherapy alone can potentially down-stage the tumor, particularly squamous cell carcinoma. It can also potentially eliminate or delay the appearance of metastasis. There is no evidence, however, that it can prolong survival of patients with resectable carcinoma of the esophagus. Most failures are due to distant metastatic disease, underscoring the need for improved systemic therapy. Postoperative septic and respiratory complications are more common in patients receiving chemotherapy.

Preoperative Combination Chemo- and Radiotherapy

Preoperative chemoradiotherapy using cisplatin and *5-fluorouracil (5-FU)* in combination with radiotherapy has been reported by several investigators to be beneficial in both adenomatous and squamous cell carcinoma of the esophagus. There have been six randomized prospective studies: four with squamous cell carcinoma, one with both squamous and adenocarcinoma, and one with only adenocarcinoma (Table [23-19](#)). Only one showed any survival benefit with preoperative chemoradiotherapy over surgery alone. Most authors report substantial morbidity and mortality to the treatment. However, many have been encouraged by the observation that some patients, who had a complete response, had remained free of recurrence at 3 years.

Caution must be exercised in trying to isolate the effects of chemotherapy, because the addition of preoperative radiation therapy to chemotherapy elevates the complete response rate and inflates the benefit of chemotherapy. With chemoradiation the complete response rates for adenocarcinoma range from 17 to 24 percent (Table [23-20](#)). When radiation is removed, the complete response falls to 0 percent to 5 percent, which suggests that the effects of chemotherapy are negligible. If radiotherapy is the factor responsible for improved response rate, surgery alone could do the job as well, since numerous studies in the past have shown that the combination of surgery and radiation does not provide any survival advantages.

The real question is, should a patient with carcinoma of the esophagus go through three cycles of chemotherapy on the 5 percent chance that they may get a complete response in the primary tumor and in the face of the paucity of evidence that such a response controls systemic disease? Studies have shown that the rates of infection, anastomotic breakdown, incidence of adult respiratory distress syndrome, and long-term use of a respirator were greater in patients receiving adjuvant therapy as compared with surgery alone.

Current data support giving chemoradiotherapy as a mater of routine in a limited number of clinical settings including: (1) preoperatively to reduce tumor size in a young person with surgically incurable squamous cell carcinoma above the carina, and (2) chemotherapy as salvage therapy for patients who have not had previous chemotherapy and develop recurrent systemic disease after surgical resection (Fig. [23-94](#)). Adjuvant therapy in patients not in those categories should be limited to the setting of a controlled clinical trial. At present, the strongest predictors of outcome of patients with esophageal cancer are the anatomic extent of the tumor at diagnosis and the completeness of tumor removal by surgical resection. After incomplete resection of an esophageal cancer the 5-year survival rates are 0 to 5 percent. In contrast, after complete resection, independent of stage of disease, 5-year survival ranges from 15 to 40 percent according to selection criteria and stage distribution. The importance of early recognition and adequate surgical resection cannot be overemphasized.

SARCOMAS OF THE ESOPHAGUS

Sarcomas and carcinosarcomas are rare neoplasms, accounting for approximately 0.1 to 1.5 percent of all esophageal tumors. They present with the symptom of dysphagia, which does not differ from the dysphagia associated with the more common epithelial carcinoma. Tumors located within the cervical or high thoracic esophagus can cause symptoms of pulmonary aspiration secondary to esophageal obstruction. Large tumors originating at the level of the tracheal bifurcation can produce symptoms of airway obstruction and syncope by direct compression of the tracheobronchial tree and heart (Fig. [23-95](#)). The duration of dysphagia and age of the patients affected with these tumors are similar to those with carcinoma of the esophagus.

A barium swallow usually shows a large polypoid intraluminal esophageal mass, causing partial obstruction and dilatation of the esophagus proximal to the tumor. The smooth polypoid nature of the lesion, although not itself diagnostic, is distinctive enough to suggest the presence of a sarcoma rather than the more common ulcerating, stenosing carcinoma.

Esophagoscopy commonly shows an intraluminal necrotic mass. When biopsy is attempted, it is important to remove the necrotic tissue until bleeding is seen on the tumor's surface. When this is not done, the biopsy specimen will show only tissue necrosis. Even when viable tumor is obtained on biopsy, it has been our experience that it cannot be definitively identified as either carcinoma, sarcoma, or carcinosarcoma on the basis of the histology of the portion biopsied. Biopsy results cannot be totally relied on to identify the presence of sarcoma, and it is often the polypoid nature of the lesion which arouses suspicion that it may be something other than carcinoma.

Polypoid sarcomas of the esophagus, in contrast to infiltrating carcinomas, remain superficial to the muscularis propria and are less likely to metastasize to regional lymph nodes. In one series of 14 patients, local extension or tumor metastasis would have prevented a potentially curative resection only in 5. Thus the presence of a large polypoid tumor should not deter the surgeon from resecting the lesion.

Sarcomatous lesions of the esophagus can be divided into epidermoid carcinomas with spindle cell features, such as carcinosarcoma, and true sarcomas that arise from mesenchymal tissue, such as leiomyosarcoma, fibrosarcoma, and rhabdomyosarcoma. Based on current histologic criteria for diagnosis, fibrosarcoma and rhabdomyosarcoma of the esophagus are extremely rare lesions and may not in fact exist.

Surgical resection of polypoid sarcoma of the esophagus is the treatment of choice, since radiation therapy has little success and the tumors remain superficial, with local invasion or distant metastases occurring late in the course of the disease. As with carcinoma, the absence of both wall penetration and lymph node metastases is necessary for curative treatment, and surgical resection is consequently responsible for the majority of the reported 5-year survivals. Resection also provides an excellent means of palliating the patient's symptoms. The surgical technique for resection and the subsequent restoration of the gastrointestinal continuity is similar to that described for carcinoma.

Four of the eight patients with carcinoma survived for 5 years or longer. Even though this number is small, it suggests that resection produces better results in epithelial carcinoma with spindle cell features than in squamous cell carcinoma of the esophagus. Similarly, with leiomyosarcoma of the esophagus, the same scattered reports exist with little information on survival. Of seven patients with leiomyosarcoma, two died from their disease—one in 3 months and the other 4 years and 7 months after resection. The other five patients were reported to have survived more than 5 years.

It is difficult to evaluate the benefits of resection for leiomyoblastoma (Fig. [23-96](#)) of the esophagus, due to the small number of reported patients with tumors in this location. Most leiomyoblastomas occur in the stomach, and 38 percent of these patients succumb to the cancer in 3 years. Fifty-five percent of patients with extragastric leiomyoblastoma also die from the disease, within an average of 3 years. Consequently, leiomyoblastoma should be considered a malignant lesion and apt to behave like a leiomyosarcoma. The presence of nuclear hyperchromatism, increased mitotic figures (more than 1 per high-power field), tumor size larger than 10 cm, and clinical symptoms of longer than 6 months' duration are associated with a poor prognosis.

BENIGN TUMORS AND CYSTS

Benign tumors and cysts of the esophagus are relatively uncommon. From the perspectives of both the clinician and the pathologist, benign tumors may be divided into those that are within the muscular wall and those that are within the lumen of the esophagus.

Intramural lesions are either solid tumors or cysts, and the vast majority are leiomyomas. They are made up of varying portions of smooth muscle and fibrous tissue. Fibromas, myomas, fibromyomas, and lipomyomas are closely related and occur rarely. Other histologic types of solid intramural tumors have been described, such as lipomas, neurofibromas, hemangiomas, osteochondromas, granular cell myoblastomas, and glomus tumors, but they are medical curiosities.

Intraluminal lesions are polypoid or pedunculated growths which usually originate in the submucosa, develop mainly into the lumen, and are covered with normal stratified squamous epithelium. The majority of these tumors are composed of fibrous tissue of varying degrees of compactness with a rich vascular supply. Some are loose and myxoid, e.g., myxoma and myxofibroma; some are more collagenous, e.g., fibroma; and some contain adipose tissue, such as fibrolipoma. These different types of tumor are frequently collectively designated as fibrovascular polyps or simply as polyps. Pedunculated intraluminal tumors should be removed. If the lesion is not too large, endoscopic removal with a snare is feasible.

Leiomyoma

Leiomyomas constitute more than 50 percent of benign esophageal tumors. The average age at presentation is 38, which is in sharp contrast to that seen with esophageal carcinoma. Leiomyomas are twice as common in males. Because they originate in smooth muscle, 90 percent are located in the lower two-thirds of the esophagus. They are usually solitary, but multiple tumors have been found on occasion. They vary greatly in size and shape. Tumors as small as 1 cm in diameter or as large as 10 lb have been removed.

Typically, leiomyomas are oval. During their growth, they remain intramural, having the bulk of their mass protruding toward the outer wall of the esophagus. The overlying mucosa is freely movable and normal in appearance. Neither their size nor location correlates with the degree of symptoms. Dysphagia and pain are the most common complaints, the two symptoms occurring more frequently together than separately. Bleeding directly related to the tumor is rare, and when hematemesis or melena occurs in a patient with an esophageal leiomyoma, other causes should be investigated.

A barium swallow is the most useful method to demonstrate a leiomyoma of the esophagus (Fig. [23-97](#)). In profile the tumor appears as a smooth, semilunar, or crescent-shaped filling defect which moves with swallowing, is sharply demarcated, and is covered and surrounded by normal mucosa. Esophagoscopy should be performed to exclude the reported observation of a coexistence with carcinoma. The freely movable mass, which bulges into the lumen, should not be biopsied because of an increased chance of mucosal

perforation at the time of surgical enucleation.

Despite their slow growth and limited potential for malignant degeneration, leiomyomas should be removed unless there are specific contraindications. The majority can be removed by simple enucleation. If during removal the mucosa is inadvertently entered, the defect can be repaired primarily. After tumor removal, the outer esophageal wall should be reconstructed by closure of the muscle layer. The location of the lesion and the extent of surgery required will dictate the approach. Lesions of the proximal and middle esophagus require a right thoracotomy, whereas distal esophageal lesions require a left thoracotomy. Videothoracoscopic approaches have been reported. The mortality rate associated with enucleation is less than 2 percent, and success in relieving the dysphagia is near 100 percent. Large lesions or those involving the gastroesophageal junction may require esophageal resection.

Esophageal Cyst

Cysts may be congenital or acquired. Congenital cysts are lined wholly or partly by columnar ciliated epithelium of the respiratory type, by glandular epithelium of the gastric type, by squamous epithelium, or by transitional epithelium. In some, epithelial lining cells may be absent. Confusion over the embryologic origin of congenital cysts has led to a variety of names, such as enteric, bronchogenic, and mediastinal cysts. Acquired retention cysts also occur, probably as a result of obstruction of the excretory ducts of the esophageal glands.

Enteric and bronchogenic cysts are the most common and arise as a result of developmental abnormalities during the formation and differentiation of the lower respiratory tract, esophagus, and stomach from the foregut. During its embryologic development, the esophagus is lined successively with simple columnar, pseudostratified ciliated columnar, and finally stratified squamous epithelium. This sequence probably accounts for the fact that the lining epithelium may be any or a combination of these; the presence of cilia does not necessarily indicate a respiratory origin.

Cysts vary in size from small to very large and are usually located intramurally in the middle to lower third of the esophagus. Their symptoms are similar to those of a leiomyoma. The diagnosis similarly depends on radiographic and endoscopic findings. Surgical excision by enucleation is the preferred treatment. During removal, a fistulous tract connecting the cysts to the airways should be looked for, particularly in patients who have had repetitive bronchopulmonary infections.

ESOPHAGEAL PERFORATION

Perforation of the esophagus constitutes a true emergency. It most commonly occurs following diagnostic or therapeutic procedures. Spontaneous perforation, referred to as Boerhaave's syndrome, accounts for only 15 percent of cases of esophageal perforation, foreign bodies for 14 percent, and trauma for 10 percent. Pain is a striking and consistent symptom and strongly suggests that an esophageal rupture has occurred, particularly if located in the cervical area following instrumentation of the esophagus or substernally in a patient with a history of resisting vomiting. If subcutaneous emphysema is present, the diagnosis is almost certain.

Spontaneous rupture of the esophagus is associated with a high mortality rate because of the delay in recognition and treatment. Although there usually is a history of resisting vomiting, in a small number of patients the injury occurs silently, without any antecedent history. When the chest radiogram of a patient with an esophageal perforation shows air or an effusion in the pleural space, the condition is often misdiagnosed as a pneumothorax or pancreatitis. An elevated serum amylase caused by the extrusion of saliva through the perforation may fix the diagnosis of pancreatitis in the mind of an unwary physician. If the chest radiogram is normal, a mistaken diagnosis of myocardial infarction or dissecting aneurysm is often made.

Spontaneous rupture usually occurs into the left pleural cavity or just above the gastroesophageal junction. Fifty percent of patients have concomitant gastroesophageal reflux disease, suggesting that minimal resistance to the transmission of abdominal pressure into the thoracic esophagus is a factor in the pathophysiology of the lesion. During vomiting, high peaks of intragastric pressure can be recorded, frequently exceeding 200 mmHg, but since extragastric pressure remains almost equal to intragastric pressure, stretching of the gastric wall is minimal. The amount of pressure transmitted to the esophagus varies considerably depending on the position of the gastroesophageal junction. When it is in the abdomen and exposed to intraabdominal pressure, the pressure transmitted to the esophagus is much less than when it is exposed to the negative thoracic pressure. In the latter situation, the pressure in the lower esophagus will frequently equal intragastric pressure if the glottis remains closed. Cadaver studies have shown that when this pressure exceeds 150 mmHg, rupture of the esophagus is apt to occur. When a hiatal hernia is present and the sphincter remains exposed to abdominal pressure, the lesion produced is usually a Mallory-Weiss mucosal tear, and bleeding rather than perforation is the problem. This is due to the stretching of the supradiaphragmatic portion of the gastric wall. In this situation, the hernia sac represents an extension of the abdominal cavity, and the gastroesophageal junction remains exposed to abdominal pressure.

Diagnosis

Abnormalities on the chest radiogram can be variable and should not be depended upon to make the diagnosis. This is because the abnormalities are dependent on three factors: (1) the time interval between the perforation and the radiographic examination, (2) the site of perforation, and (3) the integrity of the mediastinal pleura. Mediastinal emphysema, a strong indicator of perforation, takes at least 1 h to be demonstrated and is present in only 40 percent of patients. Mediastinal widening secondary to edema may not occur for several hours. The site of perforation can also influence the radiographic findings. In cervical perforation, cervical emphysema is common and mediastinal emphysema rare; the converse is true for thoracic perforations. Frequently, air will be visible in the erector spinae muscles on a neck radiogram before it can be palpated or seen on a chest radiogram (Fig. 23-98). The integrity of the mediastinal pleura influences the radiographic abnormality in that rupture of the pleura results in a pneumothorax, a finding that is seen in 77 percent of patients. In two-thirds of patients the perforation is on the left side, in one-fifth it is on the right side, and in one-tenth it is bilateral. If pleural integrity is maintained, mediastinal emphysema (rather than a pneumothorax) appears rapidly. A pleural effusion secondary to inflammation of the mediastinum occurs late. In 9 percent of patients the chest radiogram is normal.

The diagnosis is confirmed with a contrast esophagogram, which will demonstrate extravasation in 90 percent of patients. The use of a water-soluble medium such as Gastrografin is preferred. Of concern is that there is a 10 percent false-negative rate. This may be due to obtaining the radiographic study with the patient in the upright position. When the patient is upright, the passage of water-soluble contrast material can be too rapid to demonstrate a small perforation. The studies should be done with the patient in the right lateral decubitus position (Fig. 23-99). In this position the contrast material fills the whole length of the esophagus, allowing the actual site of perforation and its interconnecting cavities to be visualized in almost all patients.

Management

The key to optimum management is early diagnosis. The most favorable outcome is obtained following primary closure of the perforation within 24 h, resulting in 80 to 90 percent survival. Figure 23-100 is an operative photograph taken through a left thoracotomy of an esophageal rupture following a pneumatic dilation for achalasia. The most common location for the injury is the left lateral wall of the esophagus just above the gastroesophageal junction. To get adequate exposure of the injury a dissection similar to that described for esophageal myotomy is performed. A flap of stomach is pulled up and the soiled fat pad at the gastroesophageal junction is removed. The edges of the injury are trimmed and closed using a modified Gambee stitch (Fig. 23-101A). The closure is reinforced by the use of a pleural patch or construction of a Nissen fundoplication (Fig. 23-101B).

Mortality associated with immediate closure varies between 8 and 20 percent. After 24 h survival decreases to less than 50 percent and is not influenced by the type of operative therapy, that is, drainage alone or drainage plus closure of the perforation. If the time delay prior to closing a perforation approaches 24 h and the tissues are inflamed, division of the cardia and resection of the diseased portion of the esophagus are recommended. The remainder of the esophagus is mobilized and as much normal esophagus as possible is saved and brought out as an end cervical esophagostomy. In some situations the retained esophagus may be so long that it loops down into the chest. The contaminated mediastinum is drained and a feeding jejunostomy tube is inserted. The recovery from sepsis is often immediate, dramatic, and reflected by a marked improvement in the patient's condition over a 24-h period. On recovery from the sepsis the patient is discharged and returns on a subsequent date for reconstruction with a substernal colon interposition. Failure to apply this aggressive therapy can result in a mortality rate in excess of 50 percent in patients in whom the diagnosis has been delayed.

Nonoperative management of esophageal perforation has been advocated in select situations. The choice of conservative therapy requires skillful judgment and necessitates careful radiographic examination of the esophagus. This course of management usually follows an injury occurring during dilation of esophageal strictures or pneumatic dilations of achalasia. Conservative management should not be used in patients who have free perforations into the pleural space. Cameron proposed three criteria for the nonoperative management of esophageal perforation: (1) the barium swallow must show the perforation to be contained within the mediastinum and drain well back into the esophagus (Fig. 23-102), (2) symptoms should be mild, and (3) there should be minimal evidence of clinical sepsis. If these conditions are met, it is reasonable to treat the patient with hyperalimentation, antibiotics, and cimetidine to decrease acid secretion and diminish pepsin activity. Oral intake is resumed in 7 to 14 days, dependent on subsequent radiographic examinations.

CAUSTIC INJURY

Accidental caustic lesions occur mainly in children and, in general, rather small quantities of caustics are taken. In adults or teenagers, the swallowing of caustic liquids is usually deliberate, during suicide attempts, and greater quantities are swallowed. Alkalies are more frequently swallowed accidentally than acids because strong acids cause an immediate burning pain in the mouth.

Pathology

The swallowing of caustic substances causes both an acute and a chronic injury. During the acute phase, care focuses on controlling the immediate tissue injury and the potential for perforation; during the chronic phase, the focus is on treatment of strictures and disturbances in pharyngeal swallowing. In the acute phase the degree and extent of the lesion are dependent on several factors: the nature of the caustic substance, its concentration, the quantity swallowed, and the time the substance is in contact with the tissues. Acids and alkalies affect tissue in a different manner. Alkalies dissolve tissue and, therefore, penetrate more deeply, while acids cause a coagulative necrosis which limits their penetration. Animal experiments have shown that there is a correlation between the depth of lesion and the concentration of sodium hydroxide (NaOH) solution. When a solution of 3.8% comes into contact with the esophagus for 10 s, it causes a necrosis of the mucosa and the submucosa but spares the muscular layer. A concentration of 22.5% penetrates the whole esophageal wall and into the periesophageal tissues. Cleansing products can contain up to 90% NaOH. The strength of esophageal contractions varies according to the level of the esophagus, being weakest at the striated muscle-smooth muscle interface. Consequently, clearance from this area may be somewhat slower, allowing caustic substances to remain in contact with the mucosa longer. This can explain why the esophagus is preferentially and more severely affected at this level than in the lower portions.

The lesions caused by lye injury occur in three phases. First is the acute necrotic phase, lasting 1 to 4 days after injury. During this period, coagulation of intracellular proteins results in cell necrosis and the living tissue surrounding the area of necrosis develops an intense inflammatory reaction. Second is the ulceration and granulation phase, starting 3 to 5 days after injury. During this period the superficial necrotic tissue sloughs, leaving an ulcerated, acutely inflamed base, and granulation tissue fills the defect left by the sloughed mucosa. This phase lasts 10 to 12 days, and it is during this period that the esophagus is the weakest. Third is the phase of cicatrization and scarring, which begins the third week following injury. During this period the previously formed connective tissue begins to contract, resulting in narrowing of the esophagus. Adhesions between granulating areas

occurs, resulting in pockets and bands. It is during this period that efforts must be made to reduce stricture formation.

Clinical Manifestations

The clinical picture of an esophageal burn is determined by the degree and extent of the lesion. In the initial phase, complaints consist of pain in the mouth and substernal region, hypersalivation, pain on swallowing, and dysphagia. The presence of fever is strongly correlated with the presence of an esophageal lesion. Bleeding can occur, and frequently the patient vomits. These initial complaints disappear during the quiescent period of ulceration and granulation. During the cicatrization and scarring phase, the complaint of dysphagia reappears and is due to fibrosis and retraction resulting in narrowing of the esophagus. Of the patients who develop strictures, 60 percent do so within 1 month, and 80 percent within 2 months. If dysphagia does not develop within 8 months, it is unlikely that a stricture will occur. Serious systemic reactions such as hypovolemia and acidosis resulting in renal damage can occur in cases where the burns have been caused by strong acids. Respiratory complications such as laryngospasm, laryngedema, and occasionally pulmonary edema can occur, especially when strong acids are aspirated.

Inspection of the oral cavity and pharynx can indicate that caustic substances were swallowed, but does not reveal that the esophagus has been burned. Conversely, esophageal burns can be present without apparent oral injuries. Because of this poor correlation, early esophagoscopy is advocated to establish the presence of an esophageal injury. To lessen the chance of perforation, the scope should not be introduced beyond the proximal esophageal lesion. The degree of injury can be graded according to the criteria listed in Table [23-21](#). Even if the esophagoscopy is normal, strictures may appear later. Radiographic examination is not a reliable means to identify the presence of early esophageal injury but is important in later follow-up to identify strictures. The most common locations of caustic injuries are shown in Table [23-22](#).

Treatment

Treatment of a caustic lesion of the esophagus is directed toward management of both the immediate and late consequences of the injury. The immediate treatment consists of limiting the burn by administering neutralizing agents. To be effective, this must be done within the first hour. Lye or other alkali can be neutralized with half-strength vinegar, lemon juice, or orange juice. Acid can be neutralized with milk, egg white, or antacids. Sodium bicarbonate is not used because it generates CO₂, which might increase the danger of perforation. Emetics are contraindicated, since vomiting renews the contact of the caustic substance with the esophagus and can contribute to perforation if too forceful. Hypovolemia is corrected and broad-spectrum antibiotics are administered to lessen the inflammatory reaction and prevent infectious complications. If necessary a feeding jejunostomy tube is inserted to provide nutrition. Oral feeding can be started when the dysphagia of the initial phase has regressed.

In the past, surgeons waited until the appearance of a stricture before starting treatment. Currently, dilations are started the first day after the injury, with the aim of preserving the esophageal lumen by removing the adhesions that occurred in the injured segments. This approach, however, is controversial in that dilations can traumatize the esophagus, causing bleeding and perforation, and there are data indicating that excessive dilations cause increased fibrosis secondary to the added trauma. The use of steroids to limit fibrosis has been shown to be effective in animals, but their effectiveness in human beings is debatable.

Extensive necrosis of the esophagus frequently leads to perforation and is best managed by resection. When there is extensive gastric involvement, the esophagus is nearly always necrotic or severely burned, and total gastrectomy and near-total esophagectomy are necessary. The presence of air in the esophageal wall is a sign of muscle necrosis and impending perforation and is a strong indication for esophagectomy.

Management of acute injury is summarized in the algorithm in Fig. [23-103](#). Some authors have advocated the use of an intraluminal esophageal stent (Fig. [23-104](#)) in patients who are operated upon and found not to have evidence of extensive esophagogastric necrosis. In these patients, a biopsy of the posterior gastric wall should be performed in order to exclude occult injury. If histologically there is a question of viability, a second-look operation should be done within 36 h. If a stent is inserted it should be kept in position for 21 days, and removed after a satisfactory barium esophagogram. Esophagoscopy should be done and if strictures are present, dilations initiated.

Once the acute phase has passed, attention is turned to the prevention and management of strictures. Both antegrade dilation with a Hurst or Maloney bougie and retrograde dilation with a Tucker bougie have been satisfactory. Occasionally, particularly with severe strictures, the patient is instructed to swallow a string, over which metal Sippy dilators are passed until an adequate lumen can be obtained for passage of a mercury bougie. In a series of 1079 patients, early dilations started during the acute phase gave excellent results in 78 percent, good results in 13 percent, and poor results in 2 percent. Fifty-five patients died during the treatment. In contrast, of 333 patients whose strictures were dilated when they became symptomatic, only 21 percent had excellent results, 46 percent good, and 6 percent poor, with 3 dying during the process. The length of time the surgeon should persist with dilation before consideration of esophageal resection is problematic. An adequate lumen should be reestablished within 6 months to 1 year, with progressively longer intervals between dilations. If during the course of treatment an adequate lumen cannot be established or maintained, that is, smaller bougies must be used, operative intervention should be considered. Surgical intervention is indicated when there is (1) complete stenosis in which all attempts from above and below have failed to establish a lumen, (2) marked irregularity and pocketing on barium swallow, (3) the development of a severe periesophageal reaction or mediastinitis with dilatation, (4) a fistula, (5) the inability to dilate or maintain the lumen above a 40 French bougie, or (6) a patient who is unwilling or unable to undergo prolonged periods of dilation.

The variety of abnormalities seen requires that creativity be used when considering esophageal reconstruction. Skin tube esophagoplasties are now used much less frequently than they were in the past, and are mainly of historical interest. Currently the stomach, jejunum, and colon are the organs used to replace the esophagus through either the posterior mediastinum or the retrosternal route. A retrosternal route is chosen when there has been a previous esophagectomy or there is extensive fibrosis in the posterior mediastinum. When all factors are considered, the order of preference for an esophageal substitute is (1) colon, (2) stomach, and (3) jejunum. Free jejunal grafts based on the superior thyroid artery have provided excellent results. Whatever method is selected, it must be emphasized that these procedures cannot be taken lightly; minor errors of judgment or technique may lead to serious or even fatal complications.

Critical in the planning of the operation is the selection of cervical esophagus, pyriform sinus, or posterior pharynx as the site for proximal anastomosis. The site of the upper anastomosis depends on the extent of the pharyngeal and cervical esophageal damage encountered. When the cervical esophagus is destroyed and a pyriform sinus remains open, the anastomosis can be made to the hypopharynx (Fig. [23-105](#)). When the pyriform sinuses are completely stenosed, a transglottic approach is used to perform an anastomosis to the posterior oropharyngeal wall (Fig. [23-106](#)). This allows excision of supraglottic strictures and elevation and anterior tilting of the larynx. In both of these situations, the patient must relearn to swallow. Recovery is long and difficult and may require several endoscopic dilations and, often, reoperations. Sleeve resections of short strictures are not successful because the extent of damage to the wall of the esophagus can be greater than realized, and almost invariably the anastomosis is carried out in a diseased area.

The management of a bypassed damaged esophagus after injury is problematic. If the esophagus is left in place, ulceration from gastroesophageal reflux or the development of carcinoma must be considered. The extensive dissection necessary to remove the esophagus, particularly in the presence of marked periesophagitis, is associated with significant morbidity. Leaving the esophagus in place preserves the function of the vagus nerves, and in turn the function of the stomach. On the other hand, leaving a damaged esophagus in place can result in multiple blind sacs and subsequent development of mediastinal abscesses years later. Most experienced surgeons recommend that the esophagus be removed unless the operative risk is unduly high.

DIAPHRAGMATIC HERNIAS

With the advent of clinical radiology, it became evident that a diaphragmatic hernia was a relatively common abnormality and was not always accompanied by symptoms. Three types of esophageal hiatal hernia were identified: (1) the sliding hernia, type I, characterized by an upward dislocation of the cardia in the posterior mediastinum (Fig. [23-107A](#)); (2) the rolling or paraesophageal hernia, type II, characterized by an upward dislocation of the gastric fundus alongside a normally positioned cardia (Fig. [23-107B](#)); and (3) the combined sliding-rolling or mixed hernia, type III, characterized by an upward dislocation of both the cardia and the gastric fundus (Fig. [23-107C](#)). The end stage of type I and type II hernias occurs when the whole stomach migrates up into the chest by rotating 180° around its longitudinal axis, with the cardia and pylorus as fixed points. In this situation the abnormality is usually referred to as an intrathoracic stomach (Fig. [23-107D](#)).

Incidence and Etiology

The true incidence of a hiatal hernia in the overall population is difficult to determine because of the absence of symptoms in a large number of patients who are subsequently shown to have a hernia. When radiographic examinations are done in response to gastrointestinal symptoms, the incidence of a sliding hiatal hernia is seven times higher than that of a paraesophageal hernia. The age distribution of patients with paraesophageal hernias is significantly different from that observed in sliding hiatal hernias. The median age of the former is 61; of the latter, 48. Paraesophageal hernias are more likely to occur in women by a ratio of 4:1.

Structural deterioration of the phrenoesophageal membrane over time may explain the higher incidence of hiatal hernias in the older age group. These changes involve thinning of the upper fascial layer of the phrenoesophageal membrane (i.e., the supradiaphragmatic continuation of the endothoracic fascia) and loss of elasticity in the lower fascial layer (i.e., the infradiaphragmatic continuation of the transversalis fascia). Consequently, the phrenoesophageal membrane yields to stretching in the cranial direction due to the persistent intraabdominal pressure and the tug of esophageal shortening on swallowing. The upper fascial layer is formed only by loose connective tissue and is of little importance. The lower fascial layer is thick, stronger, and more important. It divides into an upper and lower leaf about 1 cm before attaching intimately with the esophageal adventitia. Due to stretching in the cranial direction, the attachment of the lower leaf protrudes upward and can frequently be identified in the thoracic cavity (Fig. [23-108](#)).

These observations point to the conclusion that the development of a hiatal hernia is an age-related phenomenon secondary to repetitive upward stretching of the phrenoesophageal membrane. A paraesophageal hernia rather than a sliding hernia develops when there is a defect, perhaps congenital, in the esophageal hiatus anterior to the esophagus. The persistent posterior fixation of the cardia to the preaortic fascia and the median arcuate ligament is the only essential difference between a sliding and a paraesophageal hernia. When an anterior defect in the hiatus occurs in association with a loss of fixation of the cardia, a mixed, or type III, hernia develops.

Clinical Manifestations

The clinical presentation of a paraesophageal hiatal hernia differs from that of a sliding hernia. There is usually a higher prevalence of symptoms of dysphagia and postprandial fullness with paraesophageal hernias, but the typical symptoms of heartburn and regurgitation present in sliding hiatal hernias can also occur. Both are caused by gastroesophageal reflux secondary to an underlying mechanical deficiency of the cardia. The symptoms of dysphagia and postprandial fullness in patients with a paraesophageal hernia are explained by the compression of the adjacent esophagus by a distended cardia, or twisting of the gastroesophageal junction by the torsion of the stomach that occurs as it becomes progressively displaced in the chest.

About one-third of patients with a paraesophageal hernia complain of hematemesis, which is due to recurrent bleeding from ulceration of the gastric mucosa in the herniated portion of the stomach. Respiratory complications are frequently associated with a paraesophageal hernia and consist of dyspnea from mechanical compression and recurrent pneumonia from aspiration. With time the stomach migrates into the chest and can cause intermittent obstruction due to the rotation that has occurred. In contrast, many patients with paraesophageal hiatal hernia are asymptomatic or complain of very minor symptoms. However, the presence of a paraesophageal hernia is life-threatening in one-fifth of patients in

that the hernia can lead to sudden catastrophic events, such as excessive bleeding or volvulus with acute gastric obstruction or infarction. With mild dilatation of the stomach, the gastric blood supply can be markedly reduced, causing gastric ischemia, ulceration, perforation, and sepsis.

The symptoms of sliding hiatal hernias are usually due to functional abnormalities associated with gastroesophageal reflux and include heartburn, regurgitation, and dysphagia. These patients have a mechanically defective LES, giving rise to the reflux of gastric juice into the esophagus and the symptoms of heartburn and regurgitation. The symptom of dysphagia occurs from the presence of mucosal edema, Schatzki's ring, stricture, or the inability to organize peristaltic activity in the body of the esophagus as a consequence of the disease.

There are a group of patients with sliding hiatal hernias not associated with reflux disease who have dysphagia without any obvious endoscopic or manometric explanation. Video barium radiograms have shown that the cause of dysphagia in these patients is an obstruction of the swallowed bolus by diaphragmatic impingement on the herniated stomach. Manometrically, this is reflected by a double-humped high-pressure zone at the gastroesophageal junction (Fig. 23-109). The first pressure rise is due to diaphragmatic impingement on the herniated stomach and the second to the true distal esophageal sphincter. These patients usually have a mechanically competent sphincter, but the impingement of the diaphragm on the stomach can result in propelling the contents of the supradiaphragmatic portion of the stomach up into the esophagus and pharynx, resulting in complaints of pharyngeal regurgitation and aspiration. Consequently this abnormality is often confused with typical gastroesophageal reflux disease. Surgical reduction of the hernia results in relief of the dysphagia in 91 percent of patients.

Diagnosis

A radiogram of the chest with the patient in the upright position can diagnose a hiatal hernia if it shows an air-fluid level behind the cardiac shadow (Fig. 23-110). This is usually caused by a paraesophageal hernia or an intrathoracic stomach. The accuracy of the upper gastrointestinal barium study in detecting a paraesophageal hiatal hernia is greater than for a sliding hernia, since the latter can often spontaneously reduce. The paraesophageal hiatal hernia is a permanent herniation of the stomach into the thoracic cavity, so that a barium swallow provides the diagnosis in virtually every case. Attention should be focused on the position of the gastroesophageal junction, when seen, to differentiate it from a type II hernia (see Fig. 23-107 B, C).

Fiberoptic esophagoscopy is very useful in the diagnosis and classification of a hiatal hernia because the scope can be retroflexed. In this position, a sliding hiatal hernia can be identified by noting a gastric pouch lined with rugal folds extending above the impression caused by the crura of the diaphragm (Fig. 23-111), or measuring at least 2 cm between the crura, identified by having the patient sniff, and the squamous-columnar junction on withdrawal of the scope (Fig. 23-112). A paraesophageal hernia is identified on retroversion of the scope by noting a separate orifice adjacent to the gastroesophageal junction into which gastric rugal folds ascend (Fig. 23-113). A sliding-rolling or mixed hernia can be identified by noting a gastric pouch lined with rugal folds above the diaphragm, with the gastroesophageal junction entering about midway up the side of the pouch (Fig. 23-114).

Pathophysiology

It has been assumed for a long time that a sliding hiatal hernia is associated with an incompetent distal esophageal sphincter, whereas a paraesophageal hiatal hernia constitutes a pure anatomic entity and is not associated with an incompetent cardia. Accordingly, surgical therapy for patients with a sliding hernia has been directed toward restoration of the physiology of the cardia, but for patients with a paraesophageal hernia, treatment consisted of simply reducing the stomach into the abdominal cavity and closing the crura.

Physiologic testing with 24-h esophageal pH monitoring has shown increased esophageal exposure to acid gastric juice in 60 percent of the patients with a paraesophageal hiatal hernia compared with the observed 71 percent incidence in patients with a sliding hiatal hernia. It is now recognized that paraesophageal hiatal hernia can be associated with pathologic gastroesophageal reflux.

Physiologic studies have also shown that the competency of the cardia depends on an interrelationship between distal esophageal sphincter pressure, the length of the sphincter that is exposed to the positive-pressure environment of the abdomen, and the overall length of the sphincter. A deficiency in any one of these manometric characteristics of the sphincter is associated with incompetency of the cardia regardless of whether a hernia is present. Patients with a paraesophageal hernia who have incompetent cardias have been shown to have a distal esophageal sphincter with normal pressure but a shortened overall length and displacement outside the positive-pressure environment of the abdomen (Fig. 23-115). In a sliding hernia, even though the sphincter appears to be within the chest on a radiographic barium study, it can still be exposed to abdominal pressure because of the surrounding hernial sac, which functions as an extension of the abdominal cavity. A high insertion of the phrenoesophageal membrane into the esophagus gives adequate length of the distal esophageal sphincter exposed to abdominal pressure. A low insertion gives inadequate length (Fig. 23-116). The importance of the anatomic length of esophagus within the hernial sac has been emphasized by Bombeck, Dillard, and Nyhus in their careful postmortem dissections of the hiatus in 55 patients. Of these patients, 8 had a hiatal hernia. Five of the eight had no evidence of esophagitis and, therefore, a competent cardia, and in these 5 patients, the phrenoesophageal membrane inserted 2 to 5 cm (with a mean of 3.6 cm) above the gastroesophageal junction. The other three patients had evidence of esophagitis and therefore an incompetent cardia, and in these patients the membrane inserted 1 cm or less (with a mean of 0.5 cm) above the gastroesophageal junction. This difference was significant and underscores the importance of an adequate length of intraabdominal esophagus in maintaining competency of the cardia even in the presence of a hiatal hernia.

In contrast to a paraesophageal hernia, where the sphincter remains fixed in the abdomen, in a mixed (type III) hernia the sphincter moves extraperitoneally into the thorax through the widened hiatus along with a portion of the lesser curvature of the stomach and cardia and forms part of the wall of the hernial sac. Consequently, the LES lies outside the abdominal cavity and is unaffected by its environmental pressures. The loss of normal esophageal fixation that occurs in a type I (sliding) hernia or a type III (mixed) hernia results in the body of the esophagus being less able to carry out its propulsive function. This contributes to a greater exposure of the distal esophagus to refluxed gastric juice when components of an incompetent cardia are present. The causes for a mechanical incompetency of the cardia are similar regardless of the type of hernia and are identical with those in patients who have an incompetent cardia and no hiatal hernia.

Treatment

Because of the catastrophic life-threatening complications of bleeding, infarction, and perforation that are part of the natural history of a paraesophageal hiatal hernia in about 25 percent of patients, surgical repair is indicated, even in the elderly.

In the report of Skinner and Belsey, 6 of 21 patients with a paraesophageal hernia treated medically died from the complications of strangulation, perforation, or exsanguinating hemorrhage secondary to acute dilatation of the herniated intrathoracic stomach. These catastrophes occurred for the most part without warning. With this in mind, patients with a paraesophageal hernia are counseled to have elective repair of their hernia regardless of the severity of their symptoms or the size of the hernia. If surgery is delayed and repair is done on an emergency basis, there is a 19 percent operative mortality, compared with less than 1 percent for an elective repair.

Based on pathophysiologic studies on patients with a paraesophageal hiatal hernia, the repair of a paraesophageal hernia should include an antireflux procedure to correct the sphincter characteristics associated with a mechanically incompetent cardia. This is particularly important when the operation is performed on an emergency basis, without preoperative studies. If time permits, preoperative evaluation with 24-h esophageal pH monitoring and esophageal manometry allows the identification of patients with competent cardias. Such patients are candidates for a simple anatomic repair, provided it can be done without surgical dissection of the cardia. If dissection of the cardia is necessary, an antireflux procedure should be added to the repair. Operative repair of sliding hiatal hernias is driven by symptoms of or complications of gastroesophageal reflux disease, unless it is determined that impingement on the stomach by the diaphragm is the cause of the patient's symptoms.

MISCELLANEOUS LESIONS

Plummer-Vinson Syndrome

This uncommon clinical syndrome is characterized by dysphagia associated with atrophic oral mucosa, spoon-shaped fingers with brittle nails, and chronic anemia. It characteristically occurs in middle-aged edentulous women. Because iron-deficiency anemia is a common finding, another name for this condition is sideropenic dysphagia. The syndrome is more common in the Scandinavian countries than in the United States, and its presentation is variable. Not all patients exhibit the classic syndrome; some lack iron-deficiency anemia and others have the typical clinical stigmata but lack dysphagia or the presence of an esophageal web.

Clinical observation suggests that the esophageal web once thought to be a component of the syndrome in some patients may actually be a drug-induced lesion, caused by ingestion of ferrous sulfate, a drug commonly prescribed in cases of iron-deficiency anemia. Ferrous sulfate is known to cause esophageal injury, and a number of patients may have had a drug-induced esophageal injury develop at the site where the web is commonly observed. Not knowing the cause of the esophageal abnormality, early observers reported the web as part of the syndrome. Malignant lesions of the oral mucosa, hypopharynx, and esophagus have been noted to occur in up to 100 percent of patients when followed long-term.

Videoradiographic study as well as endoscopic findings have demonstrated a fibrous web just below the cricopharyngeus muscle as the cause of dysphagia in these patients. Treatment consists of dilation of the web and iron therapy to correct the nutritional deficiency.

Schatzki's Ring

Schatzki's ring is a thin submucosal circumferential ring in the lower esophagus at the squamocolumnar junction, often associated with a hiatal hernia. Its significance and pathogenesis are unclear (Fig. 23-117). The ring was first noted by Templeton, but Schatzki and Gary defined it as a distinct entity in 1953. Its prevalence varies from 0.2 to 14 percent in the general population, depending on the technique of diagnosis and the criteria used. Stiennon believed the ring to be a pleat of mucosa formed by infolding of redundant esophageal mucosa due to shortening of the esophagus. Others believe the ring to be congenital, and still others suggest it is an early stricture resulting from inflammation of the esophageal mucosa caused by chronic reflux.

Schatzki's ring is a distinct clinical entity having different symptoms, upper gastrointestinal function studies, and response to treatment when compared with patients with a hiatal hernia but without a ring. Twenty-four-hour esophageal pH monitoring has shown that patients with a Schatzki's ring have a lower incidence of reflux than hiatal hernia controls. They also have better LES function. This, together with the presence of a ring, could represent a protective role to prevent gastroesophageal reflux.

Symptoms associated with Schatzki's ring are episodes of short-lasting dysphagia during hurried ingestion of solid foods. Its treatment has varied from dilation alone to dilation with antireflux measures, antireflux procedure alone, incision, and even excision of the ring. Little is known about the natural progression of Schatzki's rings. Chen et al., using radiologic techniques, showed progressive stenosis of rings in 59 percent of patients, whereas Schatzki found that the rings decreased in diameter in 29 percent of patients and remained unchanged in the rest.

Symptoms in patients with a ring are caused more by the presence of the ring than by gastroesophageal reflux. Most patients with a ring but without proven reflux respond to one

dilation, while most patients with proven reflux require repeated dilations. In this regard, the majority of Schatzki's ring patients without proven reflux have a history of ingestion of drugs known to be damaging to the esophageal mucosa. Bonavina et al. have suggested drug-induced injury as the cause of stenosis in patients with a ring but without a history of reflux. Since rings also occur in patients with proven reflux, it is likely that gastroesophageal reflux also plays a part. This is supported by the fact that there is less drug ingestion in the history of these patients. Schatzki's ring is probably an acquired lesion that can lead to stenosis from chemical-induced injury by pill lodgment in the distal esophagus or from reflux-induced injury to the lower esophageal mucosa.

The best form of treatment of a symptomatic Schatzki's ring in patients who do not have reflux consists of esophageal dilation for relief of the obstructive symptoms. In patients with a ring who have proven reflux and a mechanically defective sphincter, an antireflux procedure is necessary to obtain relief and avoid repeated dilation.

Mallory-Weiss Syndrome

In 1929, Mallory and Weiss described four patients with acute upper gastrointestinal bleeding who were found at autopsy to have mucosal tears at the gastroesophageal junction. This syndrome, characterized by acute upper gastrointestinal bleeding following repeated vomiting, is considered to be the cause of up to 15 percent of all severe upper gastrointestinal bleeds. The mechanism is similar to spontaneous esophageal perforation: an acute increase in intraabdominal pressure against a closed glottis in a patient with a hiatal hernia.

Mallory-Weiss tears are characterized by arterial bleeding, which may be massive. Vomiting is not an obligatory factor, as there may be other causes of an acute increase in intraabdominal pressure, such as paroxysmal coughing, seizures, and retching. The diagnosis requires a high index of suspicion, particularly in the patient who develops upper gastrointestinal bleeding following prolonged vomiting or retching. Upper endoscopy confirms the suspicion by identifying one or more longitudinal fissures in the mucosa of the herniated stomach as the source of bleeding.

In the majority of patients the bleeding will stop spontaneously with nonoperative management. In addition to blood replacement, the stomach should be decompressed and antiemetics administered, as a distended stomach and continued vomiting aggravate further bleeding. A Sengstaken-Blakemore tube will not stop the bleeding, as the pressure in the balloon is not sufficient to overcome arterial pressure. Only occasionally will surgery be required to stop blood loss. The procedure consists of laparotomy and high gastrotomy with oversewing of the linear tear. Mortality is uncommon and recurrence is rare.

Scleroderma

Scleroderma is a systemic disease accompanied by esophageal abnormalities in approximately 80 percent of patients. In most, the disease follows a prolonged course. Renal involvement occurs in a small percentage of patients and signals a poor prognosis. The onset of the disease is usually in the third or fourth decade of life, occurring twice as frequently in women as in men.

Small vessel inflammation appears to be an initiating event, with subsequent perivascular deposition of normal collagen, which may lead to vascular compromise. In the gastrointestinal tract, the predominant feature is smooth muscle atrophy. Whether the atrophy in the esophageal musculature is a primary effect or occurs secondary to a neurogenic disorder is unknown. The results of pharmacologic and hormonal manipulation, with agents that act either indirectly via neural mechanisms or directly on the muscle, suggest that scleroderma is a primary neurogenic disorder. Methacholine, which acts directly on smooth muscle receptors, causes a similar increase in LES pressure in normal controls and in patients with scleroderma. Edrophonium, a cholinesterase inhibitor which enhances the effect of acetylcholine when given to patients with scleroderma, causes an increase in LES pressure that is less marked in these patients than in normal controls, suggesting a neurogenic rather than myogenic etiology. Muscle ischemia due to perivascular compression has been suggested as a possible mechanism for the motility abnormality in scleroderma. Others have observed that, in the early stage of the disease, the manometric abnormalities may be reversed by reserpine, an agent that depletes catecholamines from the adrenergic system. This suggests that in early scleroderma an adrenergic overactivity may be present which causes a parasympathetic inhibition, supporting a neurogenic mechanism for the disease. In advanced disease manifested by smooth muscle atrophy and collagen deposition, reserpine no longer produces this reversal. Consequently, from a clinical perspective, the patient can be described as having a poor esophageal pump and a poor valve.

The diagnosis of scleroderma can be made manometrically by the observation of normal peristalsis in the proximal striated esophagus, with absent peristalsis in the distal smooth muscle portion (Fig. [23-118](#)). The LES pressure is progressively weakened as the disease advances. Because many of the systemic sequelae of the disease may be nondiagnostic, the motility pattern is frequently used as a specific diagnostic indicator. Gastroesophageal reflux commonly occurs in patients with scleroderma, since they have both hypotensive sphincters and poor esophageal clearance. This combined defect can lead to severe esophagitis and stricture formation. The typical barium swallow shows a dilated, barium- filled esophagus, stomach, and duodenum, or a hiatal hernia with distal esophageal stricture and proximal dilatation (Fig. [23-119](#)).

Traditionally, esophageal symptoms have been treated with H2 blockers, antacids, elevation of the head of the bed, and multiple dilations for strictures, with generally unsatisfactory results. The degree of esophagitis is usually severe and leads to marked esophageal shortening. Consequently a Collis gastroplasty in combination with a Belsey antireflux repair is the usual procedure for the surgical management of this problem. Surgery reduces esophageal acid exposure but does not return it to normal because of the poor clearance function of the body of the esophagus. Only 50 percent of the patients have a good to excellent result. If the esophagitis is severe or there has been a previous failed antireflux procedure and the disease is associated with delayed gastric emptying, a gastric resection with Roux-en-Y esophagojejunostomy and a Hunt-Lawrence pouch has proved the best option.

Acquired Fistulas

The esophagus lies in immediate contact with the membranous portion of the trachea and left bronchus, predisposing to the formation of fistula to these structures. Most acquired esophageal fistulas are to the tracheobronchial tree and secondary to either esophageal or pulmonary malignancy. Traumatic fistulas and those associated with esophageal diverticula account for the remainder. Fistulas associated with traction diverticula are usually due to mediastinal inflammatory disease, and traumatic fistulas usually occur secondary to penetrating wounds, lye ingestion, or iatrogenic injury.

These fistulas are characterized by paroxysmal coughing following the ingestion of liquids and by recurrent or chronic pulmonary infections. The onset of cough immediately after swallowing suggests aspiration, whereas a brief delay (30 to 60 s) suggests a fistula.

Spontaneous closure is rare, owing to the presence of malignancy or a recurrent infectious process. Surgical treatment of benign fistulas consists of division of the fistulous tract, resection of irreversibly damaged lung tissue, and closure of the esophageal defect. To prevent recurrence, a pleural flap should be interposed. Treatment of malignant fistulas is difficult, particularly in the presence of prior irradiation. Generally, only palliative treatment is indicated. This can be best done by using a specially designed esophageal endoprosthesis that bridges and occludes the fistula, allowing the patient to eat. Rarely, esophageal diversion, coupled with placement of a feeding jejunostomy, can be used as a last resort.

TECHNIQUES OF ESOPHAGEAL RECONSTRUCTION

Options for esophageal substitution include gastric advancement, colonic interposition, and either jejunal free transfer or advancement into the chest. Rarely, combinations of these grafts will be the only possible option. The indications for esophageal resection and substitution include malignant and end-stage benign disease. The latter includes reflux- or drug-induced stricture formation that cannot be dilated without damage to the esophagus, a dilated and tortuous esophagus secondary to severe motility disorders, lye-induced strictures, and multiple previous antireflux procedures. The choice of esophageal substitution has significant impact upon the technical difficulty of the procedure and influences the long-term outcome.

Partial Esophageal Resection

Low-lying benign lesions, with preserved proximal esophageal function, are best treated with the interposition of a segment of proximal jejunum into the chest and primary anastomosis. A jejunal interposition can reach to the inferior border of the pulmonary hilum with ease, but the architecture of its blood supply rarely allows the use of the jejunum above this point. Because the anastomosis is within the chest, a thoracotomy is necessary.

The jejunum is a dynamic graft and contributes to bolus transport, whereas the stomach and colon function more as a conduit. The stomach is a poor choice in this circumstance because of the propensity for the reflux of gastric contents into the upper esophagus following an intrathoracic esophagogastrectomy. It is now well recognized that this occurs, and can lead to incapacitating symptoms and esophageal destruction in some patients. Short segments of colon, on the other hand, lack significant motility and have a propensity for the development of esophagitis above the anastomosis.

Replacement of the cervical portion of the esophagus while preserving the distal portion is occasionally indicated in cervical esophageal or head and neck malignancy and following the ingestion of lye. Free transfer of a portion of jejunum to the neck has become a viable option and is successful in the majority of cases. Revascularization is achieved via use of the internal mammary artery and the internal mammary or innominate vein. Removal of the sternoclavicular joint aids in performing the vascular and distal esophageal anastomosis (Fig. [23-120](#)).

Reconstruction after Total Esophagectomy

Neither the intrathoracic stomach nor the intrathoracic colon functions as well as the native esophagus after an esophagogastrectomy. The choice between these organs will be influenced by several factors, such as the adequacy of their blood supply and the length of resected esophagus that they are capable of bridging. If the stomach shows evidence of disease, or has been contracted or reduced by previous gastric surgery, the length available for esophageal replacement may not be adequate. The presence of diverticular disease, unrecognized carcinoma, or colitis prohibits the use of the colon. The blood supply of the colon is more affected than the blood supply of the stomach by vascular disease, which may prevent its use. Of the two, the colon provides the longest graft. The stomach can usually reach to the neck if the amount of lesser curve resected does not interfere with the blood supply to the fundus. Gastric interposition has the advantage that only one anastomosis is required. On the other hand, there is greater potential for aspiration of gastric juice or stricturing of the cervical anastomosis from chronic reflux when stomach is used for replacement.

Patients following an esophagogastrectomy may have discomfort during or shortly after eating. The most common symptom is a postprandial pressure sensation or a feeling of being stuffed, which probably results from the loss of the gastric reservoir. This symptom is less common when the colon is used as an esophageal substitute, probably because the distal third of the stomach is retained in the abdomen and the interposed colon provides an additional reservoir function.

King and Hölscher have reported a 40 percent and 50 percent incidence of dysphagia after reestablishing gastrointestinal continuity with the stomach following esophagogastrectomy. This incidence is similar to Orringer's results after using the stomach to replace the esophagus in patients with benign disease. More than half of the patients

experienced dysphagia postoperatively; two-thirds of this group required postoperative dilation and one-fourth have persistent dysphagia and require home dilation. By contrast, dysphagia is uncommon and the need for dilation is rare following a colonic interposition. Isolauri reported on 248 patients with colonic interpositions and noted a 24 percent incidence of dysphagia 12 months after the operation. When it occurred, the most common cause was recurrent mediastinal tumor. The high incidence of dysphagia with the use of the stomach is probably related to the esophagogastric anastomosis in the neck and the resulting difficulty of passing a swallowed bolus.

Another consequence of the transposition of the stomach into the chest is the development of postoperative duodenogastric reflux, probably due to pyloric denervation, and adding a pyloroplasty may worsen this problem. Following gastric advancement, the pylorus lies at the level of the esophageal hiatus, and a distinct pressure differential develops between the intrathoracic gastric and intraabdominal duodenal lumina. Unless the pyloric valve is extremely efficient, the pressure differential will encourage reflux of duodenal contents into the stomach. Duodenogastric reflux is less likely to occur following colonic interposition, because there is sufficient intraabdominal colon to be compressed by the abdominal pressure and the pylorus and duodenum remain in their normal intraabdominal position.

Although there is general acceptance of the concept that an esophagogastric anastomosis in the neck results in less postoperative esophagitis and stricture than one at a lower level, reflux esophagitis following a cervical anastomosis does occur, albeit at a slower rate than when the anastomosis is at a lower level. Most patients undergo cervical esophagogastrostomy for malignancy; thus the long-term sequelae of an esophagogastric anastomosis in the neck are not of concern. Patients who have had a cervical esophagogastrostomy for benign disease, however, may develop problems associated with the anastomosis in the fourth or fifth postoperative year severe enough to require anastomotic revision. This is less likely in patients who have had a colonic interposition for esophageal replacement. Consequently, in patients who have a benign process or a potentially curable carcinoma of the esophagus or cardia, a colonic interposition is used to obviate the late problems associated with a cervical esophagogastrostomy. Colonic interposition for esophageal substitution is a more complex procedure than gastric advancement, with the potential for greater perioperative morbidity, particularly in inexperienced hands.

Composite Reconstruction

Occasionally a combination of colon, jejunum, and stomach is the only reconstructive option available. This situation may arise when there has been previous gastric or colonic resection, when dysphagia has recurred after a previous esophageal resection, or following postoperative complications such as ischemia of an esophageal substitute. Although not ideal, combinations of colon, jejunum, and stomach used to restore gastrointestinal continuity function surprisingly well, and allow alimentary reconstruction in an otherwise impossible situation.

CHAPTER 24 - Stomach

Stanley W. Ashley
Denis Evoy
John M. Daly

ANATOMY

Gross Anatomy

The stomach is an asymmetric dilatation of the proximal gastrointestinal tract, responsible for the initial digestion and storage of food. The stomach's capacity in the adult is approximately 1.5 to 2.0 L. It lies in the epigastrium, beginning at the gastroesophageal junction and extending distally to the proximal duodenum. The long axis first passes downward and then forward, upward, and to the right. It has two curvatures: the greater curvature, which constitutes its left and inferior margin, and the lesser curvature, its right and superior margin.

The stomach has been divided into anatomic regions based on its external and functional anatomy. The cardia of the stomach is poorly defined externally but represents the region immediately adjacent to the gastroesophageal junction. The fundus is the domed portion of the stomach to the left and superior to the cardia. The corpus or body extends from the fundus distally to the incisura angularis, a notch in the lesser curvature seen at the junction of the middle and distal thirds of the stomach; the greater curvature margin of the corpus is poorly defined by external anatomy. These landmarks are useful during operations on the stomach (Fig. 24-1). Functionally, the antral mucosa usually begins on the lesser curvature at the junction of the proximal and middle thirds and extends distally to the pylorus. This difference in functional and external anatomy is important when resection of the functional antrum is the goal of operation; the lesser curvature margin should extend considerably proximally to the incisura angularis.

Visceral peritoneum covers all but a small posterior portion of the stomach near the entry of the esophagus. The mucosal lining has a velvet appearance and is lined by numerous longitudinal folds, the rugae.

Embryology

The stomach arises during the fourth week of embryonic life as a dilatation of the primitive foregut. As gestation progresses, growth of the left gastric wall is accelerated relative to the right, rotating the organ so that at full term it assumes a more transverse, J-shaped orientation. This developmental pattern is responsible for the asymmetry in the length of the lesser and greater curvatures and causes the left vagus nerve to assume an anterior position while the right lies behind the distal esophagus. As they course along the stomach, the left and right nerves then lie in the anterior and posterior leaflets of the lesser omentum.

Anatomic Relationships

The close anatomic relationship of the stomach to a variety of upper abdominal organs is of considerable clinical significance. The left lobe of the liver extends over the anterior wall of the proximal stomach and frequently must be retracted laterally to obtain adequate exposure of the gastroesophageal junction. The spleen lies superior and to the left of the stomach, sharing its blood supply with that of the greater curvature, and is at risk of iatrogenic injury during operations on the proximal stomach. The stomach has anterior and posterior relations with the diaphragm and is subject to several forms of diaphragmatic herniation. The lesser sac separates the stomach from the pancreas, but this space may be obliterated by inflammation. As a result, pancreatic pseudocysts are often densely adherent to the posterior gastric wall; in this instance, cystogastrostomy (surgical drainage into the gastric lumen) represents the most appropriate therapy. Splenic and pancreatic enlargement can directly impinge on the gastric lumen, producing symptoms of early satiety. The transverse colon lies immediately inferior to the stomach and neoplasms of either organ may extend to involve the other. Gastric neoplasms may extend directly into any adjacent organ.

Blood Supply

The stomach has a particularly rich blood supply from four major and several minor arteries, all of which arise from the celiac axis (Fig. 24-2). The lesser curvature is supplied by the right gastric artery, arising from the hepatic artery, and by the left gastric artery, originating directly from the celiac axis. It is not unusual for the left hepatic artery to originate from the left gastric artery, in which case hepatic perfusion can be compromised when the left gastric artery is divided. The greater curvature is supplied by the right and left gastroepiploic arteries, which arise from the gastroduodenal and splenic arteries, respectively. The short gastric vessels arise directly from the splenic artery and supply the fundus and proximal body of the stomach. These arteries are closely interconnected through a dense submucosal vascular plexus, permitting division of up to three of the stomach's major arteries without significantly compromising perfusion. This vascular redundancy facilitates the mobilization of the stomach for reconstruction of the esophagus because it may be based on a single vascular pedicle, although the right gastric and gastroepiploic arteries are usually both preserved. It also explains the profuse bleeding that can occur with relatively small mucosal lesions.

The venous drainage of the stomach parallels the arterial supply, eventually draining into the portal circulation. The coronary vein, which corresponds to the left gastric artery, assumes particular significance in portal hypertension when it serves as a conduit between the portal and systemic circulations via the esophageal plexus, forming esophageal varices. The vein of Mayo or prepyloric vein is a typically prominent vein on the anterior pylorus, useful in identifying this region at the time of operation.

Lymphatics

The lymphatics also follow the vascular distribution and are extensively interconnected (Fig. 24-3). Malignant disease involving the gastric lymphatics often spreads to nodal groups well beyond the area of primary drainage. The primary drainage site of the proximal lesser curvature is the superior gastric lymph nodes near the gastroesophageal junction, while the proximal greater curvature is served by splenic and omental nodal groups. The distal stomach drains into suprapyloric and subpyloric nodes. Secondary nodal regions include the celiac axis, the porta hepatis, and the pancreas. This anatomy has received increasing attention as a result of reports suggesting that a more extensive lymph node dissection during gastrectomy for gastric cancer may be associated with improved survival rates.

Innervation

The autonomic nervous system plays an important role in controlling gastric secretory and motor function. The left and right vagus nerves, carrying parasympathetic efferent and afferent fibers, lie on the anterior and posterior surfaces of the esophagus, respectively (Fig. 24-4). The left or anterior vagus is usually smaller and more closely approximated to the anterior surface of the distal esophagus; the larger posterior trunk is typically found in a more intermediate position between the esophagus and the aorta. Often small fibers branch from the main trunks on the esophagus and travel separately to innervate acid-secreting cells of the proximal stomach. The "criminal" nerve of Grassi is one such fiber that arises from the posterior trunk and may play a role in recurrent ulceration after vagotomy if the nerve is sectioned distal to where it leaves the vagus. Below the diaphragm, the anterior vagus gives off a hepatic branch, and the celiac branch arises from the posterior vagus. The remaining fibers, the nerves of Latarget, travel in the anterior and posterior leaflets of the lesser omentum and give off branches to the adjacent corpus. At the antrum the final fibers innervating the antral and pyloric musculature are referred to as the "crow's foot." Sympathetic nerves also reach the stomach via the celiac plexus. They travel to the gastric wall in association with the major vessels.

Histology

The wall of the stomach is composed of four distinct layers: mucosa, submucosa, muscularis, and serosa. The surface of the mucosa is lined by a columnar epithelium believed to play a protective role, secreting both mucus and bicarbonate. The surface is spotted or cobblestoned with pits that lead into gastric glands that differ in each of the three functional regions of the stomach (Fig. 24-5). In the cardia, the transition zone between the squamous epithelium of the esophagus and the simple columnar epithelium of the stomach, the gastric glands are lined by clear-staining, mucus-secreting cells. The cardiac glands probably serve to lubricate foodstuffs and also to protect the mucosa of this region from acid injury. The glands of the fundus and body, oxyntic glands, are lined by acid-secreting parietal cells and pepsinogen-secreting chief cells (Fig. 24-6). Several glands may enter into a single pit. They also contain undifferentiated stem cells, mucus neck cells, and a variety of argentaffin endocrine cells. The glands of the pylorus and antrum are lined with mucus-secreting cells and gastrin-producing G cells. The gastric glands consist of six major cell types: surface, mucous neck, progenitor, chief, parietal, and endocrine. The surface epithelial cells are distinguished by abundant mucous granules within their apical surface. These cells are designed to protect the epithelium from ingestants and from the injurious effects of gastric acid. They are also the source of a sodium-rich alkaline secretion. The mucous neck cells line the entrance to the gastric glands. Cells at the base of the gastric pits serve as stem or progenitor cells for the development of new surface cells and also the cells of the gastric glands. Chief cells are the source of pepsinogen, a proteolytic enzyme that is converted to its active form, pepsin, at a pH below 2.5. A variety of endocrine cells exist within the gastric gland.

The parietal cells, secreting both hydrogen ions and intrinsic factor, contain numerous mitochondria, consistent with the intense energy requirements for acid secretion. They possess deeply invaginated intracellular secretory canaliculi that connect with the luminal or apical membrane and, in the resting state, numerous intracellular membranous structures called tubulovesicles (Fig. 24-7). With secretory stimulation, the tubulovesicles fuse with the canaliculi, markedly increasing the luminal surface area for secretion of acid.

The chief cells contain an abundant rough endoplasmic reticulum for packaging of protein. Zymogen granules, containing inactive pepsinogen, are concentrated within the apical cytoplasm for luminal secretion via exocytosis. In contrast, antral G cells contain many basally located granules, which fuse with the basolateral membrane, releasing gastrin into the circulation.

The muscularis mucosa is a thin layer of smooth muscle that separates the mucosa, consisting of the epithelium and its underlying lamina propria, from the submucosa. The submucosa is composed of connective tissue and a rich plexus of arteries, veins, lymphatics, and nerves. External to this, the muscularis is composed of an inner layer of oblique muscles and a middle layer of circular muscle and is surrounded by longitudinal muscle. Proximally, the three layers are easily recognized, and through the process of receptive relaxation, they permit the remarkable dilatation of the stomach that occurs after ingestion of a meal. The circular layer is most developed in the antrum and the pylorus, where it serves to grind and mix the meal, regulating the release of food particles into the duodenum.

PHYSIOLOGY

The stomach performs two interrelated functions in the initial phase of digestion. It begins the process of food breakdown, exposing a solid meal to the proteolytic action of acid and pepsin, and grinding and diluting the mixture to form a more uniformly consistent chyme. It acts as a reservoir, relaxing to accommodate the meal and regulating the release of swallowed food into the duodenum in small boluses. The process of early digestion requires that solid foodstuffs be stored for a prolonged period of time (4 h) as they undergo reduction in size and preliminary breakdown into basic metabolic constituents.

The storage function of the stomach is greatly enhanced by the process of receptive relaxation. This is an event in which the upper portion of the stomach relaxes as the intake of food is anticipated. Solid food settles and layers within the greater curvature of the fundic area of the stomach. Liquids pass rapidly from the stomach along its lesser curve (the magenstrasse or canalis gastricus), thereby leaving the solid mass quite undisturbed. Processing of the food mass is initiated by a skimming from the outermost layers of the gastric bolus. Salivary digestion occurs within the middle of the bolus, and gastric digestion at its periphery. Food particles are reduced in size by a grinding action of the antrum as well as

digestion and dilution by the gastric secretions. The storage function of the stomach is enhanced by the antrum and pylorus, which constantly return material to the proximal stomach until it is ready for delivery to the duodenum.

Gastric Secretion

Digestion, which occurs in the stomach, is designed to reduce the size of food particles and begin the dispersion of nutrients so that they can be absorbed. There is considerable redundancy in these actions and most of the digestion occurs beyond the pyloric sphincter. The action of gastric acid and pepsin, in conjunction with the grinding that occurs in the distal stomach, increases the efficiency of the process and allows consumption of larger and less frequent meals.

Acid Secretion

The main component of gastric secretion is hydrochloric acid and its accompanying water. Acid is secreted by parietal cells in the glands of the fundus and body of the stomach. The acid pump mechanism is the hydrogen-potassium–stimulated adenosine triphosphatase (H^{+}/K^{+} -ATPase) enzyme system that exchanges cellular H^{+} for luminal K^{+} (Fig. 24- 8). Adenosine triphosphate (ATP) is hydrolyzed to catalyze the exchange, and the H^{+} is concentrated approximately 2.5 million times in the secretory canaliculi. K^{+} and Cl^{-} are secreted into the lumen down their electrochemical gradients by passive diffusion across the parietal cell apical membrane. The OH^{-} generated during the formation of the H^{+} from water is converted to HCO_3^{-} by carbonic anhydrase. The bicarbonate is released into the submucosal capillaries, in exchange for Cl^{-} , producing the so-called “alkaline tide,” which can be measured in venous blood from the stomach during acid secretion.

The regulation of gastric secretion is an extremely complex phenomenon, involving endocrine, neural, paracrine, and even autocrine mechanisms. The three major stimulants appear to be gastrin, acetylcholine, and histamine. Gastrin reaches the parietal cell after it is released into the systemic circulation from the antrum and proximal duodenum. Acetylcholine is secreted by cholinergic nerve terminals in close proximity to the acid- secreting mucosa. Histamine acts in a paracrine fashion following its secretion from mast cells in the lamina propria of the fundus and body.

The parietal cell has been shown to possess receptors for histamine, acetylcholine, and gastrin, the three major stimulants of acid secretion. Each of these is believed to act through second messenger mechanisms to increase protein phosphorylation in the parietal cell (Fig. 24-9); this in turn increases the activity of the ATPase. Histamine acts via adenylate cyclase, and gastrin and acetylcholine are believed to increase intracellular calcium through a pathway involving the phosphatidylinositols. Pharmacologically, the histamine is directed at H_2 receptors, and the acetylcholine receptor on parietal cells is of the muscarinic variety. The resulting phosphorylation in turn activates the H^{+}/K^{+} -ATPase, increasing acid secretion. The response to a combination of these stimulants is greater than the sum of the responses to each agent administered individually, a phenomenon referred to as potentiation. A reduction in the amount of stimulation at one receptor also reduces the responsiveness to the other agonists, an interaction exploited in both medical and surgical management of acid-peptic disease (e.g., blockade of the histamine receptor decreases the responsiveness to acetylcholine and gastrin). The parietal cell also possesses inhibitory receptors for somatostatin and the prostaglandins.

Between meals the stomach secretes 2 to 5 mEq of acid per hour, although there is some diurnal variation, with a maximum during the early evening hours. This resting secretion is believed to be related to vagal tone and basal histamine secretion. The response to a meal has been divided conceptually into three phases: cephalic, gastric, and intestinal.

The cephalic phase, originally described by Pavlov, is triggered by the sight, smell, and taste of food. Acid secretion is mediated through the vagus nerve. The acetylcholine stimulates parietal cells directly, inhibits somatostatin release, and directly induces gastrin release from antral G cells. The cephalic phase produces approximately 10 mEq of acid per hour.

The gastric phase, in which gastrin is the most important mediator, is the result of food entering the stomach. Antral distention, amino acids and small peptides, and the increase in luminal pH produced by the buffering capacity of the meal all increase gastrin release. Gastrin is a family of polypeptides of varying lengths, formed from the breakdown of preprogastrin, the 101 amino acid precursor. A 34 amino acid breakdown product (G34) is the major circulating form, while G17 appears to be the predominant hormonal stimulus to secretion. In addition to its effects on acid secretion, gastrin is a trophic hormone, stimulating growth not only of the gastric mucosa but also of duodenum, pancreas, and colon. The gastric phase produces approximately 15 to 25 mEq of acid per hour; it is limited not only because gastric distention also causes somatostatin release but also because acidification eventually inhibits gastrin release. When luminal pH falls to 2.0, gastrin release is completely abolished.

The entry of chyme into the duodenum initiates the intestinal phase of secretion. The effect is small and variable, accounting for approximately 5 percent of meal-induced secretion. It is probably the result of absorbed amino acids and gastrin release from the proximal duodenum. Of greater significance are the inhibitory effects of the duodenum. A variety of hormones, including secretin, peptide YY, *gastric inhibitory peptide (GIP)*, and neurotensin, may be important in this process. The complete integration of this redundant regulatory system is only partially understood.

Gastric secretion has several other important consequences. The acidic conditions sterilize the proximal gastrointestinal tract; only a few fastidious organisms, such as *Helicobacter pylori*, can withstand the low luminal pH. In contrast, when acid secretion is inhibited, the stomach and small intestine are rapidly colonized with enteric organisms. This usually is of no consequence, but achlorhydric patients have been shown to be more susceptible to salmonellosis and cholera. Patients undergoing operation on the proximal gastrointestinal tract are vulnerable to infection and in preparation should receive prophylactic antibiotics.

The stomach also plays a role in iron and calcium absorption; after gastrectomy, iron deficiency anemia and bone disease are not uncommon. Gastric acid appears to play an important role in the mobilization and solubilization of dietary iron and calcium. The acidic conditions contribute to the conversion of iron to the ferrous state, in which it is best absorbed in the duodenum.

Other Secretory Functions

In addition to hydrochloric acid, the parietal cells also secrete intrinsic factor in response to many of the same stimuli. Secretion is usually in considerable excess (approximately 100×) of that needed for cobalamin (vitamin B₁₂) absorption in the terminal ileum. Gastrectomy and atrophic gastritis, conditions that can produce a reduction in parietal cell mass, can be associated with vitamin B₁₂ deficiency and megaloblastic anemia.

Pepsinogen is secreted by the chief cells in response to many of the same stimuli that affect the parietal cells; the most important stimulus is acetylcholine. Like acid secretion, pepsinogen secretion seems to be inhibited by somatostatin. Pepsinogen is autocleaved to active pepsin under acidic conditions; it is most active at pH 2.5 and denatures at pH 7.0 or greater. Pepsin catalyzes the hydrolysis of a variety of peptide bonds and initiates the digestion of collagen and other proteins. In human beings, two distinct forms, PG I and II, have been identified. Despite extensive investigation, there is no clear evidence of any correlation with gastric disease states.

The surface epithelial cells of the mucosa secrete a combination of mucus and bicarbonate. The bicarbonate is generated by carbonic anhydrase within the epithelium and then secreted across the apical membrane in exchange for Cl^{-} . It is believed that the combination of mucus and bicarbonate plays an important role in protecting the mucosa from acid injury. Recent evidence suggests that as a consequence of the bicarbonate secretion, a pH gradient is established in the mucous layer that coats the luminal surface. At its luminal surface the mucus is acidic, but as H^{+} ions diffuse through the layer toward the epithelium they are buffered by the bicarbonate, protecting the mucosa from acid injury.

Gastric Motility and Emptying

Gastric motor activity involves two distinct patterns that are distinguished anatomically and functionally (Fig. 24-10). The first pattern involves the smooth muscle of the proximal one-third of the stomach. Myocytes of this region demonstrate no spontaneous myoelectric activity and instead relax in response to the stretch produced by increasing gastric volumes. This receptive relaxation means that a meal can be accommodated with little increase in intragastric pressure. Relaxation is believed to occur via a vagally mediated reflex and permits the stomach to act as a reservoir for several hours after a meal. Contractile activity in the proximal stomach gradually increases, and food is propelled distally by the pressure gradient.

The motility pattern of the distal stomach is quite different. Beginning at a pacemaker site on the greater curvature, a series of myoelectric complexes pass distally at a rate of three times per minute. Action potentials are sometimes superimposed on these spontaneous depolarizations, resulting in a peristaltic wave that propagates distally. Vagal activity, gastrin, and motilin all increase the frequency of the action potentials, and secretin, glucagon, and *GIP* seem to reduce it.

The movement of the meal is influenced by each of the motility patterns (Fig. 24-11). Initially food enters the stomach and is stored in its proximal portion, where it is gradually digested and diluted. As pressure increases proximally, the bolus enters the antrum, where it is propelled toward the pylorus by a peristaltic wave. The pylorus actually closes several seconds before the arrival of the wave, allowing only a small amount of liquid and suspended food particles to enter the duodenum, while the main mass of food is repulsed back into the proximal stomach. This process, referred to as trituration, serves to grind the food into smaller pieces and mix it further with gastric secretions.

Sphincters

The stomach is bounded proximally and distally by sphincters. The *lower esophageal sphincter (LES)* is a high- pressure zone of the distal esophagus just proximal to the cardia. It normally relaxes only in response to a peristaltic wave from above, allowing the passage of a meal and swallowed secretions into the proximal stomach. Between relaxations, the high pressure prevents the reflux of gastric contents into the esophagus. LES physiology is discussed in detail in Chap. 23.

In contrast with the *LES*, which has no anatomic correlate, the pyloric sphincter is a thickening of smooth muscle that not only regulates gastric emptying but also prevents reflux of duodenal contents into the stomach. The consequence of duodenogastric reflux after surgical disruption of the sphincter, alkaline reflux gastritis, is discussed later, in the section Postgastrectomy Syndromes.

DIAGNOSIS OF GASTRIC DISEASE

Symptoms and Signs

Patients with disorders of the stomach present with a variety of symptoms and signs, depending on the condition. None of the symptoms and signs alone is specific enough to make a diagnosis, but a constellation of them can strongly suggest a diagnosis of gastric disease.

The loss of appetite is not unusual in a variety of conditions, ranging from viral syndromes to malignant tumors. Any form of gastric obstruction produces early satiety and accompanying anorexia. This may occur with both ulcer disease and neoplasms of the stomach. Infiltrating tumors tend to interfere with receptive relaxation, producing early satiety and a sense of fullness after consuming only small quantities of food. Significant anorexia with weight loss is often a symptom of a malignant tumor, although anorexia may not develop until the tumor is considerably advanced.

Nausea and vomiting accompany a variety of gastric disorders, although they are most common with gastric outlet obstruction. Nausea is a sensation that defies precise definition but is probably best described as a feeling of impending emesis. Vomiting itself occurs as the gastric contents are forcefully ejected from the alimentary tract in a retrograde direction. This complex reflex occurs when a contraction of the abdominal musculature is combined with elevation of the cardia (to open the gastroesophageal sphincter) and closure of the pylorus. Retching is essentially unsuccessful vomiting. Nausea and vomiting occur with peptic ulcer and neoplasms of the stomach, even in the absence of obstruction. Nausea and vomiting related to gastric outlet obstruction typically occur more than 1 h after a meal. Vomiting of undigested material eaten 12 h previously is characteristic of such disorders. Unlike in most other conditions, vomiting often relieves the pain of peptic ulcer. Compared with obstructions of the gastric outlet, the vomiting that accompanies more distal obstructions is typically bile-stained and may be accompanied by more significant abdominal distention.

Reflux of gastric contents is associated with heartburn, respiratory symptoms from aspiration, and “water brash” (a sour taste from reflux of gastric contents into the mouth). Although regurgitation may occur with gastric outlet obstruction, it is most commonly a result of disease of the *LES* (see Chap. 23).

Pain of gastric origin is typically localized to the epigastrium and may radiate to the back. A variety of disorders can produce discomfort, and the character of the pain is far from diagnostic. The gastric mucosa is devoid of pain fibers, and many disorders may be relatively painless until far advanced. Pain from gastric cancer is typically continuous and is often increased by food. Patients with a duodenal ulcer develop burning epigastric pain several hours after meals, and the pain is characteristically relieved by antacids and food. In contrast, patients with gastric ulcers have more severe pain, which occurs soon after meals and is not relieved by antacids or food consumption. Ulcer perforation is associated with severe generalized pain.

Blood loss is a common manifestation of gastric disease. Chronic mild blood loss may be occult, detected only by testing the stool with a chemical reagent. More significant upper gastrointestinal bleeding typically produces melena, which is produced by degradation of blood in the gut. Gastric bleeding can be so massive that on occasion patients present with hematochezia (bright red blood per rectum), although this is more typical of lower gastrointestinal bleeding. Hematemesis is bloody vomitus and may be fresh or “coffee-ground,” implying some contact with gastric acid.

Gastric neoplasms can produce mild chronic blood loss, and ulcer disease and gastritis may be associated with hemorrhage of varying magnitude. Mallory-Weiss tears of the gastric mucosa, typically associated with vomiting, and Dieulafoy’s lesion, small erosions from pressure ulceration from a mucosal artery, are characterized by massive hemorrhage. If upper gastrointestinal bleeding is suspected in the patient with melena or hematochezia, a nasogastric tube should be placed. This confirms bleeding from an esophageal or gastric lesion but, if negative, does not rule out a source distal to the pylorus. Most patients with suspected upper gastrointestinal hemorrhage should undergo endoscopy, which localizes the lesion and permits directed therapy and biopsy procedures.

Weight loss may be a sign of gastric disease. Benign gastric ulcer is more often associated with weight loss than duodenal ulcer, because food in the stomach aggravates the pain. Gastric malignant tumor is associated with significant weight loss and, in advanced cases, produces severe cachexia.

Distention of the stomach (gastric dilatation) may produce significant symptoms if it develops acutely. Acute distention develops in a variety of settings but is most common after abdominal operations and in the critically ill. The stomach is typically massively enlarged with gas and may be associated with activation of the autonomic nervous system, producing pallor, tachypnea, bradycardia, and hypotension. Percussion of the abdomen reveals tympany that may extend into the pelvis. Nasogastric suction will usually relieve the problem, but if allowed to progress, acute distention can produce necrosis and perforation. In contrast, distention associated with gastric outlet obstruction typically develops more slowly and may be almost asymptomatic. The characteristic physical finding is a succussion splash, audible with palpation, produced by liquid sloshing in the chronically distended stomach.

Tenderness is elicited by deep palpation of the epigastrium. Tenderness is more common with duodenal ulcer but may be associated with gastric ulcer, gastritis, and malignant tumor. It is neither a sensitive nor a specific finding. Perforated ulcers are associated with a chemical peritonitis related to irritation by the acidic gastric contents. Patients typically present with marked abdominal tenderness and “boardlike rigidity” from the guarding that occurs.

Gastric cancer has often metastasized by the time of diagnosis, and a palpable epigastric mass is not unusual. Several eponyms have been applied to common sites of such disease: Virchow’s node, an enlarged left supraclavicular lymph node; Sister Joseph’s nodule, a palpable mass at the umbilicus suggesting diffuse involvement of the peritoneal surfaces or carcinomatosis; Irish’s node, an involved left axillary lymph node; Krukenberg’s tumor, ovarian involvement with metastatic disease, and Blumer’s shelf, an anterior ridge palpable on rectal examination produced by drop metastasis into the cul-de-sac.

Diagnosis

Radiography

Radiography may be a useful initial diagnostic maneuver in the evaluation of patients with upper gastrointestinal complaints (Fig. 24-12). There has been some debate about the relative merits of radiography versus endoscopy. Radiography is more easily tolerated and is probably the procedure of choice in younger patients. In contrast, the patient over 50 years of age needs to have malignant tumor ruled out by endoscopic biopsy. Several criteria have been used to distinguish benign from malignant ulcers radiographically, such as the position of the ulcer relative to the gastric wall. Benign ulcer craters tend to extend outside the lumen, whereas the malignant ulcer is typically limited to the tumor that projects into the gastric lumen. In benign ulcers, the gastric folds radiate from the ulcer crater; in malignant disease, the normal orientation of the rugae persists. Such criteria are not completely reliable, and endoscopy with biopsy is usually indicated.

Radiography is not very sensitive for acute lesions involving only the mucosa; endoscopy is usually preferred for the diagnosis of upper gastrointestinal bleeding. Routine studies will reveal approximately two-thirds of chronic gastric ulcers and only a slightly smaller proportion of duodenal lesions (Fig. 24-13). With special techniques such as double contrast and compression, this sensitivity can be increased to 90 percent. Contrast radiography is not usually indicated in the evaluation of suspected acute perforations; a flat plate of the abdomen demonstrating free air is usually sufficient evidence to proceed with surgery, and the specific lesion can be identified at the time of operation. A contrast study will identify most advanced gastric neoplasms; it is an unreliable screening test for early lesions and usually must be followed by endoscopic biopsy.

Endoscopy

Over the past thirty years, improvements in endoscopic techniques for evaluation and treatment have revolutionized the management of lesions of the upper gastrointestinal tract. The gastroscope reveals even the most subtle mucosal lesions and permits biopsy procedures when diagnosis cannot be made on the basis of the endoscopic appearance alone. It is particularly useful in the evaluation of malignant ulcers; biopsy specimens are taken from multiple areas of the ulcer. It helps to rule out the presence of a second primary lesion. Seven or eight biopsy specimens should be taken, sampling both the crater base and the rim; additional specimens do not significantly improve the chances of identifying a malignant tumor. Cytology may increase the yield.

Endoscopic biopsy can also be used for the diagnosis of *H. pylori* infection, which appears to be a significant factor in peptic ulcer and gastritis. A combination of special stains (Giemsa or Warthin-Starry) to identify the organism histologically and assay for the presence of urease, which is produced by *H. pylori*, are typically used to establish the diagnosis in the biopsy specimen.

Endoscopy is particularly useful in the evaluation of upper gastrointestinal bleeding. The technique is safe and establishes the diagnosis in more than 90 percent of patients. Endoscopic therapy has been demonstrated with esophageal varices and peptic ulcer to reduce the incidence of rebleeding, decrease requirements for transfusion and operation, and in some instances, improve survival. A variety of effective techniques have been developed for endoscopic control of gastric and duodenal bleeding. These include thermal coagulation with the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, bipolar electrocautery, heater probe, and injection therapy with epinephrine or sclerosing agents.

Gastric Secretory Analysis

Gastric secretory analysis has traditionally been used to assess acid secretory capacity. A nasogastric tube is inserted and the patient is placed in a semirecumbent position on the left side. Basal acid output (BAO) and maximum acid output (MAO) are analyzed. Aspirations are then done by hand syringe every 5 min for 1 h. The aspirates are pooled in 15-min aliquots. At the end of the final aspirate, the stomach is stimulated to secrete by the intravenous administration of histalog in a dose of 2 mg/kg, or pentagastrin in a dose of 6 mg/kg. Aspiration is continued as described above, with four 15-min collections obtained over a 1-h period. The volume of the collections is measured, and an aliquot is titrated electrometrically to determine its content of H⁺. The rate of secretion is then expressed as the number of milliequivalents produced per hour during the basal or prestimulatory phase and during maximal and peak output. MAO is obtained by averaging the output of the two final 15-min periods. Peak output is the highest rate of secretion obtained during a 15-min period after stimulation. BAO is normally 2 to 3 mEq/h; secretory output (MAO) is in the range of 10 to 15 mEq/h. Patients with duodenal ulcer generally have higher values, and those with gastric ulcer may have lower values, but there is remarkable overlap between either condition and the normal range. Identifying patients with peptic ulcer disease using acid secretory data alone is usually not possible. For this reason most clinicians have found routine use of gastric analysis to be of little value in the workup of patients suspected of having gastric or duodenal ulcers. One beneficial situation of gastric analysis is its use as a screen for the *Zollinger-Ellison (ZE)* syndrome. In this illness, characterized by flagrant ulcer disease, BAO may be in excess of 50 mEq/h. Secretory studies may also be indicated in patients who develop recurrent ulceration after previous surgery for peptic ulcer, and may help to identify the patient who has had an incomplete vagotomy.

Gastric Emptying and Motility Studies

The saline load test has been used as a rough qualitative measure of gastric emptying; 750 mL saline solution is infused into the stomach and the nasogastric tube is clamped. At 30 min, the remaining fluid is aspirated. A residual volume of more than 400 mL suggests a significant delay in emptying.

Gastric emptying can be more precisely evaluated using gamma scintigraphy (Fig. 24-14). Liquids or solids can be labeled with technetium (^{99m}Tc) and abnormalities in the emptying of each assessed. These studies, sometimes combined with gastroduodenal manometry, are useful in the diagnosis and treatment of gastric motility disorders, e.g., postoperative atony and diabetic gastropathy.

ACID-PEPTIC DISEASE

Classification

Acid-peptic disease of the stomach and duodenum includes erosive gastritis and peptic ulcer. Each of these lesions is associated with an imbalance in the normal interplay between acid-pepsin and mucosal defense mechanisms. A complete discussion of acid-peptic disease should include the various disorders related to acid-pepsin secretion by the stomach. Although gastroesophageal reflux is such a disorder, it primarily affects the esophagus (see Chap. 23).

The distinction between gastritis and ulceration is an important one. In general terms, gastritis is inflammation confined to the mucosa of the stomach and can occur in acute and chronic forms. Chronic gastritis is important in its role in the pathogenesis of other disorders. Acute gastritis is a frequently encountered problem in the care of the critically ill. It occurs typically after major physical or thermal trauma, shock, sepsis, head injury, and ingestion of a variety of chemical agents, such as aspirin and alcohol. This lesion is generally classified under the generic term “stress erosion.”

True ulcers extend through the mucosa into the submucosa and muscularis mucosa (Fig. 24-15). Although this extension may occur occasionally in acute erosive gastritis, initiating massive hemorrhage from a large submucosal vessel, ulceration is usually chronic in nature. Chronic gastric and duodenal ulcers are distinguished by the presence of an established inflammatory reaction.

Peptic Ulcer

Peptic ulcer disease continues to affect between 3.5 to 7.5 million people annually in the United States, with an annual direct cost of almost \$4 billion, and even greater indirect costs from loss of work and diminished quality of life. There are approximately half a million new cases of duodenal ulcer and 90,000 of gastric ulcer diagnosed each year, and approximately 10 percent of the population is affected at some point in life. Compared with duodenal ulcer, gastric ulcer is a disease of the elderly; the average patient is 10 years older than patients with duodenal ulcers, and the incidence in those over 65 years of age, particularly women, is increasing.

Duodenal ulcer usually occurs in the proximal duodenum within 1 to 2 cm of the pylorus, the portion of the intestine first exposed to gastric secretion. Such ulcers have been associated with hypersecretion of acid, although this is not the case in all patients. Since acid is usually neutralized rapidly in the duodenum, ulcers occurring distal to the bulb are atypical, and an unusual cause, such as Zollinger-Ellison syndrome, must be suspected.

Three locations of gastric ulcer are recognized. Type I gastric ulcer, the most common, is located in the proximal antrum, but it may occur anywhere throughout the corpus and antrum. Its pathogenesis has been associated with a disturbance in mucosal defense. Although some acid is required for such ulcers, they are associated with hyposecretion. Type II gastric ulcer, which arises secondary to duodenal ulcer with pyloric stenosis, and Type III, the prepyloric and pyloric channel ulcer, develop in the setting of acid hypersecretion and are assumed to share a common etiology with duodenal ulcer.

Pathogenesis

The paradigm for peptic ulcer pathogenesis is an imbalance in the aggressive activity of acid and pepsin and the defensive mechanisms that resist mucosal digestion. Many different derangements have been identified, and it remains unclear which abnormalities are most important. It has become clear in the past decade that three different etiologies underlie virtually all ulcers: infection with *H. pylori*, use of nonsteroidal anti-inflammatory drugs (NSAIDs), and massive acid hypersecretion secondary to gastrinoma (the ZE syndrome).

Perhaps the most dramatic change regarding peptic ulcer has been the recognition of an association with *H. pylori*, leading many experts to conclude that ulcer is an infectious disease. *H. pylori*-induced gastritis is found in more than 95 percent of duodenal and 80 percent of gastric ulcer patients, in the absence of NSAIDs use or gastrinoma. Although the relationship between *H. pylori* and ulceration is difficult to prove, the most convincing evidence is that eradication of infection is associated with a near elimination of recurrence of peptic ulcer following treatment. The infection causes a number of physiologic abnormalities, each of which may be related to ulcer formation. *H. pylori* infection is associated with a decrease in the resistance of the mucus layer to acid permeation, a property referred to as its hydrophobicity. There is a strong link between infection and antritis or duodenitis, common denominators in patients with gastric and duodenal ulcer, respectively. Only a minority (10 percent over a lifetime) of people harboring *H. pylori* develop ulcers.

The association between NSAIDs and gastric ulcer has long been recognized; recent data have suggested an important role for NSAIDs in the pathogenesis of duodenal ulcer. The effect of NSAIDs in stress erosion is primarily topical; chronic ulcer seems to be most directly related to the systemic effects of these agents. Suppression of prostaglandin synthesis appears to be the common denominator. Prostaglandins inhibit acid secretion and have important roles in stimulating mucus and bicarbonate secretion and mucosal blood flow. The prevalence of peptic ulcers in chronic NSAID users is reported to range from 10 to 30 percent. Although most gastric ulcer patients have an element of chronic gastritis in association with their ulcer, studies of gastrectomy specimens reveal that habitual aspirin users may develop ulcers in otherwise normal mucosa.

Zollinger-Ellison syndrome is uncommon, occurring in 0.1 to 1.0 percent of all patients with peptic ulcer, but it is the best understood form of gastroduodenal mucosal injury. Ulceration results from massive hypersecretion of acid, which is stimulated by ectopic gastrin production from a nonbeta islet cell tumor, the gastrinoma. These tumors produce several forms of gastrin; the predominant form in the tumor is gastrin-17, whereas gastrin-34, with its longer half-life, is the major circulating form. Gastrinomas may be located in the pancreas but have also been identified in the duodenum. They are assumed to represent ectopic lesions. The cells are histologically distinct from those in the antrum that normally produce gastrin, and gastrin cells have not been identified in the normal pancreas. Accompanying islet cell hyperplasia has been recognized, although its significance is not yet clear. In about 20 percent of patients there is an association with the multiple endocrine neoplasia Type I (MEN I) syndrome, which includes, in addition to islet cell tumors, hyperparathyroidism and pituitary tumors. In this group, the disease has a genetic basis. At least 20 percent of gastrinomas are multiple, and more than two-thirds are malignant. They are very slow-growing, indolent tumors. The parietal cell mass is expanded enormously as a result of the trophic effects of gastrin and has been estimated to be at least three to six times as large as that in normal individuals.

Although *H. pylori* or NSAIDs probably play a role in most patients with chronic ulcer, not all patients with these risk factors develop disease. A variety of other abnormalities, specific to the individual and to the type of ulcer, may contribute to the development of peptic ulceration (Table 24-1).

Duodenal Ulcer

Patients with duodenal ulcer hypersecrete more acid, at rest and in response to stimulation, than do normal control subjects. There is considerable overlap, and there appears to be no direct relationship, between the degree of acid hypersecretion and the severity of the ulcer diathesis.

Multiple sources for this increase in acid secretion have been identified. Duodenal ulcer patients have more parietal cells, and chief cell numbers increase in parallel. Explanations have been provided for this increase in secretory mass. In some patients there is probably a genetic basis for the increase; in others it may be the result of an increase in the release of trophic factors such as gastrin. The hypergastrinemia associated with *H. pylori* infection may be significant in this regard. It may be that there is an increase not only in cell numbers but also in the capacity of the individual cell to secrete. There is an increase in basal secretion and in the response to exogenous stimuli. Some studies have demonstrated an increase in peak secretion with meals, and others demonstrate a more prolonged response.

In addition to these disorders in acid secretion, some duodenal ulcer patients have a motility abnormality. There is more rapid gastric emptying of meals, particularly liquids, and acid and food in the duodenum slow emptying to a lesser extent than in control subjects. As a result, the proximal duodenum is exposed to more acid.

Recent studies have clearly demonstrated a defect in duodenal acid disposal. Most patients with duodenal ulcer have a reduction in basal and peak duodenal bicarbonate secretion, paralleled by a loss of mucosal buffering capacity. This appears to be the most prevalent physiologic abnormality in duodenal ulcer. Defects in a variety of other duodenal defense mechanisms have been proposed. Impaired motility of the proximal duodenum, decreased production of prostaglandins, reduced mucosal blood flow, and defects in mucus or bicarbonate secretion have been hypothesized, but are difficult to demonstrate in humans. Chronic duodenitis, associated with *H. pylori*, may affect any of these parameters, setting the stage for ulceration.

Smoking is also associated with an increased incidence and impaired healing of duodenal ulcers. This may be a result of an associated decrease in prostaglandin synthesis, enhanced acid secretion, or reductions in duodenal and pancreatic bicarbonate secretion.

Although *H. pylori* and NSAIDs contribute to the pathogenesis of duodenal ulceration, a variety of other abnormal physiologic patterns have been described. These include hypersecretion of acid, rapid gastric emptying, and a defect in duodenal acid disposal or mucosal defense. The common denominator in most patients appears to be *H. pylori* infection. Recent evidence suggests that apart from NSAIDs-induced and some atypical ulcers, this disorder would not exist without *H. pylori*.

Gastric Ulcer

In contrast to duodenal ulcer patients, gastric ulcer patients secrete in a range from normal to barely detectable. Cases have been reported with no detectable acid secretion or achlorhydria, but it is believed that at least some acid-pepsin is required for ulceration, and it is clear that the defect in these patients must include a significant disorder of defense.

It has been suggested that the most basic abnormality in gastric ulcer is reflux of duodenal contents (biliary and pancreatic secretions) into the stomach, resulting in gastritis and eventual ulceration. This appears to be the result of pyloric sphincter dysfunction. Normally the pylorus has a low resting pressure that increases in response to acid, fat, amino acids, and cholecystokinin from the duodenum. In some gastric ulcer patients, low basal pressures have been documented, and in others pressure increases in response to duodenal infusion of acid or fat are significantly less than those of control subjects. Cigarette smoking, which has been linked to the initiation and delayed healing of gastric ulcer, also increases duodenogastric reflux.

The physiologic link between reflux and gastric ulceration has not been clearly established. Bile acids (particularly deoxycholate and taurocholate), lysolecithin, and pancreatic secretions are the agents in duodenal contents speculated to have the most negative effects. It is believed that they damage the mucosa topically, disturbing the surface mucus layer and somehow producing a low-grade gastritis. Aspirin seems to have similar effects. Chronic gastritis is the widely assumed intermediary step between repeated injury to the gastric mucosal barrier by reflux of duodenal contents and development of gastric ulceration. This concept of gastritis producing ulceration is unproved, and chronic atrophic gastritis is very common in the elderly, found in approximately 40 percent of persons over 50 years of age. Although chronic ulcer is usually associated with gastritis, the primary event has not been established clearly. Gastritis may be limited to the area around the ulcer, but it usually persists after ulcer healing. The extension of the usual antral pattern of gastritis into the fundus helps to explain the generally low rates of acid secretion in gastric ulcer patients. Some increase in basal hydrogen ion back-diffusion may play a role. Gastrin cells are apparently spared the gastritis because, in response to the reduced acidity, fasting serum gastrin levels are usually slightly elevated and may double the normal increase after a meal.

Gastric ulcer seems to result from a defect in gastric mucosal defense against digestion by acid-pepsin. Hypersecretion cannot be incriminated in its pathogenesis. There is evolving evidence that pyloric dysfunction, acting as a result of duodenogastric reflux, allows endogenous agents to exert injurious effects on the mucosa. These agents, in combination with acid-pepsin, produce ulceration in areas of reduced mucosal resistance. NSAIDs and *H. pylori* infection predispose to this reduction.

Clinical Manifestations and Diagnosis

Classically, duodenal ulcer pain is relieved by food or alkali and usually develops several hours after a meal when food has passed the duodenum and the crater is exposed to unbuffered gastric secretions. In contrast, gastric ulcer is associated with a gnawing or burning epigastric pain brought on by or closely following the secretory stimulus of eating. Symptoms in these two disorders are very nonspecific, and even the correlation of pain with the actual presence of peptic ulceration is a poor one. Although intractable pain has generally been considered an indication for surgery in peptic ulcer, because of its nonspecific nature, such pain is difficult to define. The actual physiology of ulcer pain is not understood, although two explanations have been proposed. Acidic luminal contents may irritate afferent nerves within the ulcer crater itself or, alternatively, peristaltic waves passing through the ulcer might produce discomfort. The relative importance of these two possibilities has not been determined. Pain symptoms in gastric and duodenal ulcer usually is chronic and recurrent. Although these ulcers cannot be differentiated on the basis of clinical findings, the fact that the mean age of gastric ulcer patients is approximately 10 years older than that of patients with duodenal lesions might help in the differentiation. Gastric ulcers have a peak incidence from the ages of 50 to 65 years, whereas most duodenal ulcers develop in the fourth decade of life. Other common symptoms include nausea and weight loss, even in the absence of pyloric obstruction, and mild epigastric tenderness.

In the patient with pain, diagnosis is usually fairly straightforward. Routine laboratory studies add little to the diagnostic workup. Because of the overlap in secretory rates between ulcer patients and control subjects, and because secretory studies have not been found to be useful in selecting therapy, they usually are not indicated. The two mainstays of diagnosis are upper gastrointestinal radiography and endoscopy. The decision of when to study a patient with dyspepsia or epigastric pain is a complex issue requiring consideration of the character, severity, and duration of symptoms. In the young patient, it may be more cost-effective to initiate a course of medical therapy and determine whether the symptoms resolve; the risk of malignant tumor precludes such an approach in the elderly.

The choice between radiography and endoscopy is not a simple one. With optimal double-contrast studies, more than 90 percent of gastric and duodenal ulcer craters will be detected, a sensitivity rate comparable to that achieved with endoscopy. Endoscopy is indicated in the case of a poor-quality x-ray study. The question of malignancy in gastric ulcer complicates the decision. Because 3 to 7 percent of gastric malignancies appear benign on x-ray study, endoscopy and biopsy procedures in all cases has been recommended. A variety of tests for *H. pylori* are now available. Biopsies can be examined histologically or by urease assay. Alternatively, a noninvasive breath test may be performed. With an endoscopically or radiographically proved duodenal ulcer, testing is often eliminated in favor of empiric treatment because the probability of a positive test for *H. pylori* exceeds 90 percent.

Complications

Peptic ulcer may produce one of three main complications: hemorrhage, perforation, or obstruction. These can develop without any premonitory symptoms but typically appear as an abrupt change from preexisting dyspepsia. All complications result from the extension of ulceration and the accompanying inflammation deeper into the wall of the gastroduodenum.

When the crater extends into a major vessel, significant hemorrhage can result. Fifteen to twenty percent of patients with peptic ulcer at some point develop gross bleeding; occult blood loss is even more common. Emergent bleeding requiring operation is often the result of posterior erosion of a duodenal ulcer into the gastroduodenal artery. Bleeding gastric ulcers present with hematemesis or melena in roughly equal proportion, whereas duodenal ulcers tend to produce melena alone. Widely disparate symptoms may stem from the resultant hypovolemia; patients have presented with transient ischemic attacks, myocardial infarction, and intestinal ischemia. Diagnostic maneuvers can be performed at the time the patient is being stabilized. The diagnosis of upper gastrointestinal hemorrhage is confirmed by passage of a nasogastric tube. Bleeding peptic ulcer accounts for only one-third of massive upper gastrointestinal bleeds; endoscopy is therefore indicated to identify the nature and site of the lesion.

When the ulcer erodes through the full thickness of the gastroduodenum, it may produce a perforation or penetrate into adjacent structures. This occurs in 5 to 10 percent of patients with peptic ulcer. With perforation, the spilled gastric juice incites both peritonitis and consequent catastrophic abdominal pain, marked tenderness, and paralytic ileus. This peritoneal irritation also is responsible for the accompanying leukocytosis and hypovolemia secondary to fluid sequestration. Pneumoperitoneum is present in 75 percent of patients. Upright films of the chest and abdomen reveal free air beneath the diaphragm (Fig. 24-16). If a perforation seals quickly, patients may seek medical attention only after a localized intraabdominal abscess develops. If the perforation is diverted by the falciform ligament into the right colic gutter, it may infrequently be confused with appendicitis. Penetration into the biliary tract or colon can produce a fistula.

Gastric outlet obstruction develops, usually in the context of chronic ulcer disease, when secondary edema or scarring occludes the lumen. Obstruction develops in less than 5 percent of patients, usually with duodenal ulcer, but occasionally with gastric ulcer. Onset is insidious, but patients present with nausea, vomiting, and abdominal distention. Vomiting of hydrochloric acid may produce severe dehydration and a metabolic alkalosis. This is perpetuated by a paradoxical aciduria as the kidneys retain bicarbonate with sodium to maintain pH in the absence of the hydrochloric acid lost in the vomitus. The diagnosis can be documented with barium x-ray, the saline load test, or sequential scintigraphy with technetium-labeled liquids or solids. Endoscopy can differentiate atony from true obstruction when the diagnosis is in question.

Zollinger-Ellison Syndrome

In patients with gastrinoma, symptoms tend to be more severe, unrelenting, and less responsive to therapy than those of usual ulcers. Although most ulcers are located in the proximal duodenum, gastric and more distal ulceration also occurs. Lesions are usually single and small, but multiple and giant ulcers have been described with greater frequency than in common duodenal ulcer. Diarrhea is also a frequent symptom and may occur in the absence of gross ulceration. This is a consequence of large quantities of hydrochloric acid entering the small bowel. There are frequently morphologic abnormalities throughout the small bowel, with stunted villi and mucosal inflammatory infiltrates. Steatorrhea may also be present, and probably results because the low pH inactivates pancreatic lipase, impairing hydrolysis of dietary fats. In addition, bile salts are precipitated at low pH, reducing the formation of the micelles required for lipid absorption. A low pH also appears to interfere with vitamin B₁₂ absorption, although intrinsic factor secretion by the stomach is normal.

The diagnosis of gastrinoma has been increasingly refined. A diagnostic search for ZE syndrome is warranted in patients with multiple, giant, or distal ulcers, ulcer disease refractory to the usual medical therapy, and recurrences after adequate surgery for peptic ulcer. Diagnostic techniques include acid secretory studies and contrast radiography. These patients have elevated acid secretion, and basal acid output is usually greater than 60 percent of maximal. There is considerable overlap with normal control subjects and patients with duodenal ulcer. Upper gastrointestinal x-ray films may reveal ulceration, prominent rugal folds indicating hypertrophy, dilated small intestine, and even the occasional tumor in the duodenum. Determination of basal serum gastrin levels by radioimmunoassay can be diagnostic, but elevations may also be detected in several other pathologic conditions.

In pernicious anemia, which is an atrophic and inflammatory gastric process that reduces the number of parietal cells but typically spares the antrum, hypergastrinemia results from both an increase in the number of gastrin cells and a loss of the normal acid feedback inhibition of secretion. Patients with renal insufficiency also develop elevated serum gastrin, although the mechanism has not yet been defined and gastrin clearance is normal even in anephric patients. Antral gastrin-cell hyperplasia or hyperfunction occurs in a small proportion of patients with duodenal ulcer. These patients have hypergastrinemia and hypersecretion, although an actual increase in the number of gastrin cells has not been documented.

Three provocative tests have improved the specificity of biochemical diagnosis. In the secretin test, 2 U/kg of secretin is given intravenously over 30 seconds, and serum gastrin is measured 5 min before, immediately before, and at 5-min intervals for one-half hour after injection. In normal patients and in patients with duodenal ulcer, secretin has no significant effect, but in patients with ZE syndrome there is a dramatic increase in serum gastrin levels. The mechanism for this is unknown, although it has been suggested that secretin may release gastrin by a direct local effect on blood flow to the tumor. In the calcium infusion test, calcium gluconate is given intravenously at a rate of 5 mg/kg for a 3-h period, and serum gastrin levels are determined 30 min before and at half-hour intervals for 4 h. In ZE patients, there is more than a 400 pg/mL increase, possibly through release of peptide hormone through the calmodulin system, and much smaller increases occur in patients with duodenal ulcer and other conditions. A combination test using both secretin and calcium is even more sensitive. A third provocative test, the use of a standard meal, produces little change from basal levels in gastrinoma patients when compared with the marked increase produced in control subjects or in patients with gastrin-cell hyperplasia. Gastrin secretion by the gastrinoma is independent of normal control mechanisms.

Computerized tomographic scanning and angiography are useful, though not in the diagnosis of gastrinoma but in preoperative tumor localization. In some cases venous sampling has provided additional information for localization, although most surgeons will explore a patient without recourse to such invasive diagnostic methods.

Treatment

Consistent with the general concept of a disturbance in the interplay between acid secretion and mucosal defense underlying peptic ulcer, the medical and surgical therapies represent attempts to restore a balance. Most treatments have approached this task by methods designed to reduce acid secretion, and some have been devised to improve mucosal resistance.

Medical Therapy

In the past, a variety of measures, generally unrelated to the pathophysiology of these lesions, were adapted empirically as part of the treatment regimen. Dietary therapy with frequent feeding of bland foods, has not been shown to be particularly effective and has little if any effect on gastric acid secretion. Milk, another home remedy, is actually a strong secretory stimulus. Hospitalization for peptic ulcer was believed to improve healing, although recent evidence suggests that there is little added benefit. Cigarette smoking has clearly been shown to retard ulcer healing and should be avoided. Aspirin and NSAIDs have a detrimental effect on mucosal resistance and should not be prescribed. Coffee strongly stimulates acid secretion, and alcohol may damage the mucosa; moderation in consumption should be suggested.

Pharmacologic therapy restores the balance of secretion by three general mechanisms: neutralization of gastric secretion, inhibition of secretion, and protection of the gastric mucosa from further injury. Table 24-2 summarizes the classes of drugs available. A combination of drugs acting by different mechanisms may have more than an additive effect in improving ulcer healing.

Antacids are the oldest drugs used. They reduce gastric acidity by reacting with hydrochloric acid to form a salt and water, inhibit peptic activity through the increase in pH, and bind bile acids, which may have a special role in the treatment of gastritis and gastric ulcer. Antacids differ greatly in their buffering strength, absorption, taste, and side effects. Magnesium antacids tend to be the best buffers but cause significant diarrhea by a cathartic action. Aluminum antacids precipitate with phosphorus, resulting in occasional hypophosphatemia and, in addition, may produce significant constipation. Calcium compounds can cause a delayed acid secretory rebound, believed to result largely from the effect of absorbed calcium ion. For each equivalent of hydrochloric acid neutralized, bicarbonate is released in the tissue, and all these drugs may produce a systemic alkalosis. Normal renal function usually prevents this from becoming significant. Antacids are best taken an hour after meals because food tends to prolong gastric emptying. Many patients have found large, frequent doses (30 mL of liquid antacid four to seven times daily) to be unacceptable.

The H₂-receptor antagonists are a group of agents that have revolutionized the treatment of peptic ulcer by directly reducing acid secretion. There are two types of gastric histamine receptors: H₁ receptors, located on smooth muscle cells, and H₂ receptors, located on the parietal cells; it is the latter that this class of drugs was devised to block. Because of the

independent but mutually augmenting parietal cell receptors for histamine, acetylcholine, and gastrin, inhibition of the histamine receptor alone also reduces the effects of acetylcholine and gastrin. These drugs all consist of a five-member organic ring and a side chain similar to histamine itself. Cimetidine was the first widely used H₂-receptor antagonist. Alteration of the ring or side chain has produced agents of increasing antagonistic potency and more specific gastric action. The physiologic effects include a decrease in both basal and stimulated acid secretion by what is believed to be competitive inhibition at the parietal cell level. Pepsin output is also reduced. The decrease in antral acidity elevates serum gastrin levels. These agents also reduce gastric blood flow, a finding that could explain the observation that they may be less effective than antacids in preventing stress erosions. Cimetidine is a potent inhibitor of acid secretion with a half-life of approximately 2 h, requiring a dosage schedule of four tablets per day. Patient compliance is much better with cimetidine than with antacids, but a number of significant side effects, including azoospermia, gynecomastia, and a reversible central nervous system toxicity, have been described. Ranitidine and famotidine, longer acting agents, appear to be less likely to cause some of the side effects of cimetidine.

Anticholinergic agents act to inhibit the action of acetylcholine at muscarinic receptors. In the stomach they act directly at the parietal cell level. Atropine and propantheline bromide are anticholinergic agents that, at equal doses, are even more potent than H₂-receptor antagonists. Side effects, including urinary retention, blurred vision, dry mouth, delayed gastric emptying, and mental disturbances, restrict use of these agents except at lower, less effective doses. Pirenzepine, a selective M1 anticholinergic, inhibits secretion with minimal side effects.

An even more potent class of secretory inhibitors is the substituted benzimidazoles, which selectively inhibit parietal cell H⁺/K⁺-ATPase, the enzyme responsible for acid secretion. Omeprazole is a highly potent agent that is effective even in patients with refractory ulcers and gastrinoma. It is a weak base and accumulates selectively within the acidic environment of parietal cell. Long-term side effects may become evident, but at present this drug represents the most effective secretory inhibitor.

Several different agents are effective by improving gastric mucosal resistance. The prostaglandins are naturally occurring fatty acids that prevent or heal mucosal injury by several mechanisms. The methylated E2 analogs are absorbed orally and significantly inhibit gastric acid secretion; at doses required for this effect, they also produce dramatic diarrhea. At smaller doses they still exert what has been called a "cytoprotective" action, probably by increasing mucosal blood flow and bicarbonate and mucus secretion. Misoprostol, the most widely used analog, appears to be comparable to H₂-receptor antagonists in the healing of duodenal ulcers.

Sucralfate is related structurally to heparin, although it has no anticoagulant effects. Sucralfate's unique mechanism of action has proved effective in the treatment of established ulcer disease, and it is the only agent currently in widespread clinical use that acts by enhancing resistance. It is an aluminum salt of sulfated sucrose that dissociates under the acidic conditions in the stomach. The sucrose polymerizes and binds to proteins in the ulcer crater, producing a kind of protective coating that lasts up to 6 h. It inhibits peptic activity and appears to bind and concentrate endogenous basic fibroblast growth factor, stabilizing and concentrating this substance, which is important in mucosal healing. The liberated aluminum hydroxide may have some slight additional antacid effect; little of this is absorbed, and side effects are minimal.

Colloidal bismuth coats exposed protein and has been shown to protect against acute mucosal lesions in a variety of experimental models. An antipeptic activity has been postulated to explain its effectiveness. It also has activity against *H. pylori*, although complete eradication typically employs combined therapy.

For eradication of *H. pylori*, two different regimens are used: bismuth- based triple therapy and proton pump inhibitor—based antibiotic therapy. In the former, bismuth is combined with tetracycline and metronidazole; it is highly effective and inexpensive. Alternatively, a proton pump inhibitor, such as omeprazole, is combined with two of the three following antibiotics: clarithromycin, amoxicillin, and metronidazole.

Surgical Therapy

Several operations have been devised for the treatment of acid-peptic disease. Some of these procedures have been commonly used in the elective setting when operation is performed for recurrent disease and intractable pain. The recognition that *H. pylori* plays a role in many of these patients, and that eradication of the infection prevents recurrence in more than 90 percent of patients, has almost eliminated the need for elective surgical procedures. Occasionally elective operation will be required for the noncompliant patient or for the patient who requires NSAIDs for control of other conditions. Nonhealing of a gastric ulcer also may be an indication for elective operation. For the most part, surgery for peptic ulcer is now performed for complications in an emergent or semi-urgent setting.

Treatment for Specific Entities

Duodenal Ulcer

Many patients are able to self-medicate their disease with nonprescription medication, never seeking formal medical therapy. Of those who seek professional treatment, more than 95 percent will have their disease controlled by pharmacologic therapy designed to reduce acid secretion. Antacids are extremely effective, but their inconvenience has made the H₂-blockers the drugs of choice. Combination therapy usually is only necessary in refractory patients; antacids or cimetidine alone will heal all but about 25 percent of duodenal ulcers within 4 weeks. Sucralfate is as effective as cimetidine. Colloidal bismuth, in a few clinical trials, also appears to equal the H₂-receptor antagonists. There is debate as to whether an actual ulcer crater need be documented by x-ray film or endoscopy before starting therapy; it has been suggested that the symptoms and potential complications should be the most important factors in determining treatment. Many ulcers heal, and most symptoms disappear with placebo. Though pharmacologic treatment is more expensive, the more rapid response and greater probability of healing justify the use of antiulcer medication. Patients should be advised to stop smoking and to avoid NSAIDs if possible.

None of these regimens affects the natural progression of the disease process itself. When therapy stops, ulcers will recur within 6 months in about 80 percent of patients. Continuation of cimetidine at lower doses, perhaps only once daily, after healing has been shown to reduce significantly the risk of recurrence, and prior to the recognition of the role of *H. pylori* in this disorder, some patients were maintained on such therapy. Treatment of *H. pylori* with either the bismuth-based or proton pump inhibitor regimen prevents recurrence in more than 95 percent of cases, and reinfection is unusual. There is some controversy about whether every duodenal ulcer patient should be treated with antibiotics; most clinicians now base therapy on the results of testing for the organism, but it may be judged more cost effective to treat empirically in the future.

Classically the four indications for surgery include: intractability, complications of hemorrhage, perforation, and obstruction. Elective operation for intractability has become an increasingly rare occurrence. The choice of an operative procedure, and its ultimate results, depends critically on the indication for surgery and the specific pathophysiology of the indicating condition. In the treatment of intractable pain, surgery is elective, the patient is adequately prepared for the procedure, time is not a crucial factor, and there is little justification for exposing the patient to the potential for severe early or late postoperative complications. Under these circumstances, highly selective cell vagotomy is clearly the procedure of choice. The lumen of the gastrointestinal tract is not entered, reducing the risk of septic complications. Because the normal functional anatomy of the stomach and pylorus are preserved and distal vagal innervation is not interrupted, the potential for the serious long-term side effects of dumping and diarrhea is greatly reduced. Some have argued that this is now the only definitive operation that should be performed under any circumstances.

Hemorrhage is the principal cause of death from duodenal ulcer. These patients are sometimes critically ill and often have significant associated medical problems delaying the decision to operate, although most studies indicate that early operation is the only way to reduce mortality and morbidity. Upper endoscopy should be performed early to establish the diagnosis and initiate therapy. Once bleeding has stopped, H₂blockers reduce the rebleeding rate. Indications for operation include continued bleeding of more than 6 units and recurrent bleeding after the hemorrhage has been controlled endoscopically. At operation, the initial maneuver should be to attend directly to the bleeding lesion through a pyloroduodenotomy. Most surgeons would then perform some form of definitive ulcer operation, although there is some evidence now that, with appropriate medical therapy, there is no need for such a procedure. In the past vagotomy and antrectomy were performed in patients with a good risk profile. This is probably not indicated today because of the long-term side effects and the lower recurrence rates after treatment of *H. pylori*. Highly selective vagotomy should be performed after closure of the pyloroduodenotomy, if the patient can tolerate the longer operating time. In the higher-risk patient, vagotomy and pyloroplasty can be performed quickly and simply.

Formerly, perforation was treated by simple closure, usually reinforced with omentum (the Graham patch). This is a rapid, effective treatment and is still recommended for patients with preoperative shock, perforation exceeding 48 h, and significant coexistent medical problems. Before development of therapy for *H. pylori*, 80 percent of those treated with simple closure developed a recurrence, and one-third required another operation. With proper patient selection, definitive treatment can be performed, and vagotomy, pyloroplasty, and parietal cell vagotomy have been used. The latter seems to be receiving greater support, although there may be a trend back toward patching alone because of the development of effective medical therapy to prevent recurrence.

Treatment for obstruction is designed to relieve the blockage. Highly selective vagotomy and dilatation of the pylorus have been used. Although there has been some hesitation in using vagotomy in the presence of already disturbed motility patterns, it should probably be included in the definitive operation. Vagotomy with antrectomy, resecting the scarred pylorus, is the procedure of choice, although vagotomy with gastroenterostomy is preferred by some surgeons.

Gastric Ulcer

Trials of medical therapy for chronic gastric ulcer have not been as successful as those for duodenal ulcer. Several conclusive clinical studies have shown cimetidine to be significantly more effective than placebo in healing gastric ulcers, although other investigators were unable to replicate this finding. Two considerations are important in evaluating the therapy for chronic ulcer: healing and pain relief. There is evidence of better pain relief with cimetidine in most studies of gastric ulcer; antacids have not been shown to be effective, but the physiologic reasons for this difference are still unclear. The anticholinergics also have not proved particularly useful in chronic gastric ulcer. Sucralfate appears to speed healing, but in one study it was found to be less effective than cimetidine. Omeprazole appears to be equally efficacious. Current recommendations suggest that these patients be started on an H₂ blocker. If *H. pylori* is involved, triple therapy is also instituted. If pain relief has not been achieved after 2 weeks, a second medication should be added. At 8 weeks, follow-up x-ray films or endoscopy should be performed. If the ulcer is not completely healed, these studies should be repeated again at 12 and 15 weeks. Patients whose ulcers have not healed by this time should be offered surgery.

Gastric ulcer has been treated with surgery somewhat earlier than duodenal ulcer. There are several reasons for this approach. One is the fear of malignancy in ulcers that appear benign. Improvements in the endoscopic diagnosis of cancer have reduced this risk. Most data indicate that gastric ulcer patients are more often hospitalized for their illness than duodenal ulcer patients, and their complications more often require operation, suggesting that gastric ulcer is a more virulent disease. The older gastric ulcer patient has a distinctly higher mortality for a complication of the ulcer than the corresponding younger patient with a duodenal lesion. Surgery is generally recommended for the recurrent ulcer refractory to medical therapy, the ulcer that recurs during treatment with cimetidine, the ulcer that fails to heal within 12 to 15 weeks, or one of the complications of ulcer disease.

Prepyloric ulcers or those in association with duodenal ulcers share a common cause with duodenal lesions and should be treated as such. Parietal cell vagotomy for such lesions is associated with high recurrence rates, although some surgeons believe that even if it is combined with antisecretory medication, this is preferable to a major resection. It is unnecessary to remove a large amount of stomach for elective treatment of gastric lesions. For the usual Type I gastric ulcer, distal gastric resection to remove the ulcer with or without vagotomy has proved effective. The ulcer itself should be excised completely and submitted for pathologic analysis. Because gastric ulcer does not primarily result from a secretory disturbance, the use of vagotomy has been questioned. For proximal gastric ulcers, in the fundus or the corpus, total gastrectomy is often used because proximal gastrectomy is invariably associated with emptying problems. The specific operations for complications of gastric ulcer are similar in rationale to those performed for duodenal ulcer.

Zollinger-Ellison Syndrome

Treatment of gastrinoma continues to evolve. In the past, recognition that these tumors were frequently multicentric and metastatic, though slow- growing, led to the use of the only operation believed to reduce acid secretion reliably and consistently: the total gastrectomy. With the advent of cimetidine, most clinicians adopted pharmacologic therapy in preference to such a major procedure with its considerable accompanying morbidity and mortality. This trend was strengthened with the development of even more effective omeprazole therapy. Recently there has been a move back to surgery for several reasons. First, using a combination of intraoperative endoscopy and ultrasonography to visualize duodenal lesions, and thorough exploration of the head of the pancreas and hepatoduodenal ligament to localize others, much higher success rates have been reported for resection. In addition, compliance problems have raised some doubts about the desirability of continuing medical therapy. Most patients without evidence of liver metastases should be explored. Because of the low grade of this malignancy, even if it is unresectable, if acid secretion is effectively inhibited medically, long-term survival is possible. Little other effective treatment, e.g., radiotherapy or chemotherapy, is available.

Acute Gastritis

Improvements in resuscitation and care of the critically ill patient, along with prophylactic measures directed specifically at reducing gastric injury, have considerably reduced the incidence and severity of acute erosive gastritis. Stress erosions are usually multiple, small, punctate lesions situated in the proximal acid- secreting portion of the stomach, although they may extend into the antrum and even the duodenum. They occur in three clinical settings, two of which are associated with a reduction in the ability of the gastric mucosa to protect itself against injury. The first is that of patients with severe illness, trauma, burns, or sepsis, virtually all of whom develop these lesions, although they achieve clinical significance only in the small percentage of lesions that extend into larger submucosal vessels, producing life- threatening hemorrhage. In the setting of thermal injury, acute erosions have been referred to as Curling's ulcers, although no real difference exists. Patients in this critically ill group have multiple reasons for a depression of normal defense mechanisms, although mucosal ischemia seems to be a predominant factor. The second setting for acute erosions is in the context of drug and chemical ingestion. Aspirin, a variety of other NSAIDs, and alcohol may produce an acute erosive gastritis. These agents directly alter gastric mucosal resistance, allowing back-diffusion of acid and further damage. The third underlying condition, central nervous system trauma, is not clearly related to a defect in mucosal defense. These patients have elevated levels of serum gastrin and, most likely, a secondary increase in acid secretion. This lesion, Cushing's ulcer, is characteristically deeper than other acute erosions and more frequently perforates.

Pathogenesis

Several different illnesses appear to predispose to the development of acute erosive gastritis. Most of these reduce the ability of the stomach to protect itself against acute injury rather than increasing the amount of acid secretion. Experimental evidence suggests that in the critically ill patient with hemorrhagic shock and sepsis there may actually be a reduction in acid secretion. In general, Schwarz's "no acid, no ulcer" dictum remains valid, and complete neutralization of gastric acidity prevents the development of these lesions.

Given that the presence of luminal acid is a necessary but not sufficient prerequisite for the development of stress lesions, it seems reasonable to postulate that there might be a decreased mucosal resistance to this acid. The gastric mucosa possesses a unique resistance to luminal acid and pepsin; virtually any other region of the gastrointestinal tract ulcerates rapidly when exposed to gastric juices. Davenport suggested that there was normally a gastric mucosal barrier to the back-diffusion of acid into the tissue. He noted that substances such as aspirin, bile salts, and alcohol reduced this normal resistance, allowing the backward flux of hydrogen ions that might produce histamine release, vasodilatation, and eventual bleeding (Fig. 24-17). This concept of a barrier has been supported by a number of subsequent experimental studies with chemically induced erosions. Other models for stress lesions suggest that barrier disruption may not be an essential component of the pathologic process in all types of injury; hemorrhagic shock and endotoxemia, for example, can produce lesions without overt evidence of a back-diffusion. Even in these instances, diffusion of a smaller magnitude probably occurs. In severely traumatized or septic patients, endogenous bile salts may chemically disrupt the barrier. Clinical observations suggest that reflux of bile from duodenum to stomach is more common in critically ill patients, probably as a result of the loss of normal intestinal motility. The combination of acid, bile salts, and mucosal ischemia is remarkably ulcerogenic.

Mucosal ischemia is a critical pathogenic factor. Many of these patients have experienced an episode of shock from hemorrhage, sepsis, or cardiac dysfunction, and decreased mucosal blood flow is a common denominator in many experimental models of stress erosion. The exact role of blood flow in maintaining mucosal defense remains uncertain. The leading hypothesis is that it somehow functions to dispose of or to buffer acid entering the tissue. Ischemia reduces this capacity, lowering intramucosal pH. It may also reduce mucosal resistance by producing a deficit in mucosal adenosine triphosphate and other high-energy phosphate intermediates.

Systemic and gastric acid-base balance are also significant. Acidosis has been shown to reduce the ability of the gastric mucosa to protect itself against injury in animal studies. The secretory status of the mucosa may be a critical factor. With acid secretion, bicarbonate is released into the tissue and blood (the "alkaline tide"), and this appears to play a role in buffering back- diffusing acid. In animal studies, the actively secreting stomach is more resistant to luminal acid than it is under conditions of secretory inhibition.

A variety of other mechanisms are important to mucosal defense and may somehow be impaired in patients who develop stress ulcers. It has been demonstrated that the mucus layer over surface epithelial cells may serve as a layer in which actively secreted bicarbonate neutralizes luminal acid before it can reach and damage the cells. There is some evidence that the maintenance of this pH gradient is altered in these patients. A reduction in the rate of epithelial renewal, or restitution, may also be a factor. Prostaglandins exert a protective effect in the gastric mucosa, and the inhibition of their production by aspirin and other NSAIDs may be a primary mechanism for gastric injury. Prostaglandins in high doses inhibit acid secretion, but even at lower concentrations they seem to exert a "cytoprotective" effect. They increase mucosal blood flow, but they also enhance bicarbonate and mucus secretion.

The recognition of these pathogenic mechanisms has provided a rationale for the successful prevention of stress erosions in critically ill patients. The prerequisite of acid secretion provides a basis for the regular use of antacid or H₂-receptor blockade, the efficacy of which has been demonstrated in a number of clinical trials. The correction of abnormalities in cardiac output and intravascular volume and the treatment of any septic focus may be critical in the prevention of mucosal ischemia. Adequate nutritional therapy is suggested by the concept of a mucosal energy deficit; the correction of systemic acid-base balance may play a role.

Clinical Manifestations and Diagnosis

The predominant clinical manifestation of erosive gastritis is gastrointestinal bleeding. Prodromal signs, such as abdominal pain, are infrequent. Although erosion formation can often be demonstrated within 24 h of the acute insult, massive bleeding usually occurs after 7 to 10 days when the superficial erosion extends into the larger submucosal vessels. Only rarely do these lesions perforate.

If a high index of suspicion is maintained in conditions that predispose to this illness, diagnosis is fairly straightforward. Routine upper gastrointestinal series are of little value: the critical condition of these patients often precludes a good-quality study, and the erosions are usually too superficial to visualize. Upper endoscopy is the procedure of choice and is diagnostic in more than 90 percent of patients. If the diagnosis remains in doubt, radionuclide scanning and visceral angiography may prove useful.

These patients are usually critically ill, and it is essential to stabilize and correct any predisposing conditions at the same time that diagnostic maneuvers are being performed. Hypovolemia and coagulopathy should be identified and treated as early as possible. Nasogastric intubation, preferably with a large-lumen Ewald tube, decompresses the stomach, eliminating the stimulating effects of distention and blood on acid secretion. In addition, it provides information about the rate of bleeding, clears the stomach for endoscopy, and allows saline lavage, which alone will control the bleeding in more than 80 percent of patients. Although suggested by some, the efficacy of lavage with iced solutions and levaterenol for their vasoconstrictor effects has not been demonstrated. Once the diagnosis is established, additional steps in medical and possibly surgical management should be initiated.

Treatment

If gastric evacuation and lavage are successful in halting the bleeding, antacid administration is useful in preventing the development of further hemorrhage. The pH of gastric contents should be checked regularly, probably every hour, and magnesium or aluminum antacids that are insoluble and remain in the stomach for prolonged periods should be instilled to keep the pH above 5. There is some evidence that antacids may be superior to H₂ blockers in the prevention of bleeding in critically ill patients. Omeprazole, the H⁺/K⁺-ATPase inhibitor, is as effective as antacids. Sucralfate, which binds to the ulcer bed and promotes healing, may also be utilized. The use of sucralfate has been associated with a decrease in pulmonary infections, presumably resulting from aspiration of gastric contents that become colonized when acid is neutralized with the antisecretory agents.

Intraarterial infusion of vasopressin controls hemorrhage in approximately 80 percent of patients. Any of the variety of endoscopic techniques for controlling upper gastrointestinal hemorrhage may also prove useful. Surgery should be considered when the bleeding exceeds 6 to 8 units over 48 h, but the underlying condition of the patient should enter into this decision. Mortality for surgery in this group of patients is in the range of 40 percent, and there is much controversy over the type of operation that offers the highest probability of success. No prospective trial has been performed, but some surgeons have advocated near-total gastrectomy in preference to the lesser procedures of vagotomy and pyloroplasty, with oversewing of the bleeding erosions, or partial gastrectomy with vagotomy. Generally, if the lesser procedures are successful, they are associated with a reduced morbidity and mortality but a greater incidence of rebleeding. Vagotomy is effective by reducing acid secretion and perhaps also by acutely decreasing mucosal blood flow. Oversewing a few bleeding erosions is often effective because, although there is usually a diffuse gastritis, only a few lesions have progressed into the deeper submucosal vessels, and it is these lesions that are responsible for the significant hemorrhage. Satisfactory results have been obtained with the use of vagotomy and pyloroplasty with oversewing of bleeding erosions as the initial procedure, reserving total resection for those who rebleed.

GASTRIC NEOPLASMS

Malignant Tumors

Gastric Cancer

Benign tumors of the stomach are rare. Over 90 percent of gastric tumors are malignant, and gastric adenocarcinoma (commonly referred to as gastric cancer) comprises 95 percent of the total number of gastric malignancies. Lymphoma (4 percent), leiomyosarcoma (1 percent), and other rare entities, e.g., squamous cell carcinoma, angiosarcoma, carcinosarcoma, and metastasis from adjacent or distant primary sites, constitute the balance.

Epidemiology

Gastric cancer is a biologically aggressive tumor that is often incurable when discovered in its symptomatic phase. Gastric cancer occurs worldwide, but its frequency varies greatly, and few cancers show as wide a variation in incidence as gastric cancer. The disease is rarely encountered in the United States. Malaysia, Chile, Iceland, and Japan have the highest incidence worldwide. The incidence of gastric cancer in Japan is greater than in the United States by a factor of eight and is the leading cause of cancer- related death in Japan.

In 1996 there were an estimated 22,000 new cases of gastric cancer in the United States and 14,000 deaths from the disease. The United States has experienced a rapid decline in gastric cancer-related deaths, from a rate of 30 per 100,000 in 1930 to 8 per 100,000 in 1996. The decline has been in antral tumors of the intestinal type, but the reason for this

favorable trend is not known.

Most populations show a 2:1 male to female ratio for gastric cancer. There is a higher incidence among blacks than whites in the United States. The peak incidence occurs in the sixth and seventh decades of life. There is a strong socioeconomic trend, with a higher frequency in lower socioeconomic groups. Although rates have decreased over the past 30 years, there has been an increase in the incidence of gastric cancer in the cardia. This is associated with a concomitant rise in the incidence of esophageal cancer.

Etiology

Diet has been the most studied risk factor for gastric cancer. Consumption of preserved, smoked, and cured foods results in a high concentration of nitrites, which form mutagenic compounds when exposed to bile acids in a stimulated gastric cavity. Colonization of the achlorhydric stomach by bacteria may also reduce dietary nitrates to nitrites and convert dietary amines in the presence of nitrite into carcinogenic *N*-nitroso compounds. A high-salt diet is a risk factor, and intake of fresh fruit and vegetables is protective; vitamin C and other antioxidants inhibit the conversion of nitrites into mutagenic compounds.

Substantial evidence has accumulated for an increased risk for gastric cancer with *H. pylori* infection, a relationship supported by numerous epidemiologic studies. The presence of immunoglobulin G antibodies to *H. pylori* in a given population is correlated with local gastric cancer incidence and mortality rates using linear regression analysis. There is a sixfold increased risk of gastric cancer in populations with 100 percent *H. pylori* infection compared with populations that have no infection (Table [24-3](#)).

Gastric ulcer disease is a marker for later development of gastric cancer with a relative increase in risk of 1.8. A contributing factor to both is atrophic gastritis induced by *H. pylori*. Other conditions associated with gastric cancer include cigarette smoking, previous partial gastrectomy (latency period of 15 years or more), radiation exposure, aflatoxin ingestion, family history, pernicious anemia, blood group A (relative risk 1.2 compared to blood group O), certain occupational exposures, and Epstein- Barr virus in the mucoid histologic subtype and in gastric remnant tumors. The number of partial gastrectomies being performed has fallen dramatically with the introduction of H₂- receptor antagonists and gastric proton pump inhibitors. The achlorhydric state produced by these agents used in the long term does not seem to have translated into an increased incidence of gastric cancer. It appears that duodenal ulcer disease actually is protective against gastric cancer.

Pathology

Gastric cancer is not a single entity but consists of several tumor types. Prognosis is more dependent on the depth of invasion through the stomach wall and the presence and extent of lymph node involvement than on any tumor classification.

Gastric cancers are divided into four subtypes by way of macroscopic appearance (Table [24-4](#)). Scirrhou cancer (linitis plastica) involves all layers of the stomach and there is a large connective tissue element, so much so that a histologic diagnosis can be obscured at endoscopic biopsy. The stomach is not distensible even when air is introduced at gastroscopy, and the condition is known as “leather bottle stomach.” Scirrhou cancer carries an extremely poor prognosis. Gross pathology is related to the histologic grade of the tumor. Scirrhou cancer is always undifferentiated, and polypoid tumors are likely to be well differentiated. There are multiple variations of the macroscopic appearances of gastric tumors between the stereotypic deep ulcerating tumor and the exophytic fungating papillary type. Lauren divided gastric cancer into two major histologic types: intestinal and diffuse. Intestinal types of gastric cancer arise on a field change of intestinal metaplasia (Fig. [24-18](#)). Intestinal metaplasia is the replacement of stomach epithelium by goblet and Paneth’s cells. Some believe that *H. pylori* initiates the stepwise sequence of superficial gastritis, atrophic gastritis, intestinal metaplasia, dysplasia, carcinoma in situ, and eventually invasive carcinoma. Only dysplasia is regarded as a positive predictor of gastric cancer. Severe dysplasia indicates imminent or concurrent gastric cancer and should be an indication for gastric resection. Most gastric tumors (85 percent) arise in a hypochlorhydric stomach. When intestinal metaplasia is found at the antrum, the risk of gastric cancer is proportional to the amount of metaplasia.

Intestinal type gastric cancer has been described as epidemic in type and predominates over the diffuse type in high-risk areas, and it is more closely associated with *H. pylori* infection than the diffuse type. The fall in incidence of gastric cancer in the United States has been due to a decrease in the intestinal type. The diffuse type of gastric cancer seems to be less related to environmental influences; it has increased in relative incidence with the falling incidence of the intestinal type, and it occurs more often in young people. The diffuse type is not associated with intestinal metaplasia, is not localized to the antrum, and arises out of single-cell mutations within normal gastric glands (Fig. [24-19](#)). The diffuse type, stage for stage, has a worse prognosis than the intestinal type. There are other classifications for gastric cancer based on histologic features such as papillary, tubular, mucinous, and signet-ring. The signet-ring cell type is caused by intracellular secretion of mucin and is associated with scirrhou gastric cancer. Gastric cancer has a great propensity to metastasize early by direct, lymphatic, hematologic, and transcoelomic routes.

The molecular events that occur in the progression of a gastric epithelial cell from benign to malignant are being investigated. Briefly, genetic instability, telomerase activity, and p53 mutation may be early events; epidermal growth factor overexpression and oncogene activation may occur later in the malignant process.

Clinical Manifestations

Anorexia with weight loss is the most common sign of gastric cancer, occurring in over 95 percent of those diagnosed with the disease. Patients are relatively asymptomatic until there is extensive involvement of the gastric wall and adjacent viscera, or widespread metastases. Massive hematemesis occurs in less than 5 percent of patients, although findings of anemia and occult blood in the stool are common. Nausea and vomiting may occur when distal lesions obstruct the pylorus. Dysphagia is a dominant symptom when cancer arises from the cardia of the stomach. Pain is a late and uncommon complaint. Abdominal tenderness is a rare finding, but a palpable abdominal mass is common (50 percent). Hepatomegaly may occur, suggesting metastatic spread. Peritoneal seeding may cause massive ascites, or involvement of the ovaries (Krukenberg’s tumor) or pelvic cul-de- sac (creating a Blumer’s shelf) by gravitational metastases. These late manifestations may lead to pelvic pain and constipation. A palpable lymph node in the left supraclavicular fossa (Virchow’s node) or a metastatic deposit to the umbilicus (Sister Joseph’s nodule) are also classic clinical signs of advanced gastric malignancy.

Diagnosis and Staging

While presenting complaints may be vague, a thorough history may provide indicators alerting the clinician to a possible diagnosis of gastric cancer. The most important specific investigation is upper gastrointestinal flexible endoscopy, permitting a biopsy procedure and tissue diagnosis. An upper gastrointestinal barium study (Fig. [24-20](#)) (single or air contrast technique) may be regarded as complementary, particularly if the scirrhou variety of tumor is suspected. Both techniques have a sensitivity and specificity above 90 percent. Upper abdominal computed tomography (CT) with the use of intravenous and oral contrast should then be used for the preoperative staging of gastric malignancy. TNM staging of gastric cancer is shown in Table [24-5](#), and preoperative CT staging in Table [24-6](#).

Endoscopic ultrasonography provides accurate information about the depth of penetration of tumor through the stomach wall. Laparoscopy is increasingly used as a staging tool to determine the presence of small intraperitoneal or liver metastases not seen on CT scan.

Early Gastric Cancer

Early gastric cancer is defined as gastric cancer confined to the mucosa or submucosa, regardless of lymph node involvement. This tumor stage was identified more than 30 years ago in Japan because of the inception of screening programs to detect gastric malignancy at an early stage. Detection of early gastric cancer ranges from 8 to 25 percent in the United States, and 35 to 50 percent of all gastric cancers in Japan because of the more effective screening programs. Early gastric cancer is divided into several types and subtypes (Table [24-7](#)) (Fig. [24-21](#)).

Seventy percent of early gastric cancers are well differentiated, and 30 percent are poorly differentiated; in 3 percent of early gastric cancers there is lymph node involvement. Early cancers of the exophytic type (I and IIA) are well differentiated, and the types with an ulcerating morphology are poorly differentiated. Five-year survival for patients when cancer is confined to the mucosa is 99 percent, when confined to the submucosa, 93 percent, and when lymph node involvement is present, survival drops precipitously to near 70 percent. The lymph drainage of the stomach has been detailed very thoroughly by the Japanese Research Society for Gastric Cancer, and an important concept is that the nodal staging of a tumor is dependent on the distance of the involved lymph nodes from the primary tumor. Systemic recurrence is strongly associated with lymph node involvement.

Treatment

Treatment of patients with gastric cancer is primarily surgical. Radiation and chemotherapy have little to offer in the way of palliation. Resection offers the only possibility of cure for gastric cancer and also provides the best palliation (Table [24-8](#)). The best palliation for patients with duodenal obstruction or bleeding is often resection, even if incomplete; the need for accurate staging is obviated by staging at laparotomy in many cases (Fig. [24-22](#)).

It is essential that a curative procedure for gastric cancer provides resection margins free of cancer. The most common operation performed for cure is a radical subtotal gastrectomy. This operation includes resection of the gastrocolic omentum and ligation and division of the right gastric, the right gastroepiploic, and the left gastric arteries at their origin, with removal of associated lymph nodes and mesentery. Approximately 2 cm of proximal duodenum is included in the resection; 50 to 85 percent of the stomach is removed, and continuity is reestablished using a gastrojejunostomy (Fig. [24-23](#)). Splenectomy and total gastrectomy may be required when the lesion is extensive, when it is in the proximal portion of the stomach, or when it directly invades within the hilum of the spleen. In the absence of a screening program, many patients present with an advanced tumor, and surgical therapy undertaken at this time is usually palliative with little hope of cure. The results of surgery for early disease are excellent.

There is a dynamic existing between extensive resection ensuring tumor clearance and the accompanying morbidity and mortality of extensive surgery. While some studies suggest that a more extensive resection of the stomach, nodes, and adjacent structures improves long-term outcome, most reports in Western countries note little additional benefit to more extensive operations. Gastrectomy is a major procedure with an overall operative mortality of 8 percent. Traditional subtotal gastrectomy includes removal of the perigastric lymph nodes within 3 cm of the stomach serosa (D1 resection). A D2 level resection involves removing gastric lymph nodes beyond this 3 cm margin; the nodes involved are found along the left gastric artery, celiac axis, common hepatic artery, and splenic artery and hilum. A D3 level resection involves removal of lymph nodes along the hepatoduodenal ligament, pancreatic head, and root of the small bowel mesentery. The specific operation performed depends on the location and extent of the gastric tumor, and the extent of lymphadenectomy varies accordingly. Splenectomy and distal pancreatectomy result in significant morbidity and should be avoided.

The precise role of adjuvant and neoadjuvant chemotherapy and radiotherapy has yet to be strictly defined in the treatment of gastric cancer. Because of the high probability of relapse after gastric resection, there is interest in defining an effective adjuvant regime. Single agents have no benefit as adjuvant therapy. Chemotherapeutic agents used in previous studies include 5-fluorouracil, methyl-lomustine (methyl-CCNU), Adriamycin, mitomycin C, and cytosine arabinoside. Radiotherapy combined with chemotherapy may yet emerge as an efficacious adjuvant treatment. The role of neoadjuvant (preoperative) therapy is less well established.

Lymphoma (Lymphosarcoma)

Gastric lymphoma can occur as an isolated neoplasm confined to the stomach or it may be the manifestation of widespread infiltrative disease involving lymphatic and other organ

systems. The lesion may present as a tumor mass or, more commonly, as a thickening of the rugal epithelial folds secondary to lymphocytic infiltration within the submucosa. Anorexia and weight loss are the most common presenting complaints. Early satiety is a prominent symptom as the gastric wall becomes thickened and the lumen is progressively compromised by the neoplastic infiltrate. Bleeding is uncommon. Definitive diagnosis is made by endoscopy and biopsy.

Bulky lesions with associated gastric outlet obstruction are best treated by subtotal gastric resection and postoperative irradiation. Radiation therapy alone, however, provides a long- standing remission that may be equal to that of resection alone in most cases. Radiation has emerged as the treatment of choice because of its low morbidity. A combined approach is associated with a 5-year survival rate of 85 percent when the malignant process is limited to the stomach. Involvement of the stomach by generalized lymphosarcoma is usually treated by combined radiation and chemotherapy. Gastrectomy is undertaken only when complications ensue such as perforation or when the stomach is the major source of disabling symptoms, e.g., obstruction.

Leiomyosarcoma

Leiomyosarcoma originates in the smooth muscle and is the least common of gastric malignancies. Frequently it grows to a very large size before detection because of its outward growth away from the gastric lumen. Distal spread is late, and even massive tumors that become adherent to the liver or pancreas can be resected, resulting in prolonged survival. Leiomyosarcomas are not usually responsive to radiation or chemotherapy. They generally are detected following a gastrointestinal hemorrhage from a breakdown of the overlying gastric epithelium or as a consequence of malnutrition secondary to compromise of gastric capacity and are often palpable on abdominal examination. Preoperative assessment is improved by abdominal CT scans done with intravenous and oral contrast. Resection is the preferred treatment. In order to excise the tumor completely, resection of the adjacent colon or spleen may be required. Extensive lymphadenectomy is not required because these tumors metastasize hematogenously to the liver and within the peritoneal cavity, but not usually via the lymphatics. Long-term survival is correlated inversely with tumor grade, size, and the status of histologic involvement of the margin.

Benign Tumors

Polyps

Polyps are the most common benign tumors of the stomach. There are two types: inflammatory and adenomatous. Adenomatous polyps are more important as they are true neoplasms and may have malignant potential. They can be distinguished from inflammatory polyps because of their long stalk and tendency to occur in the atrophic mucosa of patients with pernicious anemia. Occasionally adenomatous polyps will arise in the stomach in conjunction with the small bowel polyposis of the Peutz-Jeghers syndrome or the familial polyposis of Gardner's syndrome. Inflammatory polyps are usually sessile outgrowths within the antrum or fundus of the stomach. They are asymptomatic except when they are adjacent to, and prolapse through, the pylorus. Hypertrophic gastritis (Ménétrier's disease) may also be associated with multiple inflammatory polypoid lesions within the fundic area of the stomach. These lesions can be distinguished from multiple gastric adenomatous polyposis by biopsy and histologic examination. They do not require surgical extirpation. Gastric adenomatous polyps should be biopsied and excised by endoscopic ensnarement. Malignant polyps should be treated as gastric cancer by surgical resection.

Leiomyoma

The origin and differentiation of gastric stromal tumors has attracted much attention as immunohistochemical techniques have advanced. Gastric stromal tumors have been traditionally classified as smooth muscle tumors (leiomyomas). The origin of these tumors is usually from smooth muscle or epithelium. The correlation between histologic appearance and immunohistochemical markers is variable, making a definitive classification difficult. The majority of gastric stromal tumors are of smooth muscle origin. Gastric stromal tumors, regardless of type, have a similar natural history. Small leiomyomas are commonly found within the smooth muscle of the gastric wall at autopsy or during palpation of the stomach at laparotomy. They are of little clinical significance until they enlarge to greater than 4 cm in diameter. At this point they begin to compromise the blood supply to the overlying gastric epithelium. This leads to ulceration and proteolytic digestion of the core of the neoplasm that itself may have undergone central necrosis. This process may culminate in a massive upper gastrointestinal hemorrhage that may require emergency gastric resection for control. More typically patients present with anemia and guaiac-positive stools. Such lesions, when large, cannot be easily distinguished from their malignant counterparts and should be treated by gastrectomy with a minimum proximal margin of 4 cm. Smaller lesions (<4 cm) can be shelled out of the gastric wall or removed by wedge resection. Tumor size and histologic characteristics, including the number of mitoses per high-power field, capsular invasion, and pleomorphism are important characteristics distinguishing the benign and malignant nature of these lesions.

Lipoma

Lipomas of the stomach are asymptomatic submucosal lesions that are a radiographic curiosity distinguished by their smooth contour. Endoscopy reveals their submucosal position and often pale yellow color. They need not be biopsied or excised.

Ectopic Pancreas

Rarely, a portion of ectopic pancreas will reside within the antrum of the stomach. While this lesion is usually submucosal, it will often present within the gastric lumen as an umbilicated dimple. Excision may be necessary to exclude malignancy or when patients present with unremitting dyspeptic symptoms that are refractory to antiulcer therapy.

OTHER GASTRIC LESIONS

Hypertrophic Gastritis (Ménétrier's Disease)

Ménétrier's disease is a rare inflammatory disease of the gastric epithelium that is characterized by hypertrophic gastric folds within the proximal stomach. In advanced stages the epithelium assumes the appearance of large, multiple polypoid outgrowths. Histologic examination reveals that the thickened folds consist of a hypertrophy of the gastric glandular epithelium as well as a remarkable increase in size of the submucosa, which is edematous and contains a large number of small round cells. The latter finding suggests that the disease may have an autoimmune component. Ménétrier's disease is characterized clinically by the massive amount of plasma proteins that can be lost through an epithelium that is normally impermeable to large molecules.

Most cases of hypertrophic gastritis can be managed nonoperatively with treatment directed toward maintaining good nutrition and symptomatic relief of the vague gastric complaints offered by these patients. Hypoproteinemia rarely develops, but total gastrectomy may be required in such cases. The condition merits surveillance in view of the high incidence of gastric cancer reported in some series.

Bezoars

Bezoars are concretions of nondigestible matter that accumulate in the stomach. Trichobezoars, composed of hair, most commonly develop in young women who swallow their hair (trichophagy) (Fig. 24-24). Phytobezoars, composed of vegetable matter, are most often associated with persimmon ingestion. They may also develop after gastric surgery as a result of the loss of trituration. They are associated with symptoms of gastric outlet obstruction but may occasionally produce ulceration and bleeding. They can be diagnosed by upper gastrointestinal series. Treatment consists of proteolytic enzymes, such as papain, and can be facilitated by mechanical fragmentation with the endoscope. Occasionally operation is required for removal.

Dieulafoy's Lesion

Dieulafoy's lesion is a small, easily missed erosion of the gastric mucosa that is believed to involve a mucosal end artery that over time produces pressure necrosis of the stomach and ruptures into the lumen. Bleeding may be massive and recurrent. Endoscopy can miss the diagnosis if the lesion is not actively bleeding. Dieulafoy's lesion can be effectively treated by endoscopic thermal therapy or injection of a sclerosant, although occasionally the lesion will require operation and wedge resection.

Diverticula

True diverticula of the stomach, composed of all three layers of the gastric wall, are rare lesions, most often diagnosed between the ages of 20 and 60 years, although they are a congenital lesion. They are most commonly found in the posterior cardia and body of the stomach (Fig. 24-25) and are usually saccular. Complications are rare, but they may present with hemorrhage or diverticulitis. The majority produce no symptoms. Diagnosis is usually made by upper gastrointestinal contrast study. Operation, diverticulectomy, is reserved for cases in which there are complications, although it may be reasonable to excise a large diverticulum with a narrow neck and inspissated debris to prevent the development of diverticulitis.

Foreign Bodies

As a general rule, ingested foreign bodies that pass through the esophagus and gastroesophageal junction will also traverse the pylorus and pass into the distal gastrointestinal tract. Occasionally, objects such as safety pins will lodge in the stomach and produce symptoms of vague discomfort. Impacted larger objects can obstruct the stomach completely. Often these objects can be removed with a gastroscope and snare; operative removal is occasionally necessary.

Mallory-Weiss Tears

Mallory-Weiss tears are lacerations in the region of the gastroesophageal junction that can follow episodes of vomiting and retching. They are often associated with heavy alcohol consumption and may produce massive bleeding. They may account for as many as 15 percent of upper gastrointestinal bleeds. They stop spontaneously in 80 to 90 percent of patients. Diagnosis is most commonly made endoscopically, and the lacerations can be treated with thermal coagulation. Angiography with vasopressin infusion may also prove useful. Occasionally operation is necessary; usually oversewing the lesion through a long gastrotomy is successful, although care must be taken to identify any esophageal component.

Volvulus

Gastric volvulus, another unusual condition, is a torsion or twist of the stomach. It typically occurs along the long axis of the stomach (organoaxial volvulus) in association with a paraesophageal hernia so that the stomach appears, on contrast studies, to be rotated upside down. Because of this association, most recommend that even asymptomatic paraesophageal hernias be repaired. Gastric volvulus may occur acutely and present as either complete obstruction or strangulation of the stomach, but more commonly it is a chronic process. Acute volvulus typically presents as severe epigastric pain with inability to vomit, and it may be difficult or impossible to pass a nasogastric tube. Chronic conditions produce intermittent epigastric pain and distention. If the stomach is viable, the volvulus is reduced, any accompanying hernia repaired, and the stomach is fixed (gastropexy) to the anterior abdominal wall. A gastrostomy tube is often used to accomplish this. Necrosis may necessitate some form of gastric resection.

SURGERY OF THE STOMACH

The primary goal of surgery of the stomach is to eliminate the pathologic lesion while minimizing the consequent disruption of normal gastroduodenal physiology. Treatment must be individualized depending on the specific lesion and its mode of presentation. In the case of operations for acid-peptic disease, the common theme underlying these procedures is to restore the normal balance between secretion and mucosal resistance. It is impossible to surgically alter mechanisms of mucosal defense, and therefore all previous procedures

have approached these diseases by attempting to reduce acid secretion either by (1) sectioning the vagus, (2) eliminating the hormonal stimulation from the antrum, or (3) decreasing the number of parietal cells. Four general operations have been devised to produce these results: subtotal gastrectomy, vagotomy and drainage, vagotomy and antrectomy, and parietal cell vagotomy. When resection is performed, some form of reconstruction is required.

In contrast, in the case of neoplastic disease, the goals are somewhat different. The foremost consideration is to provide the patient with the best chance for cure, although this must be tempered by concern for the morbidity of more aggressive resection. In some patients, the malignancy is so far advanced that resection for cure is impossible. Most surgeons believe that some form of palliative resection, if it can be performed with acceptable morbidity, is preferable to leaving a patient with an obstructing or bleeding gastric tumor.

Vagotomy

The rationale for vagotomy is the elimination of the direct cholinergic stimulus to acid-pepsin secretion. Because of potentiation, this withdrawal also makes parietal cells less responsive to histamine and gastrin and abolishes the vagal stimulus for release of antral gastrin. Basal and stimulated acid secretion are reduced by 80 percent and 50 percent, respectively. Gastrin levels increase, probably as a result of the reduction in normal acid inhibition of antral G cells.

Three different types of vagotomy are performed: truncal, selective, and highly selective (Fig. 24-26). Truncal vagotomy is the simplest procedure; the anterior and posterior vagus nerves are identified on the distal esophagus, and a small section is removed and sent for tissue analysis to confirm that the nerve has been identified. The second type, selective vagotomy, was devised to prevent some of the undesirable sequelae of truncal vagotomy by preserving the innervation of the rest of the gut. The nerves of Latarjet are sectioned just distal to the hepatic and celiac branches of the vagus. Although the rationale seems logical, this operation is not any better tolerated than truncal vagotomy, and because it is more difficult, it has largely been abandoned.

Truncal vagotomy markedly alters gastric motility patterns. Both receptive relaxation and trituration are impaired. Gastric emptying of liquids is speeded with the impairment in relaxation, whereas solid evacuation is slowed significantly, leading to overt gastric stasis in some patients. As a result, some form of emptying procedure (i.e., pyloroplasty or gastrojejunostomy) should be performed (Fig. 24-27). At least three different types of pyloroplasty have been described; the Heineke-Mikulicz pyloroplasty is probably the simplest technically and is most commonly performed. Although it has never been demonstrated to be clinically superior, pyloroplasty preserves the normal anatomic relationship between the stomach and the duodenum and for that reason is generally preferred. Gastroenterostomy is typically reserved for patients with significant duodenal bulb scarring, which would make pyloroplasty more difficult. These drainage operations also have important physiologic consequences. Pyloroplasty further speeds gastric emptying and, by reducing the period of contact between gastric contents and the antral mucosa, decreases acid secretion mediated through the direct gastric phase of stimulation. Gastroenterostomy may enhance secretion by producing antral gastrin release and eliminating the secretion of inhibitory factors normally generated during the passage of chyme through the duodenum. An increase in gastrin levels may result because of stasis in the partially excluded antrum and because the gastroenterostomy allows acid to empty and be neutralized before it can bathe the antrum. Both procedures eliminate the pyloric sphincter and produce duodenogastric reflux.

The rationale for this highly selective vagotomy is to eliminate vagal stimulation to the acid-secreting portion of the stomach without interrupting motor innervation to the antrum and pylorus. The operation involves severing all branches of the nerves of Latarjet along the lesser curvature that innervate the corpus and fundus. Basal and stimulated acid secretion are reduced by more than 75 percent and 50 percent, respectively. It reduces the secretion of acid in response to gastric distention. Basal serum gastrin is increased, although the response to a meal is reduced. Receptive relaxation is impaired, and emptying of liquids is more rapid than normal; antral peristalsis, trituration, and sphincter function are preserved. The emptying of solids is normal. The normal small bowel innervation preserves intestinal motility patterns and reduces the incidence of postvagotomy complications and dumping.

Resection

Some form of resection is always required for curative treatment of malignant disease. Resections usually take longer and the morbidity and mortality are somewhat higher than those of the various vagotomies. Total gastrectomy is seldom performed for benign disease. It is usually reserved for malignancies of the proximal and midstomach and typically includes omentectomy and some form of lymph node dissection. The procedure completely eliminates the reservoir and digestive functions of the stomach. Although most patients lose considerable weight initially, with smaller, more frequent meals, most stabilize and can survive long term. Vitamin B₁₂ injections are required and deficiencies of iron and calcium can develop.

Subtotal gastrectomy was employed for the treatment of duodenal ulcer disease in the past, but is most commonly used for gastric ulcer and distal gastric malignancies. Typically the distal two-thirds of the stomach, including the pylorus, is removed. No matter what the nature of the lesion, proximal gastrectomy virtually always produces problems with emptying and should not be performed. Distal gastrectomy does reduce acid and pepsin secretion by removing not only a major portion of the parietal and chief cells in the corpus but also the antral G cells, eliminating the gastrin stimulus to secretion. The proximal stomach also atrophies in the absence of gastrin. This operation reduces basal and stimulated secretion by 75 percent and 50 percent, respectively, and eliminates the antral-pyloric mixing mechanism by which food is reduced to chyme before entering the duodenum. The emptying of both liquids and solids is more rapid. With removal of the pylorus, increased reflux of intestinal contents into the stomach may produce significant reflux gastritis.

Until recently, antrectomy combined with truncal vagotomy was one of the most commonly performed procedures for duodenal ulcer disease. This procedure seems to combine some of the advantages of both these operations. The simultaneous effects of vagotomy and antrectomy remove both the cholinergic and gastrin stimulus to acid secretion. Basal acid secretion is virtually abolished, and stimulated acid secretion is reduced by nearly 80 percent. The rationale for this procedure is to preserve some of the reservoir function eliminated by a more subtotal gastrectomy and still reduce acid secretion. Dumping complications, resulting from rapid emptying of hyperosmolar gastric contents into the duodenum, seem to be slightly less frequent than after more complete resection. Improved medical therapy and the availability of highly selective vagotomy have virtually eliminated the need for this procedure.

Reconstruction

After gastrectomy, gastrointestinal continuity may be restored by anastomosing the remnant to the duodenum, i.e., gastroduodenostomy (Billroth I), or, after closing the duodenal stump, anastomosing the remnant to the intestine just distal to the ligament of Treitz, i.e., gastroenterostomy (Billroth II) (Fig. 24-28). The latter has both an afferent limb from the duodenum and an efferent limb extending distally. The choice between the two drainage procedures has important physiologic consequences that should be considered in addition to their respective complications. The Billroth II procedure eliminates the added stimulus to acid secretion from duodenal release of gastrin in response to passing chyme. It also prevents the meal from reaching pH receptors and osmoreceptors in the proximal duodenum, which normally slow gastric emptying. Unlike reconstruction after a subtotal resection where the Billroth II procedure seems preferable in terms of suture line tension and recurrence rates, experience suggests that restoration of normal continuity with a Billroth I procedure is more desirable after vagotomy and antrectomy.

After total gastrectomy, because of the high incidence of alkaline reflux esophagitis, if the esophagus is anastomosed in continuity to the small bowel, a Roux-en-Y reconstruction is usually performed (Fig. 24-29). This interposes a segment of intestine, usually 45 cm in length, between the esophagus and the intestine in continuity with the duodenum and excludes the esophagus from exposure to bile and pancreatic secretion. Attempts to preserve reservoir function by constructing pouches with the small bowel have not been successful; they do not empty appropriately and may limit intake more than the absence of a stomach.

Choice of Operation

The choice among surgical procedures can be complex. The most important single factor is the nature of the disease process itself. Other considerations include the respective operative mortality and postoperative morbidity, the incidence of recurrence, the postgastrectomy side effects of the procedure, the long-term metabolic consequences of the operation (weight loss, bone disease, and anemia), and the potential future risk of gastric carcinoma. The surgeon's own familiarity with the various operative procedures is a crucial consideration.

Reliable data on the results of various operations have only been generated during the past quarter century. Published series in general used different criteria for patient selection and the incidence of side effects. Table 24-9 summarizes the data on the three most commonly performed procedures for duodenal ulcer. Mortality is lowest for highly selective vagotomy and highest for vagotomy with antrectomy. The relative incidence of side effects is about the same for vagotomy with antrectomy or drainage, and lower for the highly selective operations. The incidence of recurrence is significantly lower for vagotomy with antrectomy. Truncal vagotomy with drainage has both the higher recurrence rate of highly selective vagotomy and the unfavorable incidence of side effects of vagotomy with antrectomy. There is still a role for truncal vagotomy and drainage in the emergent treatment of a patient for whom time is a critical factor; this procedure can be performed considerably more quickly than antral resection or highly selective vagotomy. Some surgeons believe that highly selective vagotomy is the only acceptable operation for duodenal ulcer, although resection is still indicated for gastric ulcer. The lumen of the gastrointestinal tract is not entered, reducing the risk of septic complications. Because the normal functional anatomy of the stomach and pylorus are preserved and the distal vagal innervation is not interrupted, the potential for serious long-term side effects is greatly reduced.

The data in Table 24-9 regarding recurrence are probably no longer applicable, because they were generated before the role of *H. pylori* was recognized. This is a time when surgical approaches to peptic ulcer are being completely revised. Elective operation for peptic ulcer is unusual; most patients undergo operation for one of the complications of ulcer and are often elderly and debilitated. In this setting, it is unclear whether anything beyond dealing with the complication is necessary.

Laparoscopic approaches to the stomach, usually for benign disease, have received increasing attention. Although experience with resection has been limited, it is possible to remove portions of the stomach with laparoscopic staplers, and reconstructive techniques are being developed. Laparoscopic vagotomy also is feasible. Conventional highly selective vagotomy is a demanding procedure to perform through the laparoscope. At laparoscopy, surgeons have employed a combination of posterior truncal vagotomy and either anterior seromyotomy (dividing the muscular layers from the gastroesophageal junction to the antrum, which should interrupt the innervation of the fundus and the corpus) or anterior highly selective vagotomy. At open operation these techniques have results comparable to highly selective vagotomy; the results with the laparoscope are still preliminary, and the utility of these minimally invasive procedures cannot yet be judged accurately. Most of these operations have been performed in the elective setting; with eradication of *H. pylori*, few such procedures will be necessary in the future. Serious questions remain about the applicability of laparoscopic techniques in the emergent setting. Neither hemorrhage nor obstruction seem well suited to the laparoscope. It may be most applicable to the treatment of perforations, where patching and highly selective vagotomy seem most appropriate.

Postgastrectomy Syndromes

After operations on the stomach, a variety of chronic undesirable sequelae may develop. Although some of these conditions are related more to vagotomy than they are to resection, they have been referred to as the postgastrectomy syndromes (Table 24-10). Virtually all patients note a change in their digestive habits postoperatively, and about 20 percent are significantly affected. Most are able to adapt with time; only about 5 percent develop lifelong symptoms, and 1 percent are significantly disabled by these syndromes.

These patients are probably the only candidates for remedial operation.

Dumping occurs in about 20 percent of patients after gastrectomy or vagotomy with drainage. Although the exact mechanism has eluded definition, it appears to be related to the rapid emptying of hyperosmolar chyme, particularly carbohydrate, into the intestine. This draws fluid into the intestine and probably releases one or more vasoactive hormones, such as serotonin and vasoactive intestinal polypeptide (VIP). This is associated with epigastric distention, cramps, nausea, vomiting, dizziness, flushing, and palpitations. In most patients the symptoms tend to resolve as the patients learn to avoid foods that aggravate the problem. Frequent small meals, low in carbohydrate, might eliminate the problem. In the most refractory cases, synthetic somatostatin analog (octreotide) may be of benefit.

After truncal vagotomy, approximately 30 percent of patients develop *postvagotomy diarrhea*. The pathogenesis of postvagotomy diarrhea is unclear, but it may be related to the rapid passage of unconjugated bile salts from the denervated biliary tree into the colon, where they can stimulate secretion. Most cases are self-limiting. Long-term oral cholestyramine, which binds the bile salts, is an effective treatment of this complication.

After operations that effect the pyloric sphincter, reflux of bile into the stomach is common. Only about 2 percent of patients develop *alkaline reflux gastritis*, a syndrome of persistent, burning epigastric pain and chronic nausea that are aggravated by meals. Diagnosis is one of exclusion, although endoscopy may reveal gastritis, and technetium biliary scan can demonstrate increased reflux of bile into the stomach. A variety of medical therapies has been reported; none have proved particularly effective, although there is enthusiasm for the use of ursodeoxycholic acid. Conversion of the original drainage operation to a Roux-en-Y anastomosis, diverting the bile 45 to 60 cm from the gastric remnant, has proved effective in selected patients.

Early satiety may develop as a result of postsurgical atony, gastric stasis, as a result of denervation, or from the "small remnant syndrome" related to extensive gastric resection. In both cases, symptoms consist of epigastric fullness with meals, often followed by emesis. Atony can be distinguished with a solid food emptying test and may respond to prokinetic agents that stimulate gastric motility, such as metoclopramide, erythromycin, and cisapride; if these fail, completion gastrectomy is the procedure of choice. The small remnant syndrome usually will improve with time; frequent small feedings are recommended.

Afferent loop syndrome develops after Billroth II reconstruction or gastroenterostomy. It is related to mechanical obstruction of the afferent limb by kinking, anastomotic narrowing, or adhesion and typically is associated with postprandial epigastric pain and nonbilious vomiting that is then relieved by projectile bilious vomiting. The detection of a distended afferent loop on CT scan is diagnostic. Conversion to a Roux-en-Y anastomosis is necessary to treat this problem. *Efferent loop obstruction* is associated with epigastric pain, distention, and bilious vomiting; the cause is always mechanical, and operation is the treatment of choice.

Bezoars, obstructing concretions of undissolved food, develop after gastrectomy as a result of the alterations in gastric motility.

Gastric stump carcinoma develops in approximately 3 percent of patients who have undergone gastrectomy. There has been some controversy about this and it appears to represent a significant increase over the incidence in the general population. Symptoms are usually vague; endoscopic screening has been recommended for this group of patients, although the optimal timing remains unclear. The treatment is resection.

Operations for Morbid Obesity

A variety of criteria have been used for defining morbid obesity; perhaps the most commonly accepted definition is 100 lbs over ideal body weight. The pathogenesis of such obesity is poorly understood, but includes a genetic influence, metabolic abnormalities, disorders of satiety, and psychological abnormalities. Morbidly obese individuals typically develop problems by puberty. In many people, it is related to excessive intake; in others, the problem may be related to a low basal energy expenditure or an inability to burn off excess calories.

Severe obesity is associated with a variety of complications and with excess mortality. Complications include coronary artery disease, hypertension, impaired cardiac function, adult-onset diabetes mellitus, pulmonary dysfunction including hypoventilation and sleep apnea, hypercoagulability, degenerative arthritis, cholelithiasis, and gastroesophageal reflux. Low self-esteem and depression are not unusual.

Criteria for operation vary, but typically complete metabolic and psychological evaluation is necessary; most surgeons require documented evidence of participation in a supervised dietary management program without success. Although 100 lb over ideal weight is required, exceptions may be made for patients with a weight-related medical problem.

Surgery for morbid obesity has undergone considerable evolution. The first operation was the jejunal bypass, in which the proximal jejunum, usually 20 cm distal to the ligament of Treitz, was anastomosed to the terminal ileum, usually 10 cm from the ileocecal valve. Although this produced significant weight loss, it was associated with complications, including significant liver disease in 5 to 10 percent of patients, related both to protein-calorie malnutrition and to factors released by the bacterial overgrowth that invariably develops in the bypassed segment. Arthritis, cholelithiasis, nephrolithiasis, and metabolic abnormalities were common. This procedure has been largely abandoned.

The most commonly performed procedures today are the vertical banded gastroplasty and the Roux-en-Y gastric bypass (Fig. 24-30). Both operations are performed using a combination of surgical staplers to create a proximal gastric pouch with a capacity of approximately 30 mL. This significantly limits intake, producing weight loss. The patients are maintained on a 1000 kcal or less diet with nutritional supplements. The bypass does not allow the meal to enter the distal stomach, adding an element of maldigestion. There may also be a component of dumping syndrome as the gastric contents directly enter the small bowel. Several studies have suggested that the bypass may be superior, and it is becoming the procedure of choice. There now are several surgeons performing the procedure laparoscopically.

Morbidly obese patients are at particular risk for postoperative morbidity. Atelectasis and pulmonary infection are most common. In these patients postoperative mobilization may be particularly difficult, and venous thromboembolism can be a major problem. Wound infections are more common and more difficult to diagnose in the morbidly obese. Intraabdominal complications, such as anastomotic leak, can be difficult to detect.

Weight reduction with these procedures is significant. The average loss is one-half to two-thirds of the excess weight at 1.5 years, at which point weight typically stabilizes. This has shown to be associated with improvements in diabetes, hypertension, mobility, pulmonary problems, and arthritis. In addition, patient self-image is often markedly improved. The operations have not clearly demonstrated a reduction in the excess mortality of the morbidly obese, though it seems likely with longer follow-up.

CHAPTER 25 - Small Intestine

B. Mark Evers
Courtney M. Townsend, Jr.
James C. Thompson

Introduction

Considered teleologically, the small bowel is the *raison d'être* for the entire gut. The esophagus brings food to the stomach, which prepares it for digestion. The exocrine secretions of the liver and pancreas make digestion possible. Digestion is achieved in the lumen of the small bowel, and nutrients are absorbed through the small-bowel mucosa; the colon disposes of whatever is left.

In addition to its vital function in nutrition, the small bowel has other important roles. It is the largest endocrine organ in the body. It has tremendous defenses against infection and is one of the most important, if not the most important, organs in immune defense. It is a marvel of efficiency and works so well that, excepting the proximal 3 cm of the duodenum, it is seldom afflicted with disease. We are supplied with a great excess of small bowel and can exist on less than one-half of the absorptive surface provided.

Until recently, the small intestine had been relatively inaccessible for nonoperative diagnostic procedures, compared to the stomach or colon. Several diagnostic techniques are now available for specific diseases of the small bowel. Mucosal biopsy specimens obtained with the peroral biopsy capsule are often diagnostic in diffuse mucosal diseases. Enteroclysis is a more sensitive radiographic technique than the conventional barium follow-through examination of the small bowel. Selective mesenteric angiography often is helpful in cases of discrete lesions with abnormal vascular patterns, such as neoplasms, vascular malformations, or actively bleeding lesions. Scintigraphy may be helpful in localizing sites of bleeding. Fiberoptic endoscopy of the duodenum, proximal jejunum, and distal ileum are routinely employed.

Some diseases that affect the small intestine are discussed in other chapters: intestinal obstruction (Chap 22), mesenteric vascular disease (Chap 33), diseases of the intestine in infancy and childhood (Chap 37), the intestine in trauma (Chap 6), and duodenal and gastrojejunal peptic ulcer (Chap 24).

Embryology

The primitive gut forms during the fourth week of fetal development. The endoderm gives rise to most of the epithelium and glands of the digestive tract. The splanchnic mesoderm surrounding the endoderm gives rise to muscular connective tissue and other layers comprising the wall of the digestive tract. Early in the fourth week the duodenum begins to develop from the caudal portion of the foregut and the cranial portion of the midgut. The remainder of the small bowel is derived from the midgut. During the fifth week, the fetal gut rapidly elongates and herniates through the umbilicus (Fig. 25-1). This midgut loop has both cranial and caudal limbs; the cephalic limb develops into the distal duodenum to proximal ileum, and the caudal limb becomes the distal ileum to proximal two-thirds of the transverse colon. The juncture of the cephalic and caudal limbs is where the vitelline duct joins to the yolk sac. This duct normally becomes obliterated before birth; however, it occasionally persists as a Meckel's diverticulum. This period of midgut herniation lasts until approximately 10 weeks' gestation, after which the intestines return to the abdomen. During this period of rapid elongation and herniation the midgut rotates 90 degrees counterclockwise around an axis formed by the superior mesenteric artery. As the gut reenters the abdomen at about the tenth week, it undergoes a further 180-degree rotation, thus completing 270 degrees of rotation from the starting point. The proximal jejunum is the first portion to reenter the abdomen and occupies the left side of the abdomen, with subsequent loops lying more to the right. The cecum enters last and is located temporarily in the right upper quadrant; during the third to fifth month of fetal gestation, it descends to its normal position in the right lower quadrant. Congenital anomalies of gut malrotation and fixation can occur during this process.

The small intestine is lined with simple cuboidal epithelium during the sixth and seventh weeks of fetal gestation. The rapid epithelial proliferation may lead to occlusion of the lumen, especially in the proximal gut (particularly in the duodenum). The lumen is reestablished during weeks 9 and 10 with the formation of coalescing vacuoles that restore the patency of the lumen. Villi begin to form first in the proximal intestine at 9 weeks, proceeding caudad and eventually lining the entire gut. Differentiated crypt cells appear between the ninth and twentieth weeks of gestation. Crypt formation begins in the tenth to twelfth weeks of gestation.

This complex and regimented pattern of gut differentiation appears to be mediated by sets of genes that are characteristically turned on and off with temporal and spatial specificity during developmental transitions as the gut evolves into its adult form. This developmental pattern also appears to be dependent on interaction with the mesoderm and lamina propria, which may provide "instructive" signals for developmental progression. The epithelial cells of the gut are generated from a fixed stem-cell population localized in the lower portion of the crypts that give rise to four main cell types: absorptive enterocytes, goblet cells, enteroendocrine cells, and Paneth cells. Until recently the analysis of the factors regulating these complex developmental processes in vivo was not possible; however, elegant studies by Gordon and colleagues, using transgenic mouse techniques, have described marker systems for inferring the biologic properties of intestinal stem cells and provided direct evidence of the transcriptional regulation of spatial patterns of intestinal gene expression. Other investigators have used the intestine-specific sucrase-isomaltase and neurotensin genes as molecular models to better understand the factors regulating gut development and eventual maturation.

Anatomy

The most impressive thing about the small bowel is its immense mucosal surface area, which is responsible for the organ's tremendously efficient digestion of food. Several layers of muscle, combined with actin and myosin components in the microstructures, provide great motility, so that not only is there great surface area, but the interface between the surface and the luminal contents presented for absorption is in constant motion as well.

Gross Anatomy

The small bowel extends from the pylorus to the cecum. The length of the small intestine depends entirely on the state of bowel activity at the time of measurement. Careful estimates provide a duodenal length of 20 cm, a jejunal length of 100 to 110 cm, and an ileal length of 150 to 160 cm. The jejunoileum extends from the peritoneal fold that supports the duodenal-jejunal junction (the ligament of Treitz) downward to the ileocecal valve. The jejunoileum is estimated to constitute 60 percent of the entire length of the gut and to be approximately 160 percent of the body height, so that the small bowel is considerably longer in a 7-ft basketball player than in a 5-ft jockey.

Generally the jejunum occupies the upper abdomen, especially on the left, and is in contact with the pancreas, spleen, colon, and left kidney and adrenal gland. Affliction of these organs may affect the jejunum; pancreatitis, for example, may cause local ileus (the "sentinel loop") of the jejunum.

The jejunum has a larger circumference and is thicker than the ileum, and it may be identified at operation because of this and also because the mesenteric vessels usually form only one or two arcades and send out long, straight vasa recta to the mesenteric border of the jejunum. In contrast, the blood supply to the ileum may have four or five separate arcades; the vasa recta are shorter, and, most important, there is usually much more fat in the mesentery of the ileum than in that of the jejunum (Fig. 25-2). The jejunal mesentery may be transparent, but mesenteric fat usually reaches all the way to the bowel in the ileum. The ileum occupies the lower abdomen, especially on the right, and the pelvis. It is smaller in diameter and somewhat more mobile.

Except for the duodenum the small bowel is entirely covered with visceral peritoneum (the serosa) and is tethered only by its attachment to the mesentery, through which course arteries, veins, and lymphatics. The mesentery is obliquely attached to the posterior body wall, beginning superiorly well to the left of the second lumbar vertebra and ending obliquely downward and to the right to overlie the right sacroiliac joint. The mesentery normally is covered with glistening, nonadherent peritoneum, but after trauma (external, chemical, septic, or operative) it may become adherent to other surfaces (mesenteric, visceral, or parietal) and greatly limit bowel mobility.

Except for the proximal duodenum, which is supplied by branches of the celiac axis, the blood supply of the small bowel is entirely from the superior mesenteric artery, which is the second major branch of the infradiaphragmatic aorta. The superior mesenteric artery also supplies the appendix, cecum, and ascending and proximal transverse colon. There is an abundant collateral blood supply to the small bowel provided by the vascular arcades in the mesentery. In spite of this collateral supply, occlusion of a major branch of the superior mesenteric artery, or of the superior mesenteric artery itself, will lead to bowel death if not quickly corrected. Venous drainage of the segments of the small bowel is in parallel with the arterial supply. The superior mesenteric vein joins the splenic vein behind the neck of the pancreas to form the portal vein. The blood leaving the gut, with its relatively high oxygen content, provides a significant portion of the oxygen supply to the liver.

If the mesentery is not greatly infiltrated by fat and if there are no peritoneal adhesions, the bowel is extraordinarily mobile on its vascular tether. In some individuals jejunal segments may be sufficiently mobilized to allow anastomosis in the neck to replace the cervical esophagus.

The small bowel contains major deposits of lymphatic tissue, particularly in the Peyer's patches of the ileum. There is a rich lymphatic drainage of the entire small bowel, and this plays a major role in fat absorption. Lymphatic drainage proceeds from the mucosa through the wall of the bowel to a set of nodes adjacent to the bowel in the mesentery. Drainage continues to a group of regional nodes adjacent to the mesenteric arterial arcades and then to a group at the base of the superior mesenteric vessels. From there, lymph goes to the cisterna chyli and thence up the thoracic ducts to empty into the venous system in the neck. The lymphatics of the gut play a major role in immune defense and also in the spread of cells arising from neoplasms in the gut.

The small-bowel mucosa is characterized by transverse folds (plicae circulares, or valves or folds of Kerckring), though these are absent in the duodenal bulb and in the distal ileum. They are more prominent in the distal duodenum and the jejunum, where they may reach 1 cm in height and form interlocking transverse ridges (see Fig. 25-2). The small-bowel mucosa has a pink, velvety appearance with a glistening surface. It usually is thicker in the jejunum than in the ileum, where there may be no folds and the surface may be entirely smooth, except for small scattered lymphatic nodules.

The innervation of the small bowel comes from both sympathetic and parasympathetic systems. Parasympathetic fibers come from the vagus and traverse the celiac ganglia. They affect secretion and motility and probably all phases of bowel activity. Vagal afferent fibers are present but apparently do not carry pain impulses. The sympathetic fibers come from the three sets of splanchnic nerves and have their ganglion cells usually in a plexus around the base of the superior mesenteric artery. Their motor impulses affect blood vessel motility and probably gut secretion and motility. Pain from the intestine is mediated through general visceral afferent fibers in the sympathetic system.

Histology

The wall of the small bowel has four layers—the serosa, the muscularis, the submucosa, and the mucosa (Fig. 25-3).

Serosa

The serosa, the outermost layer, consists of visceral peritoneum that encircles the jejunum but covers the duodenum only anteriorly. It consists of a single layer of flattened mesothelial cells.

Muscularis

The muscularis consists of a thin outer longitudinal layer and a thicker inner circular layer of smooth muscle. Specialized gaps in the muscle-cell membranes permit cell-to-cell communication, which facilitates the ability of the muscle layer to function as an electrical syncytium. Ganglion cells from the myenteric (Auerbach's) plexus are interposed between the two muscle layers and send fibers into both layers.

Submucosa

The submucosa is a layer of fibroelastic connective tissue containing blood vessels and nerves. It is the strongest component of the bowel wall and therefore must be included when sutures are placed through the bowel. It contains elaborate networks of lymphatics, arterioles, and venules and an extensive plexus of nerve fibers and ganglion cells (Meissner's plexus). Although frequently subdivided, the nerves from the mucosa, submucosa, and muscle layers are interconnected by small nerve fibers, and cross-connections between adrenergic and cholinergic elements have been described.

Mucosa

Looked on as a device to increase absorptive surface, the small-bowel mucosa is an architectural marvel. The gross transverse folds, the fingerlike villi protruding into the lumen of the bowel, the microvilli (brush border) covering the cells, and the glycocalyx fuzz covering the microvilli each tremendously increase the surface area exposed to luminal contents. Villi protrude 0.5 to 1 mm into the lumen; they are tallest in the distal duodenum and the proximal jejunum and become progressively shorter toward the terminal ileum.

The mucosa can be divided into three layers—the muscularis mucosae, the lamina propria, and the epithelium. The deepest of these, the muscularis mucosae, is a thin sheet of muscle separating mucosa from submucosa. The lamina propria is a continuous layer connective tissue between the epithelium and the muscularis mucosae. It extends into the villi and around the pitlike crypts of Lieberkühn (Fig. 25-4). The lamina propria contains, additionally, a variety of cells—plasma cells, lymphocytes, mast cells, eosinophils, macrophages, fibroblasts, smooth muscle cells—and noncellular connective tissue. The lamina propria is the architectural base on which the epithelium lies, but it also has important functions of its own and apparently serves protectively to combat microorganisms that penetrate the overlying epithelium. The plasma cells are an active site of synthesis of immunoglobulins. In addition, cells in the lamina propria release various mediators (for example, cytokines, arachidonic acid metabolites, and histamine) that can modulate various cellular functions of the overlying epithelium.

The innermost mucosal layer is a continual sheet, one layer thick, of epithelial cells covering the villi and lining the crypts of Lieberkühn (see Fig. 25-4). The main functions of the crypt epithelium are cell renewal and exocrine, endocrine, water, and ion secretion; the main function of the villous epithelium is digestion and absorption. The crypts contain at least four distinct cell types: (1) goblet cells, which secrete mucus; (2) enteroendocrine cells (often called enterochromaffin or argentaffin cells in the older literature), of which there are more than ten distinct populations that produce the gastrointestinal hormones, including gastrin, secretin, cholecystokinin, somatostatin, enteroglucagon, motilin, neurotensin, and gastric inhibitory peptide; (3) Paneth cells, which secrete lysozyme, tumor necrosis factor, and the cryptidins, homologues of leukocyte defensins, and whose function is thought to be related to the host mucosal defense system; and (4) undifferentiated epithelial cells, whose function is to provide for cell renewal. The epithelium of the small intestine is a rapidly proliferating tissue in which old cells are discarded into the lumen and are replaced by newly formed cells that appear to march up from the crypt into the villus in orderly sequence. This trip takes 5 to 7 days in the proximal small bowel, but in the ileum labeled cells may travel from crypt to villous tip in 3 days.

The role of growth factors (e.g., epidermal growth factor, transforming growth factors α and β , insulinlike growth factor, and growth hormone), certain amino acids (glutamine), polyamines, prostaglandins, and gastrointestinal peptides (neurotensin, peptide YY, and glucagonlike peptide-2) in gut epithelial maturation has been the object of extensive recent investigations. All have trophic effects on the small-bowel mucosa; the precise roles, interactions, and importance have not yet been determined.

The epithelium covering the villi consists of scattered endocrine cells, goblet cells, and absorptive cells. The major known functions of the villi are digestion and absorption. These functions are carried out by the absorptive cells, tall columnar cells resting on a thin basement membrane that separates them from the lamina propria. Their luminal surface is covered by microvilli that rest on a terminal web (Fig. 25-5). The microvillar projections multiply the cell surface area exposed to the lumen by 30 times. The microvilli in turn are covered by a fuzzy coat of glycoprotein, the glycocalyx (Figs. 25-6 and 25-7). The microvilli participate actively in absorption and digestion. They contain enzymes for digestion of disaccharides and peptides, and certain cells may contain specific receptors that facilitate absorption (for example, certain ileal cells have receptors for vitamin B₁₂ on their microvilli).

The plasma (or cell) membranes of the epithelial cells consist of three layers and are thicker over the microvilli than over the lateral and basal portions of the cell (see Fig. 25-6). The lateral portion of the plasma membrane also is specialized. There are tight junctions between epithelial cells that prevent communication between intercellular spaces and the lumen. Immediately underneath the tight junction is a narrow space called an intermediate junction, and beneath that is a desmosome, which provides tight attachments of adjacent membrane by binding adjacent cells together. The depths of the tight junctions are greater between adjacent absorptive cells than between adjacent undifferentiated crypt cells. The permeability of the barrier between the intestinal lumen and the space between cells may vary from one location to another.

The cytoplasm immediately beneath the microvilli consists of fine filaments known as the terminal web. This interconnects with filaments forming the core of the microvilli, which contain actin (see Fig. 25-6). Myosin also may be present at the base of the microvilli, and these contractile proteins may allow movement and contraction of the microvilli.

The processes of digestion and absorption within the epithelial cells are carried out by specific organelles (see Fig. 25-5). The mitochondria participate in intracellular oxidation and provide energy for metabolism. The lysosomal sacs contain cytotoxic substances and intracellular waste products. The endoplasmic reticulum is the main synthesizing element within the cell and appears to be responsible for at least two major processes in fat absorption, the resynthesis of triglycerides from absorbed fatty acid fragments, and the synthesis of the lipoprotein coat for chylomicrons. It is also the major synthetic site for intracellular digestive enzymes. The Golgi apparatus segregates, stores, and chemically modifies material that is absorbed and synthesized by the cell.

It may be instructive to review the path of a food element absorbed from the intestinal lumen. Initial contact is with the glycocalyx coating the microvilli, where some digestion may occur. Products of this digestion may go through the microvillous membrane, traversing the terminal web into the cytoplasm. The absorbed material may then move either laterally into the intracellular spaces or into the channels of the endoplasmic reticulum, where it may be biochemically modified and transmitted to the Golgi material, where it may be stored. Eventually the material leaves the cell by crossing either the lateral or the basal plasma (cell) membrane. It penetrates the basal lamina to enter the lamina propria, where it traverses the lymphatic or capillary endothelial cells to gain access to lymph or blood.

Physiology

Motility

Food is propelled through the small bowel by a complex series of muscular contractions. Motility patterns in the small bowel vary greatly between the fed and the fasting states. Pacemaker potentials, probably originating in the duodenum, initiate a series of contractions that propel food through the small bowel. These contractions are of two types—segmentation and peristalsis. Contractions of the circular muscle divide the bowel into segments that are moved to and fro over the column of bowel contents for a short distance. The contents of adjacent segments then combine, and the process is repeated. About 40 percent of contractions are segmental. The circular muscle also initiates peristalsis, circular contractions migrating in an aboral direction, propelling intestinal contents onward. The peristaltic reflex may function independently of extrinsic nerves. Abnormal waves of powerful contractions (*peristaltic rushes*) may rapidly traverse the entire segment of small intestine during episodes of enteritis.

During the interdigestive (fasting) period between meals, the bowel is regularly swept by a series of contractions initiated by the migrating myoelectric complex (MMC). The MMC is under neural and humoral control and initiates a triphasic series of contractions; phase I is resting; in phase II intermittent contractions of moderate amplitude occur; and phase III is the activity front that consists of a brief series of high-pressure waves. The MMC in human beings is stimulated by some (but not all) fluctuating increases in serum concentrations of motilin.

Small-bowel motility is modulated by neural and humoral influences. Extrinsic nerves to the small bowel are vagal and sympathetic. Vagal fibers have two functionally different effects; one is cholinergic and excitatory, and the other is peptidergic and probably inhibitory. Sympathetic fibers from the splanchnics appear chiefly to modulate the activity of intrinsic nerves.

Although gut peptides clearly influence bowel motility, their physiologic function is uncertain, except for the role of motilin in initiating MMC activity. Gastrin, cholecystokinin, and motilin are known to stimulate muscle contraction, whereas muscle activity is inhibited by secretin and often by glucagon (Table 25-1). Cholecystokinin may be physiologically important, since ingestion of a fatty meal may stimulate peristaltic contraction.

Digestion and Absorption

Liters of water and hundreds of grams of food move across the intestinal mucosa from the lumen to the bloodstream each day. The process is remarkably efficient; nearly all food is absorbed unless protected by indigestible cellulose. There is no apparent governor; food absorption is just as efficient in the corpulent as in the starving.

Fat

Most individuals in Western Europe and North America consume 60 to 100 g of fat per day in the form of triglycerides. Fat digestion and absorption occur in the small intestine, where triglycerides are partially hydrolyzed by pancreatic lipase, which splits off the two exposed fatty acids to leave a single central fatty acid still combined with glycerol (beta monoglyceride) plus two fatty acids (Fig. 25-8). The monoglyceride and the fatty acids are poorly soluble in water but combine with bile salts to form micelles. A mixed micelle is composed of bile salts, fatty acids, and the beta monoglyceride, and may also include phospholipids, cholesterol, and fat-soluble vitamins. The micelle must traverse three diffusion barriers in the passive process of entry into the intestinal epithelial cell. These are the unstirred water layer, the mucous coat overlying the brush border, and the lipid bilayer membrane making up the brush border. The micelle may release its fatty acid and monoglyceride component in traversing these barriers. After disaggregation of the micelle, bile salts remain within the intestinal lumen to enter into the formation of other micelles, and the released fatty acids and monoglycerides traverse the plasma membrane into the epithelial cell. The major metabolic pathway within the cell is initiated by reformation of the triglyceride through the interactions of intracellular enzymes (see Fig. 25-8) that are associated with the endoplasmic reticulum.

The triglycerides then combine with cholesterol, phospholipids, and apoproteins to form chylomicrons, which consist of an inner core containing almost all triglycerides with a membranous outer coat of phospholipids and apoproteins. The chylomicron exits the cell from the basolateral region and preferentially enters the central lacteal of the villus, where it

moves to the thoracic duct. Small fatty acids with chain lengths of C₁₀ and less may move directly through the cell into capillaries to flow into the portal vein. The bulk of chylomicron assimilation from the intestinal cell is via lymphatics, but some direct transfer to the portal vein may take place, particularly during periods between meals.

In one of the examples of selective sites of resorption, bile salts are resorbed into the enterohepatic circulation from the distal ileum (Table 25- 2). The total bile salt pool in human beings is about 5 g, and it recirculates about six times every 24 h (the enterohepatic circulation of bile salts). Only about 0.5 g is lost in the stool every day, and this is replaced by resynthesis from cholesterol. All ingested fat is usually absorbed; the small amount appearing in the stool comes from sloughed cells and bacteria.

Protein

Protein digestion is initiated in the stomach, where gastric acid denatures proteins and proteolysis is initiated by activated pepsin. Little actual digestion takes place, however, until protein enters the duodenum and upper jejunum, where they come under the influence of pancreatic proteases. Pancreatic trypsinogen is activated by the duodenal mucosal enzyme enterokinase, and then activated trypsin further activates all proteases. Endopeptidases (trypsin, elastase, chymotrypsin) act on peptide bonds at the interior of the protein molecule, producing peptides that are substrates for exopeptidases (carboxypeptidases), which serially remove a single amino acid at a time from the carboxyl terminal end of the peptide. The final products are amino acids and peptides of two to six amino acid residues. The intraluminal action of pancreatic proteases is efficient and yields 70 percent short-chain peptides and 30 percent amino acids. Short peptides are optimal substrates for the peptide transport mechanism that brings dipeptides and tripeptides into the cell. Of peptides that are assimilated intact, at least 90 percent are hydrolyzed to free amino acids by cytosol peptidases before delivery to the portal venous system.

Carbohydrate

Western men and women take in about 400 g of carbohydrates a day, 60 percent as starch, 30 percent as sucrose, and 10 percent as lactose. Carbohydrates constitute about half the calories ingested in our society, but in underdeveloped countries they typically provide a much higher proportion.

Starch is a polysaccharide consisting of long chains of glucose molecules. Amylose makes up 20 percent of starch in the diet and has an alpha glucose-to-glucose bridge. Amylopectin (80 percent of dietary starch) has branching points every 25 molecules along the straight glucose chains. Both have an alpha₁₋₄ glucose-linked chain. Alpha amylase attacks the alpha₁₋₄ linkage and converts amylose to maltotriose and maltose. Amylase converts amylopectin to shorter dextrans. Intraluminal digestion of starch in the duodenum is rapid, because of the huge amounts of pancreatic amylase, and digestion often is complete by the time the chyme enters the jejunum.

The enzyme responsible for final surface digestion is concentrated in the brush border of the luminal surface (Fig. 25-9). After dietary carbohydrate is reduced to monosaccharides by surface digestion, transport of the released hexoses (glucose, galactose, or fructose) is carried out by a specific process. Glucose and galactose are actively transported across the intestinal membrane, whereas fructose is absorbed by facilitated diffusion. The rate-limiting phenomenon for most carbohydrate absorption occurs during transport through the intestinal cell, but luminal hydrolysis of lactose is slower than its transport capacity, so surface hydrolysis of lactose is rate-limiting.

Water and Electrolytes

In addition to ingested water, salivary, gastric, biliary, pancreatic, and intestinal fluids contribute up to 8 to 10 L of water per day, and all but about 0.5 L per day is resorbed proximal to the ileocecal valve. The small bowel secretes and absorbs huge amounts of water. Net absorption is the algebraic sum of two fluxes going in opposite directions. Water may simply diffuse in or out of the cell or may be drawn through by osmotic or hydrostatic pressures. The osmotic pressures result from active transport of sodium, glucose, or amino acids into cells. Diffusion occurs through pores in plasma cell membranes. Jejunal pores are larger (7 to 9 Å) than those in the ileum (3 to 4 Å). Hypertonic solutions in the duodenum and upper jejunum are rapidly equilibrated to isotonicity by the influx of large amounts of water.

Sodium and chloride are absorbed from the small bowel by active transport, by coupling to organic solutes, and by cotransport on carriers of neutral sodium chloride. A small portion of sodium absorption in the jejunum is by active transport, but the bulk is by coupling to organic solutes. In the ileum sodium is absorbed against steep gradients and is not stimulated by glucose, galactose, or bicarbonate. Bicarbonate is absorbed by a sodium-hydrogen exchange, so that one bicarbonate ion is released into interstitial fluid for every hydrogen ion secreted. Calcium is absorbed by active transport, particularly in the duodenum and jejunum. Absorption appears to be facilitated by an acid environment and is enhanced by vitamin D and parathormone. Potassium appears to be absorbed by passive diffusion.

Endocrine Function

The mucosa of the small bowel is the primary source of regulatory peptides of the gut, and the muscle wall of the small bowel is rich in peptidergic nerves containing neuroendocrine peptides. Although we often call these agents hormones, they do not always function in a truly endocrine fashion; that is, the active peptides are not always discharged into blood vessels to act on some distant site. Sometimes they are discharged and act locally in a paracrine fashion (for example, bombesin [gastrin-releasing peptide] and somatostatin), or they may serve as neurotransmitters, or they may be discharged into blood vessels after nerve stimulation in a true neuroendocrine manner. We will briefly describe some of these agents.

Secretin

The discovery of secretin in 1902 gave birth to the entire field of endocrinology. Secretin is a 27–amino-acid, helical peptide that is present in specialized cells in the small-bowel mucosa and is released by acidification or by contact with bile and perhaps fat. It acts to stimulate release of water and bicarbonate from pancreatic ductal cells, and when this combination flows into the duodenal lumen the bicarbonate neutralizes gastric acid. The amount of pancreatic bicarbonate released after a meal closely approximates the amount of acid secreted by the stomach. Secretin also acts to stimulate the flow of bile and to inhibit gastrin release, gastric acid secretin, and gastrointestinal motility. Secretin has the unique ability to release gastrin from gastrinomas, and intravenous secretin is used as a diagnostic test in patients in whom the Zollinger-Ellison syndrome is suspected.

Cholecystokinin

Cholecystokinin (CCK) is released from small-bowel mucosa by contact with certain amino acids (especially tryptophan and phenylalanine) and medium- to long-chain fatty acids. In addition, the concentration of intraluminal trypsin and bile acids inversely regulates CCK release. CCK has two major actions: it stimulates contractions of the gallbladder and relaxation of the sphincter of Oddi, and it stimulates the secretion of enzymes by pancreatic acinar cells. CCK also stimulates growth of bowel mucosa and pancreas, stimulates bowel motility, and releases insulin. CCK exists in multiple molecular forms (CCK-8, CCK-33, and CCK-39, among others), and the larger forms contain the smaller ones. CCK and gastrin share the identical C-terminal tetrapeptide (Trp-Met-Asp-Phe-NH₂), which explains many of the similarities in their actions.

Other Peptides

Largely through the efforts of Viktor Mutt and colleagues at the Karolinska Institute, several active agents have been isolated from the mucosa of the small bowel that greatly influence physiologic activities of the gut. Of these, only *gastric inhibitory polypeptide* (GIP) has satisfied rigid criteria for hormonal status, but others will be discussed as well. GIP is a 43–amino- acid peptide member of the secretin-glucagon family that is released by fat. Although it was initially studied for its properties of inhibition of gastric secretion, later studies showed that it was a prime incretion candidate, because it greatly stimulated insulin release when levels of glucose were elevated. Glucose-stimulated release of intestinal GIP apparently solves the conundrum posed by the fact that oral ingestion of a fixed amount of glucose releases more insulin than intravenous administration of the same amount. A family of peptides reacting with glucagon antibodies is present in small-bowel mucosa, and it has been given a variety of names. *Enteroglucagon* is a term used to designate all such gut peptides. It inhibits bowel motility. Recent findings suggest that glucagonlike peptide-2 (GLP-2), a 33–amino-acid peptide, is a potent enterotrophic factor. *Vasoactive intestinal peptide* (VIP) is a 28–amino-acid basic peptide of the secretin-glucagon family that appears to function chiefly as a neuropeptide. VIP is a potent vasodilator, and it stimulates pancreatic and intestinal secretion and inhibits gastric acid secretion. It is the chief agent in the watery diarrhea syndrome caused by pancreatic endocrine tumors. *Motilin* is a 22–amino-acid peptide widely distributed through the gut. It causes contraction of intestinal smooth muscle, including the gallbladder, and appears to be involved in the interdigestive pattern of gut motility. *Bombesin* is a 14–amino-acid peptide that was first isolated from frog skin. It has the capacity to release all gut peptides except secretin. Its mammalian equivalent, gastrin-releasing peptide, is present in small-bowel mucosa, where it probably serves as an “on” switch, regulating release of gastrointestinal hormones. *Somatostatin* is a 14–amino-acid peptide that was first isolated from the brain; it is also widely distributed in the gut, where it probably functions in a paracrine fashion as an “off” switch to inhibit gut hormone release and gastrointestinal secretion. *Neurotensin*, a 13–amino-acid peptide produced in large part by endocrine cells in the ileal mucosa, stimulates water and HCO₃⁻ secretion from the pancreas, inhibits gastric secretion, and has trophic effects for small and large bowel mucosa. *Peptide YY* (PYY) is a 36–amino-acid peptide in the distal ileum and colon. It inhibits gastric and pancreatic secretion, has no effect on gallbladder motility, and exhibits trophic effects on small-bowel mucosa. PYY is released by perfusion of the colon with fat and may be involved in the physiologic inhibition of pancreatic secretion.

Immune Function

We ingest thousands of bacteria, parasites, and viruses every day. Only a few of these are pathogenic, but the huge surface of the small-bowel mucosa represents a massive potential portal of entry. An important component of bowel defense is the secretory immune system, which produces a special group of antibodies that resist bacterial proliferation, neutralize viruses, and minimize the penetration of enterotoxins.

The small bowel is a major source of immunoglobulin A (IgA). Cells of the lamina propria of the small intestine contain plasma cells that produce IgA. The population of cells producing IgA (the secretory immunoglobulin) is ten times greater than that producing IgG (the antibody mediating general humoral immunity).

Antigens from the intestinal lumen crossing the mucosal barrier contact M cells overlying lymphoid nodules. These cells are specialized for uptake and transport of antigen, which they convey to the underlying lymphoblasts that produce IgA. After interacting with the antigen, the lymphoblasts migrate to the regional lymph nodes, from which they enter the systemic circulation. They then are returned to the intestine, where they are widely distributed in the lamina propria (Fig. 25-10). In the lamina propria, they differentiate into plasma cells that produce a specific IgA antibody directed to the absorbed antigen. This IgA antibody traverses the epithelial cell to the lumen by means of a protein carrier (the secretory component) that not only transports the IgA but also protects it against the intracellular lysosomes. The antibodies at the free surface of the cell collect in the glycocalyx, where they are in a strategic position to combat new antigens, preventing their attachment to the cell membrane and achieving immune exclusion.

Passage of viable bacteria from the intact gastrointestinal tract to the mesenteric lymph nodes and beyond, which has been termed *bacterial translocation*, has been implicated as a possible mechanism to explain septic complications and multiple organ system failure in burn and trauma patients. Small-intestinal mucosal integrity and function are profoundly affected by systemic injury. Cutaneous burn injury and sepsis cause early mucosal atrophy and subsequent defect in the gut mucosal barrier. This allows escape from local gut immune surveillance. One possible therapeutic strategy to prevent bacterial translocation and its systemic complications may involve stimulation of gut mucosal growth and maintenance of mucosal integrity and function during the early stages after systemic injury. Numerous gut peptides (e.g., gastrin, neurotensin, bombesin, epidermal growth factor) have trophic effects on small-intestinal mucosa; these growth factors may prove to be important in the development of therapeutic strategies for prevention of bacterial translocation. The magnitude of this problem, however, remains to be completely determined. In addition, the effects of polyamines on gastrointestinal growth suggest that these small polycationic substances play a central role of the regulation of intestinal cell growth and differentiation. The activity of ornithine decarboxylase (ODC), the rate-limiting enzyme

in polyamine biosynthesis, is increased dramatically in instances associated with mucosal growth and repair in the duodenum and in the remaining small bowel after injury.

The exact mechanisms that maintain the epithelial integrity of the gastrointestinal tract remain largely unknown. Recent studies suggest that members of the trefoil peptide family, proteins secreted throughout the small intestine and colon in response to injury, are important in stimulating mucosal repair, since transgenic mice lacking intestinal trefoil factor demonstrated poor epithelial regeneration and mucosal healing after injury. Moreover, mice overexpressing the trefoil peptide pS2 have an increased resistance to intestinal damage.

Gut-associated lymphoid tissue (Fig. [25-11 A](#)) consists of the cells of the mucosal immune system located between the external environment (intestinal lumen) and the internal milieu of the host. Follicle-associated epithelial cells are located over Peyer's patch areas (in animals) or lymphoid follicles (in human beings), in which immature germinal center cells and B cells reside. Antigens from the intestinal lumen are transported through specialized epithelial cells called M cells. After being brought across the follicle-associated epithelium, the antigens come into contact with lymphocytes and macrophages. A subcompartment of T suppressor/cytotoxic lymphocytes called *intraepithelial lymphocytes* resides between absorptive epithelial cells. In animals most intraepithelial lymphocytes bear the gamma/delta T cell receptor. Within the lamina propria, mature T cells, B cells, plasma cells, and macrophages carry out cell-mediated immunologic processes, including cytokine secretion, production of IgA, and phagocytosis. Two different types of mast cells (mucosal mast cells and connective tissue mast cells) are found in the mucosa and submucosa.

Antigens within the intestinal lumen (Fig. [25-11 B](#)) are transported across specialized epithelial cells (M cells) into contact with underlying lymphoid cells. Antigen-induced activation of macrophages leads to secretion of interleukin-1 and activation of helper T cells, which secrete interleukin-2. Activation of intraepithelial lymphocytes and subsequent production of γ -interferon leads to enhanced production of major histocompatibility complex (MHC) class II molecules by epithelial cells. Increased numbers of MHC class II molecules on intestinal epithelial cells may lead to enhanced antigen presentation by intestinal epithelial cells, with subsequent augmentation of antigen-specific IgA antibody production. The expansion of IgM-bearing B cells is regulated by switch factors that favor the development of IgA-bearing B cells. T cells secreting interleukin-4, interleukin-5, and interleukin-6 induce the differentiation and proliferation of B cells for subsequent maturation into plasma cells, which synthesize and secrete dimeric IgA with J chain. The dimeric IgA with J chain then interacts with secretory component receptor on the basal membrane of epithelial cells for subsequent secretion into the intestinal lumen.

Inflammatory Diseases

Crohn's Disease

Background

Crohn's disease is a chronic granulomatous disease of the alimentary tract of unknown cause that is characterized by intermittent periods of remission and exacerbation. Although earlier reports described the gross and microscopic pathologic features of this disease, it was not until the paper by Crohn, Ginsburg, and Openheimer in 1932 that the disease process was clearly and completely described. In the introduction to their landmark paper, they stated: "We proposed to describe, with pathologic and clinical details, a disease of the terminal ileum affecting mainly young adults, characterized by a subacute or chronic necrotizing and cicatrizing inflammation. The ulceration of the mucosa is accompanied by a disproportionate connective tissue reaction of the remaining walls of the involved intestine, a process which frequently leads to stenosis of the lumen of the intestine, associated with the formation of multiple fistulas."

Many different terms have been used to describe this disease process, such as regional ileitis, transmural enteritis, and granulomatous enteritis, but because of its multiple clinical appearances and because the disease is not confined to the terminal ileum, Crohn's disease has been universally accepted as its name.

Incidence and Epidemiology

Crohn's disease is the most common surgical disease of the small bowel. The annual incidence of Crohn's disease is approximately 3 to 6 cases per 100,000 of the general population, with the incidence highest in North America and northern Europe. The incidence is higher in patients in the third decade of life; however, a bimodal distribution is apparent, with a second, smaller peak in the sixth decade of life. Crohn's disease is more common in urban dwellers, and there may be a slight female predominance; some studies report an incidence approximately 20 percent higher in females, though others report a similar incidence in males and females. The risk of developing Crohn's disease is about two times higher in smokers than nonsmokers. Although Crohn's is uncommon in African blacks, blacks in the United States have rates similar to whites, suggesting that environmental influences play a role in the disease. There is a familial association, with the risk of developing Crohn's disease increased 30-fold in siblings of patients with the disease and 13-fold for all first-degree relatives.

Etiology

The cause of Crohn's disease remains unknown. Several possibilities have been suggested, including infectious, immunologic, environmental, and genetic causes.

Although controversial, proposed infectious causes that have received more than passing interest include mycobacterial infections, particularly *Mycobacterium paratuberculosis* and *M. avium*. The existence of atypical mycobacteria as a cause for Crohn's was proposed by Dalziel in 1913. Subsequent studies using the polymerase chain reaction (PCR) technique have confirmed the presence of these mycobacteria in intestinal samples of patients with Crohn's disease. Furthermore, the transplantation of intestinal samples from patients with Crohn's disease into other species has resulted in an ileitis. Koch's postulates, however, have yet to be rigorously satisfied since empirical therapy with antimicrobial agents in well-controlled clinical trials failed to ameliorate the disease process. In addition to mycobacteria, other potential sources include persistent measles virus and *Yersinia enterocolitica*.

Immunologic abnormalities that have been identified in patients with Crohn's disease have included humoral as well as cell-mediated immune reactions directed against gut cells, suggesting autoimmunity. There has been no direct correlation between these abnormalities, immunologic reactivity, and the development of Crohn's disease; therefore, these findings may represent an epiphenomenon. Other etiologic factors such as environmental and dietary factors, smoking, and psychosomatic causes have been suggested but never proved.

Genetic factors appear to have a role in the etiology of Crohn's disease, since the single strongest risk factor, by far, is having a relative with the disease. Recent European and American studies have identified a putative susceptibility locus in the centromeric region of chromosome 16 in multiply affected family members, further suggesting a genetic role in Crohn's disease. The advent of molecular biologic techniques has greatly enhanced our understanding of this disease; however, the development of an animal model (e.g., knockout mice) that simulates the findings of Crohn's disease in humans would be a great help to our understanding of this disease.

Pathology

Crohn's disease is an inflammatory disorder that is transmural in nature and associated with varying degrees of fibrosis. It can affect any portion of the gastrointestinal tract. The terminal ileum is involved in approximately 90 percent of patients with Crohn's disease; however, only about one-third of patients have small-bowel involvement alone.

Microscopic Features

The histologic features of Crohn's disease vary, but some occur with sufficient consistency to create a pattern that, though not specific, is at least characteristic of the disease. Some understanding of the pathogenesis may be gained by observing the progression of changes from early to late phases of regional enteritis.

Intense mucosal and submucosal edema may be seen microscopically before any gross changes are apparent. The earliest gross pathologic lesion is a superficial aphthous ulcer. As the disease progresses, the ulceration becomes more pronounced, and complete transmural inflammation results (Fig. [25-12 A](#)). The inflammatory reaction is characterized by extensive edema, hyperemia, lymphangiectasia, an intense infiltration of mononuclear cells and hyperplasia of lymphoid follicles. The ulcers are characteristically linear and may coalesce to produce transverse clefts and sinuses that result in the characteristic cobblestone appearance of the mucosa. Thickening and hypertrophy of the submucosa and the muscularis result in narrowing of the gut lumen; obliterative lymphangitis occurs; the bowel wall becomes thickened and edematous and quite rigid. Granulomas appear later and are found in the bowel wall and in regional lymph nodes in 60 to 70 percent of patients. These are noncaseating granulomas with Langhans' giant cells (Fig. [25-12 B](#)).

Macroscopic Features

At operation, one observes thickened, grayish pink or dull purple-red loops of bowel with areas of thick, gray-white exudate or fibrosis of the serosa. Areas of diseased bowel separated by areas of grossly normal bowel, called skip areas, are commonly encountered. A striking finding of Crohn's disease at operation is extensive fat-wrapping, caused by circumferential growth of the mesenteric fat around the wall of the bowel. The thickened bowel wall is firm, rubbery, and virtually incompressible (Fig. [25-13](#)). The uninvolved proximal bowel often is dilated as a result of the considerable degree of obstruction in the diseased segment. Involved segments often are adherent to adjacent loops or other viscera, or several loops may be matted together into a bulky conglomerate mass. Internal fistulas are common in such adherent areas. The mesentery of the segment is characteristically greatly thickened, dull, and rubbery and contains masses of lymph nodes up to 3 or 4 cm in diameter.

Clinical Manifestations

Although Crohn's disease can occur at any age, the typical patient is a young adult, and the majority present before the age of 40 years. The onset of disease is often insidious, with a slow, protracted course. There are symptomatic periods of abdominal pain and diarrhea interspersed with varying intervals of remission; but over time, symptomatic periods gradually become more frequent, more severe, and longer lasting. Pain (the most common symptom) usually is intermittent and cramping early in the course of the disease but may develop into persistent, dull, aching abdominal pain, most prominent in the lower abdomen. Diarrhea is the next most frequent symptom and is present, at least intermittently, in 85 percent of patients. The frequency of stools is less than in patients with ulcerative colitis, numbering two to five daily, and the stools rarely contain the mucus, pus, or blood seen in ulcerative colitis. Fever is present in about one-third of the patients, and moderate weight loss, loss of strength, and malaise, in over one-half. Frank nutritional disorders and steatorrhea are uncommon before surgical treatment.

The main intestinal complications of Crohn's disease include obstruction and perforation. The obstruction occurs as a result of chronic disease with fibrosis and progressive narrowing of the bowel lumen and can be partial or complete. Perforations can occur into the free peritoneal cavity and present as a generalized peritonitis. More commonly, however, development of fistulas and intraabdominal abscesses occurs. Fistulas can develop between the diseased bowel and any adjacent organ, such as small or large bowel, urinary bladder, vagina, or stomach, and through the skin, usually at the site of a previous laparotomy. Patients with Crohn's colitis may develop toxic megacolon, demonstrated by marked colonic dilatation, abdominal tenderness, fever, and leukocytosis. A potential intestinal complication of long-standing Crohn's disease is cancer of the affected segment of intestine, which occurs with an incidence six times greater than that of the general population. Cancers in patients with Crohn's disease tend to be more advanced when identified and, therefore, have a worse prognosis.

Perianal disease (fissure, fistula, stricture, or abscess) is common, occurring in 25 percent of patients with small-intestinal disease, 41 percent of patients with ileocolitis, and 48 percent of patients with exclusively colonic involvement. Perianal disease is the sole presenting feature in 5 percent of patients and may precede the onset of intestinal disease by

months or years. Crohn's disease should be suspected in any patient with multiple, chronic, recurrent perianal fistulas. Extraintestinal manifestations of Crohn's disease occur in about 30 percent of patients and include arthritis and arthralgia, uveitis and iritis, hepatitis and pericholangitis, and erythema nodosum and pyoderma gangrenosum.

Diagnosis

Patients with chronic, recurring episodes (often of long duration) of abdominal pain, diarrhea, and weight loss should be evaluated for Crohn's disease with endoscopy or radiographic studies.

When the colon is involved, sigmoidoscopy or colonoscopy reveals characteristic aphthous ulcers with granularity and a normal-appearing surrounding mucosa. With more progressive and severe disease, the ulcerations involve more and more of the bowel lumen and may be difficult to distinguish from ulcerative colitis. The presence of discrete ulcers and cobblestoning, however, particularly when discontinuous segments of bowel are involved, favors the diagnosis of Crohn's disease.

Radiographic studies of the small bowel reveal a number of findings, including a nodular contour, diffuse narrowing of the lumen, sinuses, clefts, linear ulcers, separation of bowel loops, and asymmetrical involvement of the bowel wall. A cobblestone appearance of the mucosa, composed of linear ulcers, transverse sinuses, and clefts, may be apparent. Long lengths of narrowed terminal ileum (Kantor's string sign) may be present in long-standing disease (Fig. 25-14). Fistulas between adjacent organs may be apparent (Fig. 25-15). Computed tomography may be useful to resolve diagnostic problems by ascertaining the nature of mass effects such as abscesses, separation, or displacement of segments of small intestine (Fig. 25-16).

Medical Treatment

The medical treatment of Crohn's disease is largely symptomatic and empiric and usually is followed by remissions and exacerbations until a complication that requires surgical intervention supervenes. Goals of medical therapy are relieving abdominal pain, controlling diarrhea, treating infection, and correcting any nutritional deficiencies.

Intraluminal antibiotics, particularly sulfasalazine (Azulfidine), have significant beneficial effects in certain patients. Corticosteroids, such as prednisone or the newer agent budesonide, are also useful in effecting remission of symptoms during acute exacerbations of ileitis, and a combination of sulfasalazine and steroids may be used to maintain patients for a short period after resolution of an acute inflammatory episode. Long-term maintenance therapy, with either agent alone or in combination, however, has not been shown to be of benefit in preventing recurrence of the disease. Although there have been implications of immunologic abnormalities in Crohn's disease, immunosuppressive treatment with azathioprine, 6-mercaptopurine, and cyclosporine have not been shown conclusively to be advantageous in comparison with placebo. Other immune modulators that have been tested in clinical trials with varying success include interleukin-1 receptor antagonists, monoclonal antibodies directed against helper T cells, and a diphtheria toxin–fused protein that is cytotoxic to cells that have receptors for interleukin-2. Therapies reported to be of possible benefit in early clinical trials include zileuton, a potent and specific inhibitor of the enzyme lipoxygenase that metabolizes arachidonic acid to leukotrienes, and superoxide dismutase, which blocks the toxicity of oxygen radicals; more clinical data are required before these agents can be advocated. Systemic antibiotics are valuable in the management of infectious complications but have no effect on the primary disease process and should not be considered therapeutic.

Chemically defined elemental diets and total parenteral nutrition have been touted as beneficial, even curative, in patients with acute Crohn's disease and in patients with complications such as enterocutaneous fistulas. No specific long-term benefit with any of the dietary measures has been shown; however, complete abstinence of oral intake with total parenteral nutrition may lead to temporary remission of symptoms in some patients. The provision of adequate nutrition is much more important in preparing patients for operation than it is for cure.

Surgical Treatment

Indications

Although medical management is certainly indicated during acute exacerbations of disease, the majority of patients with chronic Crohn's disease will require operation sometime during the course of their illness. In patients with more than 20 years of disease, the National Cooperative Crohn's Disease Study (NCCDS) has reported that the cumulative probability of operation was 78 percent. Indications for operation are limited to complications, including obstruction, abscess, fistula, free perforation, urologic complications, hemorrhage, cancer, and perianal disease. Children with Crohn's disease and resulting systemic symptoms such as growth retardation may benefit from resection. The extraintestinal complications of Crohn's disease, though not a primary indication for operation, often subside after resection of involved bowel.

General Tenets

Cure of patients with Crohn's disease is not possible by either medical or surgical therapy; therefore, operative intervention in patients with Crohn's disease should be directed to treating complications, and only the segment of bowel involved in the complicating process should be resected. Even if adjacent areas of bowel are clearly diseased, they should be ignored. Early in the history of surgical treatment of Crohn's disease, many surgeons tended toward wide resection in an attempt to effect cure. Repeated wide resections lead to the short bowel syndrome, a devastating surgical complication. In the past, the most common cause of the short bowel syndrome was repeated resections for Crohn's disease. During the past two decades or more most surgeons have accepted the view that it is not possible to surgically eradicate this disease. We have, for example, given up frozen-section study of the resected margin because we generally limit our resection to areas that are grossly involved adjacent to sites of obstruction or fistulization. We ignore microscopic evidence of involvement.

Management of Specific Problems

Acute Ileitis

There is a subgroup of patients with acute abdominal signs and symptoms in whom the usual preoperative diagnosis is acute appendicitis. At operation, the appendix is found to be normal, but the terminal ileum is edematous and beefy red, having a thickened mesentery with enlarged lymph nodes. The condition is acute ileitis, a self-limited disease that does not lead to subsequent development of Crohn's disease. The precise cause of acute ileitis is unknown; however, some patients have been found to have *Yersinia* or *Campylobacter* infections.

The role of appendectomy in these circumstances is less controversial now than it was in the past. In the absence of acute inflammatory involvement of the appendix or the cecum, appendectomy should be performed. This eliminates the possibility of acute appendicitis in the differential diagnosis of any subsequent abdominal complaints in these patients. In the few patients who have developed enterocutaneous fistulas after appendectomy, the fistulas originated from the ileum in all cases.

Obstruction

Intestinal obstruction is the most frequent indication for surgical therapy in most large series of patients with Crohn's disease. Obstruction in these patients often is partial, and nonoperative management is indicated initially. Operative intervention is required in instances of complete obstruction and in patients with partial obstruction that does not resolve with nonoperative management. The optimum treatment of complications of Crohn's disease is surgical resection of the involved segment with restoration of intestinal continuity (Fig. 25-17). As previously noted, the extent of resection is dictated by the extent of the complication. A short area of profound Crohn's ileitis producing partial obstruction (not involving the ileum immediately adjacent to the ileocecal valve) should be treated by local resection and primary anastomosis. It is common for the cecum and ascending colon to be involved contiguously with the terminal ileum in the disease process. In this case, the diseased bowel is removed and the ileum anastomosed to the transverse colon. No attempt should be made to dissect lymph nodes up to the origin of the ileocolic artery, since this may compromise the blood supply to uninvolved intestine. When two grossly abnormal segments of bowel have a short intervening segment of apparently normal bowel, the question arises of whether to try to save the normal "skip area." The answer depends on the length of the intervening normal segment. If it is 10 cm or longer, it probably should be saved. If it is 5 cm or shorter, it should be taken. Both areas would be excised in this instance, but each case must be individualized, and the answer will depend also on the configuration of the blood supply, the mobility of the mesentery, and other local factors. If previous resections have left the bowel critically short, we may go to great lengths to preserve small segments.

In selected patients with obstruction caused by strictures (either single or multiple), one option is to perform a stricturoplasty that effectively widens the lumen but avoids excision. Stricturoplasty is performed by making a longitudinal incision through the narrowed area of intestine followed by closure in a transverse fashion (Fig. 25-18). This technique preserves intestine and is associated with complication and recurrence rates comparable to resection. In the past, bypass procedures were commonly used, but today, bypass with exclusion is used only in elderly, poor-risk patients, in patients who have had several prior resections and can ill afford to lose any more bowel, and in patients in whom resection would necessitate entering an abscess or endangering normal structures. The reasons for this are twofold: the disease often persists in the bypassed segment with development of intraabdominal sepsis, and cancer may occur in the bypassed segment.

Fistula

Fistulas in patients with Crohn's disease usually are enteroenteral or enterocutaneous. The presence of a radiographically demonstrable enteroenteral fistula without any signs of sepsis or other complication is not in itself an indication for operation. The vast majority of patients who have radiographic demonstration of enteroenteral fistulas, however, will develop later complications, most commonly sepsis, and will require resection of the fistula. Enterocutaneous fistulas are rarely spontaneous, but follow resections or external drainage of intraabdominal abscesses. Enterocutaneous fistulas should be managed by excising the area of grossly involved small intestine and debriding the fistulous tract through the abdominal wall from the inside. After the bowel is reanastomosed, it should be separated, if possible, from the abdominal wall with omental fat. The formation of enteroenteric or enterovesical fistulas usually involves either a previous intestinal perforation with formation of a walled-off abscess that finally perforates or the adherence of one diseased loop of bowel to another diseased loop of bowel or an adjacent normal organ. If the fistula forms between two or more adjacent loops of diseased bowel, the entire involved segment should be excised. On the other hand, if the fistula involves an adjacent normal organ, such as the bladder or the colon, only the segment of the diseased small bowel and fistulous tract should be resected, and the defect that is left in the normal organ is simply closed. The majority of patients with ileosigmoid fistulas do not require resection of the sigmoid because the disease is confined to the small bowel. If the segment of sigmoid involved in an ileosigmoid fistula is found to have Crohn's disease, it should be resected along with the segment of diseased small bowel. The extent of surgical resection in patients with Crohn's disease depends on the extent of critical involvement (Fig. 25-19).

Free Perforation

Perforation into the free peritoneal cavity is not common but occurs occasionally. Free perforation usually occurs in a diseased segment of bowel but can also occur in bowel proximal to an obstruction. The segment should be resected back to relatively good bowel on each side of the perforation, and no attempt should be made to eradicate all diseased bowel. If generalized peritonitis is present, an anastomosis should not be done, because there is a high rate of anastomotic dehiscence under these circumstances; an ileostomy should be performed until intraabdominal sepsis is controlled. Later restoration of intestinal continuity can be carried out safely.

Urologic Complications

The most common urologic complication is ureteral obstruction, which is usually due to ileocolic disease with retroperitoneal abscess. Surgical treatment of the primary intestinal disease is adequate in most patients; however, in a few instances of long-standing inflammatory disease, periureteral fibrosis may be present and require extensive ureterolysis.

Hemorrhage

Although anemia from chronic blood loss is common, life-threatening hemorrhage in patients with Crohn's disease is rare. The incidence of clinical hemorrhage is more common when Crohn's disease involves the colon rather than the small bowel, but both occur much less frequently than bleeding in patients with ulcerative colitis. When life-threatening hemorrhage occurs, the segment involved should be resected and intestinal continuity restored; arteriography may be useful to localize the bleeding before surgery.

Growth Retardation

Up to one-fourth of children with Crohn's disease have significant growth retardation, which may precede the appearance of active bowel disease. The major reason for this growth retardation appears to be nutritional sequelae that accompany Crohn's disease. In these children, in the absence of other common indications, bowel resection is indicated; resection often results in restoration of normal growth when it is performed before epiphyseal closure has occurred. As in adults, children with Crohn's disease tend to have disease of the terminal ileum and colon and can be treated with limited resection and reanastomosis. Involvement of the colon and rectum appears to be more virulent and may require proctocolectomy before restoration of growth is accomplished.

Cancer

Until recently, a causal relation between Crohn's disease and the development of cancer was not accepted. Although cancer does not occur at the rate it does in patients with ulcerative colitis, a number of reports have clearly demonstrated that patients with long-standing Crohn's disease have an increased incidence of cancer. The management of these patients is the same as in any patient with cancer—that is, resection of the cancer with appropriate margins and regional lymph nodes. Patients with cancer associated with Crohn's disease tend to have a worse prognosis than those who do not have Crohn's. This can be explained in large part by the fact that many of these patients are initially managed medically and therefore present at a later time.

Anorectal Disease

Treatment of perianal disease should be conservative; wide excision of abscesses or fistulas is not indicated. Definitive fistulotomy is indicated in the majority of patients, although one must recognize that some degree of anal stenosis may occur as a result of the chronic inflammation. Fissures usually are lateral, relatively painless, large, and indolent, and they usually respond to conservative management. Abscesses should be drained, but large excisions of tissue should not be performed.

Colorectal Disease

The same principles apply to the management of Crohn's disease that is limited to the colon and rectum as to disease in the small intestine. Operative indications include a lack of response to medical management or complications of Crohn's disease. As much bowel as possible should be conserved. Procedures include segmental colectomy with colocolic anastomosis, subtotal colectomy with ileoproctostomy in a patient with mild or minimal rectal disease, and total proctocolectomy with Brooke ileostomy. Patients with a toxic megacolon should undergo colectomy, closure of the proximal rectum, and end ileostomy.

A potential problem after proctocolectomy is delayed healing of the perineal wound. Several series have reported that 25 to 60 percent of perineal wounds are open 6 months after operation. Persistent nonhealing wounds require excision with secondary closure or closure with the use of musculocutaneous flaps (most commonly gracilis or gluteus maximus flaps). Continence-preserving operations such as ileoanal-pouch anastomoses or continent ileostomies (Kock pouch) that have been used successfully in patients with ulcerative colitis are not recommended for patients with Crohn's colitis because of the high rate of recurrence of Crohn's disease in the pouch, fistulas to the anastomosis, and peripouch abscesses.

Duodenal Disease

Crohn's disease of the duodenum requiring operative intervention is rare. The primary indication for surgery in these patients is duodenal obstruction that does not respond to medical therapy. Gastrojejunostomy to bypass the disease, rather than duodenal resection, is the procedure of choice; however, stricturoplasties have been performed with success in selected patients.

Prognosis

There is no medical or surgical cure for Crohn's disease. A substantial proportion of patients who have had one operation will require another operation for complications of Crohn's disease. In one study the cumulative recurrence rates were reported to be 29 percent at 5 years, 52 percent at 10 years, 64 percent at 15 years, and 84 percent at 25 years. No important differences were noted between disease location and the type of operation. Which patients will develop recurrent disease cannot be predicted. Sex, age, duration of disease, granulomas, enteral or perirectal fistulas, length of resection, length of diseased gut, and proximal resection margin have no significant influence on the rate of disease recurrence or on functional outcome. The most common site of recurrence is the small bowel proximal to the site of previous resection. Recurrence is five times more likely to involve the adjacent or remote colon in patients with ileocolitis than in patients with ileitis. Few patients with ileitis eventually require ileostomy, whereas one-third of patients with ileocolitis or colitis require permanent ileostomy.

Crohn's disease gradually recedes with advancing age. Active disease is unusual between the ages of 50 and 55 years, but gradual cicatrization on healing may cause bowel obstruction in older patients.

Tuberculous Enteritis

A resurgence in the incidence of tuberculosis has occurred in Western countries as a result of the growing AIDS epidemic, an influx of Asian immigrants, and widespread use of immunosuppressive agents after organ transplantation. Tuberculosis continues to be a significant and relatively common disease in developing countries with incidences as high as 400 to 500 people per 100,000 in some countries. Tuberculosis of the gastrointestinal tract occurs in two forms. Primary infection usually is caused by the bovine strain of *Mycobacterium tuberculosis* and results from ingesting infected milk; this now accounts for less than 10 percent of reported cases. The majority of infections occur secondarily from the swallowing of bacilli by patients with active pulmonary tuberculosis. Chemotherapy has greatly decreased the incidence of secondary tuberculous enteritis, so that it now occurs in only about 1 percent of patients with pulmonary tuberculosis.

The ileocecal region is the site of involvement in about 85 percent of patients with tuberculous enteritis, presumably because of the abundance of lymphoid tissue in this area. Three patterns of involvement are seen: hypertrophic, ulcerative, and ulcerohypertrophic.

Occasionally a hypertrophic reaction produces contracture and stenosis of the lumen of the distal ileum, which requires resection. The diagnosis is not often made preoperatively; only 50 percent of patients have evidence of active pulmonary tuberculosis; 45 percent of patients have negative skin tests. Cultures, when positive, provide a definitive answer, but results may take longer than 4 weeks. The polymerase chain reaction technique has been used successfully to differentiate tuberculosis enteritis from Crohn's disease in biopsy specimens; results may be obtained within 2 days. If the diagnosis is suspected preoperatively, chemotherapy, best given as a combination of isoniazid (100 mg three times a day) with either rifampin (600 mg daily) or ethambutol (15 mg/kg daily), should be administered for about 2 weeks before operation. If unsuspected tuberculosis is found at operation, chemotherapy should be started. In either case drugs should be continued for 1 year after the patient has become asymptomatic. Surgical therapy of hypertrophic tuberculous enteritis usually is inadvisable unless bowel obstruction from high-grade stenosis requires relief. Resection and anastomosis should be performed unless extensive disease is present; otherwise ileocolic bypass is the safer procedure.

Symptoms of the more common ulcerative form of tuberculous enteritis include alternating constipation and diarrhea associated with nonspecific crampy abdominal pain. The diagnosis sometimes is made only by radiographic intestinal examination of patients with pulmonary tuberculosis. In severe cases diarrhea is persistent, and anemia, hypoalbuminemia, and inanition are progressive. Clinical confirmation of a presumptive diagnosis may be obtained by a prompt response to antituberculous chemotherapy. Surgical therapy is contraindicated except for the rare complications of perforation, obstruction, or hemorrhage.

Typhoid Enteritis

Typhoid enteritis is an acute systemic infection of several weeks' duration caused by *Salmonella typhosa*. Hyperplasia and ulceration of Peyer's patches of the intestine occur along with mesenteric lymphadenopathy, splenomegaly, and parenchymatous changes in the liver. Confirmation of diagnosis is obtained by culturing *S. typhosa* from blood or feces or by finding a high titer of agglutinins against the O and H antigens.

Typhoid fever is still a major disease in areas of the world that have not yet attained high public health standards, but it is now rare in Western countries. The death rate, formerly about 10 percent, is now about 2 percent, in large part because of the specific antimicrobial chloramphenicol, introduced in 1948.

There is some disagreement on whether chloramphenicol remains the drug of choice, however, because of the emergence of resistant strains, high relapse rate, and risk of marrow toxicity. Trimethoprim-sulfamethoxazole has emerged as the best successor to chloramphenicol. Trimethoprim 160 mg and sulfamethoxazole 800 mg are given, either orally or parenterally, twice daily for 2 weeks. Amoxicillin also is effective and should be given intravenously or intramuscularly in doses of 1 g every 6h for 2 weeks.

Gross hemorrhage occurs in 10 to 20 percent of hospitalized patients, even while on adequate therapy. Transfusion is indicated and usually suffices. Every effort should be made to avoid operation, since the bleeding typically is from multiple ulcers and the bowel is exceedingly friable. Rarely, laparotomy must be done for uncontrollable, life-threatening hemorrhage.

Perforation through an ulcerated Peyer's patch occurs in about 2 percent of cases. Typically it is a single perforation in the terminal ileum. Operative treatment is indicated unless the patient is moribund, since localization or walling-off of the perforation is uncommon. Simple closure of the perforation is successful in the majority of patients. With multiple perforations, which occur in about one-fourth of the patients, resection with primary anastomosis or a temporary ileostomy is preferred. The mortality rate of those with free perforation is about 10 percent.

Neoplasms

General Considerations

Primary neoplasms of the small bowel are rare, despite the much greater mucosal surface area and the rapidity of cell turnover of the small bowel compared to the stomach and colon. Neoplasms are 40 times more common in the colon; the reasons for this difference are unknown. Several theories have been proposed as possible explanations: rapid transit time decreases the time for contact of carcinogens with the mucosa; the local immune system of the small-bowel mucosa; the alkaline pH of the succus entericus; the absence of bacteria that might convert certain ingested products into carcinogens; and the presence of mucosal enzymes that destroy certain carcinogens.

Primary small-bowel neoplasms are either benign or malignant and may arise from any of the cells of the small bowel. They often are asymptomatic; when symptoms occur, they usually are those of anemia or of obstruction (e.g., enteric cramping, diarrhea, distention, and obstipation). Any tumor involving the surface mucosa of the gut will bleed from time to time, and so patients present with symptoms of anemia, as do patients with colonic tumors. Benign tumors may be hamartomas, adenomas, hemangiomas, fibromas, lipomas, or leiomyomas, among others. Benign tumors usually can be excised locally. Whether or not to excise a complete segment of bowel depends on whether the tumor can be removed easily without compromising the lumen. Malignant tumors usually are adenocarcinomas, lymphomas, or leiomyosarcomas. Any kind of soft-tissue malignancy may involve the small bowel. Malignant tumors should be resected with a good margin (about 10 cm) of normal bowel on each side, along with the subtended wedge of mesentery, so as to remove local and regional lymphatics and lymph nodes.

Adenocarcinoma of the small bowel (Fig. 25-20 A) is similar to colonic adenocarcinoma. Both often present as apple-core lesions that may cause blood loss and anemia; after producing constriction of the lumen, it causes cramping and intermittent diarrhea and, when the constricted lumen is ultimately plugged by enteric material, obstruction. The material causing the obturator obstruction may later be spontaneously passed, so that intermittent symptoms of obstruction and diarrhea may occur. Malignant soft-tissue tumors may appear in any form (Fig. 25-20 B). Sarcomas may rarely invade the mucosa and bleed. Hamartomas or adenomas may be single or multiple (Fig. 25-20 C). Benign tumors of the wall of the bowel may grow to sufficient size to cause narrowing of the lumen and even obstruction (Fig. 25-20 D). Occasionally these tumors may become sufficiently large and elongated to assume a polypoid shape and may be carried along by peristalsis; sometimes they infarct and bleed. Malignant tumors should be resected with a wide margin of normal bowel and a subtended wedge of mesentery (Fig. 25-20 E) in an attempt to capture any tumor in lymphatic transit. After resection an end-to-end anastomosis of the small bowel and repair of the mesentery are performed (Fig. 25-20 F).

The frequencies of benign and of malignant neoplasms are reported to be equal in surgical series, and benign neoplasms far exceed malignant neoplasms in autopsy series. Malignant neoplasms (75 to 80 percent) more often produce symptoms than benign neoplasms.

Symptoms associated with small-bowel neoplasms often are vague; they include epigastric discomfort, nausea, vomiting, abdominal pain (often intermittent and colicky), diarrhea, and bleeding (often manifested as symptoms of anemia). Symptoms may be present for months or years before operation. Bleeding usually is occult; hematochezia or hematemesis may occur, although life-threatening hemorrhage is uncommon. The most common indications for operation in patients with neoplasms of the small bowel are obstruction, bleeding, and pain. The mechanism of obstruction varies, depending on whether it is caused by a benign or a malignant neoplasm. Benign neoplasms are the most common cause of intussusception in the adult, whereas malignant neoplasms commonly cause obstruction by circumferential growth or kinking of the bowel as a result of longitudinal, intramural growth.

Because of their relative infrequency and the vague symptoms they produce, the diagnosis of small-bowel neoplasms requires informed suspicion. Endoscopy is useful in evaluating the duodenum and possibly the most proximal jejunum, just beyond the ligament of Treitz. However, since most of the small bowel is not accessible to endoscopic scrutiny, barium contrast radiography usually is required. Upper gastrointestinal series with small-bowel follow-through is the single most useful diagnostic test. Enteroclysis (intubation infusion for small-bowel examination) has been promoted as a sensitive technique to demonstrate small-bowel disease. In performing enteroclysis, the tip of the nasal–small bowel tube is placed just beyond the ligament of Treitz, and dilute barium is instilled at a constant rate. The examination is complete when the barium reaches the cecum. Enteroclysis (Fig. 25-21) is superior to small-bowel follow-through for detection of small filling defects and for determination of changes in mucosal pattern; the diagnostic accuracy of enteroclysis approaches 90 percent.

Benign Neoplasms

Pathology

Benign tumors of the small bowel may be of epithelial or connective tissue origin. The incidence of these tumors varies, depending on whether they are reported in autopsy or clinical series. The most common lesions are adenomas, leiomyomas, and lipomas. Other benign lesions include hamartomas, fibromas, angiomas, lymphangiomas, neurofibromas, and hemangiomas. Adenomas are the most common benign tumors reported in autopsy series, but leiomyomas are the most common benign small-bowel lesions that produce symptoms.

Clinical Manifestations

An appreciable number of small-bowel benign tumors apparently cause no serious symptoms during life and are incidental findings at autopsy. The diagnosis is delayed or missed in many patients because symptoms may be absent or vague or nonspecific until significant complications have developed. Physical examination rarely provides any clue unless intestinal obstruction is present, and radiographic studies of the small bowel and selective angiography, the only specific diagnostic aids, may fail to demonstrate an existing tumor, even if it is suspected clinically. In only about one-half of small-bowel tumors found at operation has the correct diagnosis been made preoperatively.

The two most common clinical manifestations of small-bowel tumors are bleeding and obstruction (Fig. 25-22). Rarely, perforation of the bowel wall occurs, resulting in abscess or internal fistula formation, peritonitis, or pneumatosis cystoides intestinalis. Bleeding occurs in about one-third of patients but is rarely gross. More commonly, bleeding is occult and intermittent, producing guaiac-positive stools and iron-deficiency anemia. Leiomyomas and hemangiomas are the lesions that most often cause bleeding.

Treatment

Surgical treatment of benign tumors is nearly always indicated because of the risk of subsequent complications and because the diagnosis of benign disease cannot be made without microscopic evaluation. The complications of benign neoplasms that most often require treatment are bleeding and obstruction. Segmental resection and primary reanastomosis is most commonly used except for very small lesions that may be excised by enterotomy. The entire small bowel should be searched for other lesions, since they are often multiple.

Adenoma

Adenomas, which account for approximately 35 percent of all benign tumors, are of three primary types: true adenomas, villous adenomas, and Brunner's gland adenomas. Twenty percent of adenomas are found in the duodenum, 30 percent in the jejunum, and 50 percent in the ileum. The majority of adenomas are asymptomatic; most occur singly, and most are found incidentally at autopsy. It is rare for duodenal polyps to be sufficiently large to cause symptoms. If polyps do cause symptoms, they usually are associated with bleeding or obstruction. If symptomatic, duodenal polyps can be removed by endoscopic snare, or they may be sufficiently large to be difficult to retrieve through the pylorus. In such cases, particularly if malignancy is suspected, they may best be removed in an open operation. As a rule, the question of malignancy can be settled by endoscopic biopsy; usually the polyp can be removed endoscopically.

Villous adenomas of the small bowel are rare but do occur and are most commonly found in the duodenum. Their presence may be suspected by the characteristic “soap bubble” appearance on contrast radiography. They may attain large size (> 5 cm in diameter) and usually are found because of pain or bleeding. Obstruction also may occur. There have been no reports of secretory diarrhea associated with villous tumors of the small bowel; however, the malignant potential of these lesions is reportedly between 35 and 55 percent.

Brunner's gland adenomas are hyperplastic proliferations of normal exocrine glands located in the submucosa of the duodenum. Brunner's gland adenomas may produce symptoms that mimic those of peptic ulcer disease, or they may cause obstruction. Diagnosis can be made by endoscopy and biopsy, and symptomatic lesions in an accessible region should be resected. There is no malignant potential for Brunner's gland adenomas, and a radical resection should not be employed.

Leiomyoma

The most common symptomatic benign lesions of the small bowel are leiomyomas. Leiomyomas are benign tumors of smooth muscle that are most common in the jejunum. They usually occur singly, although multiple tumors may occur. The incidence is equal in men and women. Two growth patterns are noted: the tumor may grow primarily intramurally and cause obstruction, or both intramural and extramural growth may occur and produce a dumbbell-shaped mass. These tumors may attain considerable size, outgrowing their blood supply, and tumor necrosis with bleeding may occur. The most common indication for operation on leiomyomas is bleeding. Angiography may provide the correct preoperative diagnosis.

Lipoma

Lipomas, most common in the ileum, are single intramural lesions, submucosal in location, and usually small. Fewer than one-third of lipomas are found at operation and, when found, usually they are the cause of obstruction, most commonly as the lead point of an intussusception. Bleeding may occur from ulceration of the overlying mucosa. Lipomas do not have malignant potential, and therefore when found incidentally, they should be removed only if the resection is simple. Pedunculated lipomas should be excised.

Hamartoma (Peutz-Jeghers Syndrome)

Hamartomas of the small bowel occur only as part of the Peutz-Jeghers syndrome, which is an inherited syndrome of mucocutaneous melanotic pigmentation and gastrointestinal polyps. The pattern of inheritance is simple mendelian dominant, with a high degree of penetrance. A single pleiotropic gene is responsible for both polyps and melanin spots. The classic pigmented lesions are small, 1- to 2-mm brown or black spots located in the circumoral region of the face, buccal mucosa, forearms, palms, soles, digits, and perianal area. The syndrome was first reported in 1921 by Peutz, and Jeghers and colleagues described it anew in 1949. Multiple pigmented lesions may be noted, or only a single buccal lesion may be present. Pigmentation appears in childhood. All cutaneous lesions may fade, leaving only buccal lesions. Polyposis with and without pigmentation has been reported. The entire jejunum and ileum are the most frequent portions of the gastrointestinal tract to be involved with multiple polyps. Fifty percent of patients may also have rectal and colonic polyps, and 25 percent may have gastric polyps. The chief point to note is that if a patient with multiple rectal, colonic, or gastric polyps is found to have hamartomas rather than adenomas, a search for small-bowel polyposis and pigmented lesions should be carried out.

The lesions are not true polyps but are hamartomas and hence are not premalignant (Fig. 25-23). However, there have been a few reported cases of malignant tumors of the gastrointestinal tract associated with Peutz- Jeghers syndrome. Some of these adenomatous and carcinomatous changes were noted in the hamartomatous polyps. It is not clear, however, whether this represents a coincidence or a true malignant transformation of this syndrome.

The most common symptom is recurrent colicky abdominal pain, caused by intermittent intussusception. Lower abdominal pain associated with palpable mass has been reported to occur in one-third of patients. Hemorrhage occurs less frequently and is most commonly manifested by insidious involvement of anemia. Acute life-threatening hemorrhage is uncommon but may occur.

Surgical therapy is required only for obstruction or persistent bleeding. The resection should be limited to the segment of bowel that is producing complications, that is, polypectomy or limited resection. Because of the widespread nature of intestinal involvement, cure is not possible and extensive resections are not indicated.

Hemangioma

Hemangiomas are developmental malformations consisting of submucosal proliferation of blood vessels. They can occur at any level of the gastrointestinal tract, and the jejunum is the most commonly affected small-bowel segment. Hemangiomas account for 3 to 4 percent of all benign tumors of the small bowel and are multiple in 60 percent of patients. Hemangiomas of the small bowel may occur as part of an inherited disorder known as Rendu-Osler-Weber disease. Besides the small bowel, hemangiomas may be present in the lung, liver, and mucous membranes. Patients with Turner's syndrome are likely also to have cavernous hemangiomas of the intestine. Most patients are symptomatic, and the most common symptom is diffuse intestinal bleeding. Diagnosis is often difficult; angiography and ^{99m}Tc—red cell scanning are the most useful diagnostic tools. If a hemangioma is localized preoperatively, resection of the involved segment of intestine is warranted. If the site is not localized preoperatively, intraoperative transillumination and palpation can be helpful.

Malignant Neoplasms

The most common malignant neoplasms of the small bowel, in approximate order of frequency, are adenocarcinomas, carcinoids, sarcomas, and lymphomas.

Clinical Manifestations

Rochlin and Longmire called attention to three distinct clinical presentations of patients with malignant small-bowel neoplasms: diarrhea, with large amounts of mucus, and tenesmus; obstruction with nausea, vomiting, and cramping abdominal pain; and chronic blood loss with anemia, weakness, guaiac-positive stools, and occasionally melena or hematochezia. As with benign neoplasms, symptoms of malignant neoplasms often are present for many months before the diagnosis is made, emphasizing their insidious nature.

Treatment

The treatment for malignant neoplasms of the small bowel is wide resection, including regional lymph nodes. This may require a radical pancreaticoduodenectomy (Whipple operation) for duodenal lesions. Because of the extent of the disease at the time of operation, curative resection may not be possible. Palliative resection should be performed when possible to prevent further complications of bleeding, obstruction, and perforation. If that is not possible, however, bypass of the involved segment is an alternative that may provide worthwhile relief of symptoms. If bypass is used, the proximal end of the bypassed segment should be brought out as a mucous fistula to prevent development of a closed loop. Recent reports of an increased association of small-bowel cancers in patients with celiac sprue suggest that new intestinal complaints in these patients should be evaluated to rule out small-bowel cancer.

Prognosis

The overall survival rate for patients with malignant neoplasms of the small bowel is not good. The highest survival rates are reported for duodenal periampullary carcinomas (about 30 to 40 percent), whereas adenocarcinomas occurring elsewhere in the small bowel have a 5-year survival rate of 20 percent or less. Leiomyosarcomas of the small bowel have a 5-year survival rate of 30 to 40 percent. Radiation and chemotherapy play little role in the treatment of patients with adenocarcinomas of the small bowel. There may be some improvement in survival when radiotherapy is used in patients with sarcomas. Determinants of survival for patients with lymphomas are the cell type and the extent of disease. Radiotherapy and chemotherapy combined with surgical excision provide the best survival rates for patients with lymphomas. Five-year survival rates have been reported to range from 10 to 50 percent, with an average of about 30 percent.

Carcinoma

Carcinomas constitute about 50 percent of the malignant tumors of the small bowel in most reported series. They are twice as common in men as in women, and the average age at diagnosis is 50 years. For unknown reasons, adenocarcinomas are more common in the duodenum and the proximal jejunum than in the remainder of the small bowel. About half of duodenal carcinomas involve the ampulla of Vater.

The carcinoma's location in the small bowel often determines the presenting symptoms. For example, periampullary adenocarcinomas are associated with intermittent jaundice, whereas carcinomas of the jejunum usually produce symptoms of mechanical small-bowel obstruction (Fig. [25-24](#)). The presence of jaundice, often intermittent, and a guaiac-positive stool should immediately call to mind the possibility of a periampullary carcinoma.

As with carcinomas arising in other organs, survival of patients with small-bowel carcinomas is related to the stage of disease at the time of diagnosis. Diagnosis often is delayed and disease far advanced at the time of operation. The delay in diagnosis is due to a combination of factors, including lack of suspicion because of the relative rarity of the lesions, vagueness of symptoms, and absence of physical findings.

Sarcoma

Sarcomas, which arise from mesodermal tissue, constitute about 20 percent of malignant neoplasms of the small bowel. The most common sarcoma by far is the leiomyosarcoma. Leiomyosarcomas are evenly distributed throughout the small bowel. The incidence is the same for men and women, and diagnosis usually is made in the sixth decade. The most common indications for operation are bleeding and obstruction, although free perforation as a result of hemorrhagic necrosis in large tumor masses may occur. Leiomyosarcomas are spread by direct invasion of adjacent structures, by hematogenous dissemination, or by transperitoneal seeding, producing sarcomatosis. Other rare forms of sarcoma that may affect the small bowel include fibrosarcoma, angiosarcoma, liposarcoma, and Kaposi's sarcoma.

Lymphoma

Lymphomas constitute 10 to 15 percent of small-bowel malignant tumors in the adult; in children under 10 years of age, they are the most common intestinal neoplasm. Lymphomas most commonly are found in the ileum, where the greatest concentration of gut-associated lymphoid tissue is present, and they may be primary or part of a generalized disease. Dawson and colleagues have devised criteria to determine whether lymphoma of the small bowel is primary. These include (1) absence of peripheral lymphadenopathy; (2) normal chest x-ray without evidence of mediastinal lymph node enlargement; (3) normal white blood cell count, total and differential; (4) at operation, the bowel lesion must predominate, and the only involved nodes are associated with the bowel lesion; and (5) absence of disease in the liver and spleen. Even when these criteria are used, one-third or more patients with lymphomatous involvement of the small bowel are found to have generalized lymphoma.

There are three syndromes of small-bowel lymphoma. *Western lymphoma* is a disease predominantly of adults, typically found in the Western Hemisphere and associated with severe malabsorption in 5 to 10 percent of patients. Another form, known as *Mediterranean lymphoma*, is a malignant form that was first noted in non-Ashkenazi Jews and Arabs in Israel and was subsequently reported in other countries and in other ethnic groups, including Hispanic Americans. Since this disease is not confined to the Mediterranean basin, the term *immunoproliferative small intestinal disease* has been used. One-third of the patients may be found to have an abnormal fragment of IgA heavy chain in their serum, which is produced by plasma cells infiltrating the small bowel. This variant is known as *heavy-chain disease*.

The third intestinal manifestation of lymphoma is childhood abdominal lymphoma. This is a group of lymphomas including American (nonendemic) Burkitt's lymphoma, undifferentiated non-Burkitt's lymphoma, and diffuse histiocytic lymphoma.

Carcinoid

Carcinoids of the small bowel arise from the enterochromaffin cells, or Kulchitsky cells, found in the crypts of Lieberkühn. These cells are also known as argentaffin cells because of their staining by silver compounds. Carcinoids may be classified by embryologic site of origin and secretory product (Table [25-3](#)). Carcinoids of the small bowel occur with almost the same frequency as adenocarcinoma, and together they make up the preponderance of malignant neoplasms of the small bowel. Carcinoids have variable malignant potential and are composed of multipotential cells with the ability to secrete numerous humoral agents, the most prominent of which are serotonin and substance P. Although the carcinoid syndrome, characterized by episodic attacks of cutaneous flushing, bronchospasm, diarrhea, and vasomotor collapse, occurs in fewer than 5 percent of the patients with malignant carcinoids, it is quite dramatic and has been extensively described and discussed with fascination by many authors.

The primary importance of carcinoid tumors, however, is not the carcinoid syndrome but the malignant potential of the tumors themselves. Oberndorfer coined the term *karzinoide* to indicate that this tumor is carcinomalike and to emphasize the assumed lack of malignant potential. By 1930 this concept was no longer supported, since many patients with metastatic carcinoid tumors had been reported. In 1953 and 1954 the carcinoid syndrome was described.

Pathology

Carcinoids may arise in organs derived from the foregut, midgut, and hindgut. In the gastrointestinal tract over 90 percent of carcinoids are found in three sites: the appendix is most frequently involved (46 percent), followed by the ileum (28 percent) and the rectum (17 percent), but all organs may give rise to carcinoids. Other gastrointestinal locations are listed in Table [25-4](#). The malignant potential (ability to metastasize) is related to location, size, depth of invasion, and growth pattern. Only about 3 percent of appendiceal carcinoids metastasize, but about 35 percent of ileal carcinoids are associated with metastasis. Seventy-five percent of gastrointestinal carcinoids are less than 1 cm in diameter; only 2 percent of this group metastasize. About 20 percent of primary tumors are 1 to 2 cm in diameter, and 50 percent of this group metastasize. Only about 5 percent are over 2 cm in diameter; 80 to 90 percent of these metastasize. Carcinoids limited to the submucosa do not metastasize, whereas 69 percent of carcinoids involving the serosa have metastases. The histologic growth patterns appear to be related to survival and therefore have prognostic importance.

Multiple carcinoids of the small bowel occur in 30 percent of patients with carcinoid but are rare in the appendix. This tendency to multicentricity exceeds that of any other malignant neoplasm of the gastrointestinal tract. An unusual observation that is yet unexplained is the frequent coexistence of a second primary malignant neoplasm of a different histologic type; a second primary neoplasm was reported in 25 percent of patients in one large series.

Carcinoids present grossly as a slightly elevated, smooth, rounded, hard nodule, covered with normal mucosa. On cut section, they have a characteristic yellow-gray or tan appearance. Extensive fibrosis of the mesentery and of the bowel wall, caused by an intense desmoplastic reaction, may be present (Fig. [25-25](#)). This fibrosis may produce mechanical bowel obstruction from kinking or matting of loops of small bowel together. Obstruction rarely is a result of direct tumor encroachment on the lumen of the bowel. In addition to the desmoplastic reaction, apparently produced by humoral agents elaborated by the tumor, metastases to mesenteric nodes also result in kinking and fixation by large metastatic tumor deposits. A small primary tumor associated with massive mesenteric metastases is often noted (Fig. [25-26](#)).

Clinical Manifestations

In the absence of the malignant carcinoid syndrome, symptoms of patients with carcinoid tumors of the small bowel are similar to those of patients with small-bowel tumors of other histologic types. The most common symptoms are abdominal pain, bowel obstruction, diarrhea, and weight loss. In the majority of patients (in the absence of the malignant carcinoid syndrome), the diarrhea is a result of partial bowel obstruction rather than being secretory. Rarely, malignant carcinoid tumors of the ampulla of Vater are found in patients with disseminated neurofibromatosis (von Recklinghausen's disease).

Diagnostic Findings

Radiographic studies of the small bowel may exhibit multiple filling defects, sometimes caused by tumors but more often a result of kinking and fibrosis of the bowel, mesenteric calcifications, and fixed, rigid loops of intestine. Mesenteric vascular angiography may reveal abnormal arrangement of mesenteric arteries and narrowing of peripheral branches together with poor accumulation of contrast and poor venous drainage of the tumor area. Tumor staining during angiography may be enhanced by administration of norepinephrine. Angiography is the most sensitive diagnostic test to detect hepatic metastasis, particularly diffuse metastatic disease with fine nodular distribution. Hepatic metastases are hypervascular and intensely stained during arteriography.

Treatment

The treatment of patients with small-bowel carcinoid tumors is based on the size and the site of the tumor and the presence or absence of metastatic disease. For primary tumors less than 1 cm in diameter without evidence of regional lymph node metastasis, a segmental intestinal resection is adequate. For patients with lesions greater than 1 cm, with multiple tumors, or with regional lymph node metastasis regardless of the size of the primary tumor, wide excision of bowel and mesentery is required. Since the majority of small-bowel carcinoids are found in the ileum, wide excision usually entails a right hemicolectomy. Malignant carcinoid tumors of the duodenum may require radical pancreatoduodenectomy. When carcinoids are localized, almost all are cured by surgical resection; patients with the malignant carcinoid syndrome caused by metastatic disease may receive significant palliation but are not cured with surgical resection.

Treatment of Carcinoid Tumors of the Appendix

Appendiceal carcinoids typically are diagnosed in patients 20 to 40 years of age, in contrast to the mean age at diagnosis of small-bowel carcinoids of 60 years. The majority of appendiceal carcinoids are located at the tip. Simple appendectomy is curative for patients with tumors less than 1 cm in diameter without gross evidence of metastasis. Because of the potential for metastasis, right hemicolectomy should be performed for tumors greater than 2 cm. Intramural lymphatic invasion, serosal involvement, or microscopic involvement of the mesoappendix associated with tumors less than 2 cm in diameter is not an indication for extensive resection.

Prognosis

The survival rate for patients with small-bowel carcinoid tumors has been reported to be 75 percent for those with tumors staged as local, 59 percent for regional tumors, and 19 percent for tumors with distant spread. The overall survival rate is 54 percent. The growth pattern of carcinoid tumors is an independent predictor of outcome. The median survival times of the various growth patterns, in decreasing order, are as follows: mixed insular plus glandular, 4.4 years; insular, 2.9 years; trabecular, 2.5 years; mixed insular plus trabecular, 2.3 years; glandular growth pattern, 0.9 years; and undifferentiated, 0.5 years.

When widespread metastatic disease precludes cure, extensive resection for palliation is indicated. Since these tumors are often indolent and slow-growing, long-term palliation often is obtained. Bypass procedures may be used in poor-risk patients with extensive disease. The overall 5-year survival rate after resection of intestinal carcinoids is about 50 percent. When "curative resection" is done, the 5-year survival rate is 70 percent. Chemotherapy has not been entirely successful; however, treatment with streptozotocin and 5-fluorouracil (5-FU) may provide significant palliation. In patients with palliative resections the 5-year survival rate is 25 percent.

Malignant Carcinoid Syndrome

This rare syndrome is widely described but rarely seen. Thirty to 70 percent of carcinoid tumors of the gut are metastatic at the time of diagnosis, but only 6 to 9 percent of patients with metastatic disease develop manifestations of the malignant carcinoid syndrome. By far the most commonly associated primary tumor is located in the small bowel, and massive hepatic replacement by metastatic tumor is usually found.

Clinical Manifestations

The syndrome is characterized by hepatomegaly, diarrhea, and flushing in 80 percent of patients, right heart valvular disease in 50 percent, and asthma in 25 percent. Malabsorption and pellagra (dementia, dermatitis, and diarrhea) are occasionally present and are thought to be caused by excessive diversion of dietary tryptophan to meet the metabolic requirements of the tumor.

Diarrhea is episodic, often occurring after meals, and is a result of elevated circulating levels of serotonin, which stimulates secretion of small-bowel fluid and electrolytes and increases intestinal motility. Some patients may present with acute abdominal symptoms, characterized by severe abdominal cramping without mechanical bowel obstruction, which has been called *carcinoid abdominal crisis*. The mechanism of this crisis is thought to be intestinal ischemia, caused by the vasoactive substances elaborated by the tumor, combined with decreased mesenteric blood supply from perivascular fibrosis.

Flushing is not temporally related to diarrhea, and, although both may be present, either may be present without the other. The lack of relationship between flushing and diarrhea suggests that these two manifestations of the syndrome are caused by different mediators. Although substance P produces all of the vasomotor phenomena associated with the flush, it has been questioned as the primary mediator. Besides serotonin and substance P, other substances that have been implicated include bradykinin and prostaglandins E and F.

Valvular heart disease is a result of irreversible endocardial fibrosis, which is similar in genesis to the fibrosis noted in the gut wall, in the retroperitoneum, and around the mesenteric blood vessels. It occurs in patients with hepatic metastases and is limited to tricuspid and pulmonary valves. The reason the lesions are restricted to the valves on the right side is that they are exposed to high levels of serotonin; the pulmonary filter deactivates serotonin, thereby preventing left-sided valvular lesions.

Asthma is due to bronchoconstriction, which may be produced by serotonin, bradykinin, or substance P. Treatment of asthma associated with carcinoid syndrome must be carried out very carefully, since the use of adrenergic drugs may cause the release of humoral agents that may cause status asthmaticus.

Although the syndrome is seen in patients with high circulating levels of serotonin and often substance P, these are probably not the only mediators of all components of the syndrome. The malignant enterochromaffin cells produce 5-hydroxytryptamine (5-HT), which is serotonin. Circulating serotonin is metabolized in the liver and in the lung to 5-hydroxyindoleacetic acid (5-HIAA), which is pharmacologically inactive. Elevated levels of 5-HIAA are seen only in patients with metastasis. However, not all patients with metastasis have increased levels of 5-HIAA. The majority of patients who exhibit malignant carcinoid syndrome have massive hepatic replacement by their metastatic disease. Tumors that bypass the hepatic filter, specifically ovarian and retroperitoneal carcinoids, may produce the syndrome in the absence of liver metastasis.

Diagnostic Findings

The diagnosis is most reliably established by repeated determinations of urinary 5-HIAA. A single determination may be normal in the presence of metastatic disease. Provocative testing to reproduce symptoms has employed injection of pentagastrin, calcium, or epinephrine. The pentagastrin test is by far the most reliable and safest provocative test. During times of testing for increased levels of 5-HIAA, the patient must avoid foods rich in serotonin, such as bananas, tomatoes, walnuts, and pineapples, and certain drugs, including phenothiazines, glycerol guaiacolate, and reserpine.

Treatment

Ideally, treatment of the carcinoid syndrome would require removal of all tumor, but this rarely is possible. Hepatic resection, however, even when known tumor is left behind, may result in significant relief of symptoms because of the removal of the mass of tumor. When resection is not possible, hepatic dearterialization or embolization of the hepatic arterial branches with chemotherapy (doxorubicin, 5-fluorouracil, cisplatin) may provide some relief. The duration of response after resection in one study was 6 months, compared to 4.8 months for hepatic artery ligation. In certain selected patients, liver transplantation may offer the hope of a longer disease-free interval; however, the long-term outcome of this radical approach is not known.

Drug therapy for prevention or relief of symptoms is directed at blockade of the effects of humoral agents elaborated by the tumor. Interferon has provided some symptomatic improvement in a small group of patients. Somatostatin-14 and its long-acting analog octreotide (Sandostatin) relieve symptoms (diarrhea and flushing) of the carcinoid syndrome in the majority of patients. Furthermore, Kvols and colleagues have found that survival is significantly prolonged in patients with carcinoid tumors treated with Sandostatin. In addition to preventing the devastating sequelae of the carcinoid syndrome, Sandostatin also may possess a direct antitumor effect. Chemotherapeutic attacks on the tumor itself have been disappointing, although streptozotocin, alone or combined with 5-fluorouracil, appears to be the most effective.

Treatment of carcinoid tumors is wide surgical resection of the small bowel and regional lymph nodes. In addition, significant palliation may be achieved with aggressive hepatic resection in patients with malignant carcinoid syndrome.

Diverticular Disease

Diverticula of the small bowel may be congenital or acquired. A congenital diverticulum is a true diverticulum; it is composed of all layers of the bowel wall. An acquired diverticulum is a false diverticulum; only mucosa and submucosa protrude through a defect in the muscle coat of the bowel wall. Diverticula may occur in any portion of small intestine. Duodenal diverticula are the most common acquired diverticula of the small bowel, and Meckel's diverticulum is the most common true diverticulum of the small bowel.

Duodenal Diverticula

Duodenal diverticula are common; the duodenum is the second most common site of diverticulum formation, after the colon. The true incidence of duodenal diverticula is unknown, and reported incidences vary, depending on whether they are found clinically (by x-ray, endoscopy, or operation) or at autopsy. It has been reported that 1 to 5 percent of upper gastrointestinal x-ray examinations reveal duodenal diverticula; 9 to 20 percent of upper gastrointestinal endoscopic examinations show them. In autopsy series, incidences of 10 to 20 percent are reported. More than 90 percent of these diverticula are clearly asymptomatic, and less than 5 percent will require operation because of a complication of the diverticulum itself. Duodenal diverticula occur twice as often in women as in men. They are rare in patients under 40 years of age, and the incidence increases with increasing age. Two-thirds to three-fourths of duodenal diverticula are found in a periampullary region and project from the medial wall of the duodenum (Fig. 25-27). Duodenal diverticula are clinically important for two reasons. First, they occasionally produce symptoms related to the diverticulum, including obstruction, perforation, or bleeding, and second, the presence of the diverticulum may cause recurrent pancreatitis, cholangitis, or recurrent common-duct stones after cholecystectomy.

Only those diverticula associated with the ampulla of Vater have a significant relationship to the complications of cholangitis, pancreatitis, and stone disease. In patients with these diverticula, the ampulla most often enters the duodenum at the superior margin of the diverticulum, rather than through the diverticulum itself. The mechanism proposed for the increased incidence of complications of the biliary tract is the location of the perivaterian diverticula, which may produce mechanical distortion of the common bile duct as it enters the duodenum, resulting in partial obstruction and stasis. Bile stasis allows proliferation of bacteria and subsequent formation of stones. The incidence of bacteriobilia is significantly higher in patients with perivaterian diverticula than in those with diverticula located in other parts of the duodenum. The bacteria isolated from the bile duct and from the diverticula

are identical. There is also evidence that dysfunction of the choledochal sphincter is produced by the presence of diverticula. In one study of 101 patients who had undergone cholecystectomy more than 2 years earlier, a significantly higher incidence of recurrent calculi was noted in patients with diverticula than in patients without. A causal relationship of duodenal diverticula to biliary tract stones, however, has not been demonstrated. It is important not to extend indications for operation to include people with unexplained abdominal pain. Nor should retention of barium within diverticula serve by itself as an indication for operation. The important point is that the great majority of duodenal diverticula cause no trouble; they should be left alone unless they can be conclusively related to disease.

Fewer than 60 patients have been reported with intraluminal duodenal diverticula. These diverticula, which probably originate from incomplete duodenal webs, are lined both inside and out with duodenal mucosa, have a characteristic picture of a barium-filled wind sock on contrast radiography, and most often required operation because of duodenal obstruction or recurrent pancreatitis. In these diverticula the common bile duct and pancreatic duct usually enter the diverticulum, and a second orifice is present that allows drainage of the biliary-pancreatic secretions into the lumen of the gut.

Symptoms related to duodenal diverticula, in the absence of any other demonstrable disease, usually are nonspecific epigastric complaints. Bleeding, perforation, and diverticulitis all are rare. The morbidity and mortality caused by complications of diverticula are nonetheless high as a result of delay in diagnosis because of the lack of suspicion of the underlying condition. Diagnosis is seldom made preoperatively.

Treatment

Treatment of complications of the diverticulum are directed toward the control of the complication. In patients who have bleeding or symptoms that are related to the duodenal diverticulum, several operative procedures have been described. The most common and most effective treatment in this situation is diverticulectomy. This is most easily accomplished by performing a wide Kocher maneuver that exposes the diverticulum (Fig. 25-28). The diverticulum then is excised, and the duodenum is closed in a transverse or a longitudinal manner, whichever produces the least amount of luminal obstruction. For diverticula embedded deep within the head of the pancreas, lateral duodenotomy is performed; the diverticulum is invaginated into the lumen and excised, and the wall is closed. An alternative method that has been described for duodenal diverticula associated with the ampulla of Vater is an extended sphincteroplasty through the common wall of the ampulla and the diverticulum.

A perforated diverticulum may cause a great deal of trouble. When found, the perforated diverticulum should be excised and the duodenum closed with a serosal patch from the jejunal loop. If the inflammation is severe, it may be necessary to divert enteric flow away from the site of the perforation, with a gastrojejunostomy or, preferably, a duodenojejunostomy if possible. It may be possible to interrupt duodenal continuity proximal to the perforated diverticulum with a row of staples. Great care should be taken if the perforation is adjacent to the papilla. In one early perforation, we were able simply to invert the diverticulum, close the duodenal wall, and reinforce this with a serosal patch.

Because of the relationship of the common bile duct and pancreatic duct in patients with intraluminal diverticula associated with the ampulla of Vater, subtotal resection of the diverticulum should be carried out to protect the entry of the biliary-pancreatic ducts. If an intraluminal diverticulum arises at a site distant from the ampulla, complete excision may be possible.

The vast majority of duodenal diverticula are asymptomatic and benign, and when they found incidentally they should not be resected.

Jejunal and Ileal Diverticula

Diverticula of the jejunum and the ileum are much less common than duodenal diverticula, with an incidence between 0.5 and 1 percent on small- bowel x-ray examination. Jejunal diverticula are more common and are larger than those in the ileum (Fig. 25-29). Multiple diverticula are more common in the jejunum and the ileum than in the duodenum. These are false diverticula that usually protrude from the mesenteric border of the bowel, and they may be overlooked at operation because they are embedded within the small-bowel mesentery. When jejunal and ileal diverticula cause trouble, the symptoms usually are from incomplete bowel obstruction, acute diverticulitis, hemorrhage, or malabsorption due to bacterial overgrowth within the diverticulum. A specific syndrome of intestinal pseudoobstruction or jejunal dyskinesia is characterized by symptoms of intermittent partial bowel obstruction. On enteroclysis, barium may be seen to pass back and forth from the intestinal lumen into the diverticulum rather than moving normally through the bowel. This condition may be associated with hypertrophy and dilatation of the bowel proximal to the diverticulum. A recent study found that the condition may be associated with one of three syndromes: systemic sclerosis, visceral myopathy, or visceral neuropathy. If this condition is the only finding, resection of a large segment of jejunum containing diverticula should be avoided. Treatment of complications of obstruction, bleeding, and perforation is by intestinal resection and end-to- end anastomosis.

Obstruction also may be caused by enteroliths that form in a jejunal diverticulum and are subsequently dislodged and obstruct the distal intestine. This condition mainly occurs in the elderly and may be treated by enterotomy and removal of the enterolith. Patients with malabsorption from production of the blind loop syndrome by bacterial overgrowth within the diverticulum usually can be treated with antibiotics. Asymptomatic diverticula require no treatment.

Meckel's Diverticulum

Meckel's diverticulum, the most common true diverticulum of the gastrointestinal tract, is a congenital diverticulum that results from incomplete closure of the omphalomesenteric or vitelline duct. The usual manifestation is a relatively wide projection arising from the antimesenteric side of the ileum, generally 45 to 60 cm proximal to the ileocecal valve. Occasionally the diverticulum is merely a small bump or hillock, or it may be long and narrow (1–12 cm), but usually it is short and relatively wide (Fig. 25-30 A). Various forms exist, depending on the presence or absence of communication with the umbilicus or with various stages of atrophy of the omphalomesenteric ductal connection between the ileum and the umbilical skin (variations ranging from a persistent fibrous cord to a patent fistula) (Fig. 25-30 B–H). Heterotopic gastric or pancreatic tissue often is found in Meckel's diverticula. The vast majority of Meckel's diverticula are entirely benign. Trouble arises from bleeding or inflammation, which gives rise to a symptom complex usually indistinguishable from appendicitis; from perforation, usually caused by peptic ulcer from acid and pepsin secretion from ectopic gastric fundic mucosa; and from problems associated with persistence of part or all of the omphalomesenteric duct. The great majority of symptomatic Meckel's diverticula are found in childhood, and the most common symptom in childhood is bleeding. On the basis of several autopsy series, Meckel's diverticula has a reported incidence in the general population of 2 percent. In adults most Meckel's diverticula are found incidentally by radiographic examination of the small bowel. Enteroclysis usually provides an accurate diagnosis. Another technique for detection of Meckel's diverticulum in symptomatic patients is radionuclide scanning with ^{99m}Tc-pertechnetate. The basis for this is the uptake of radioisotope by the heterotopic gastric mucosa within the diverticulum. The diagnostic accuracy of this scanning technique may be increased by administration of pentagastrin (6 mg/kg subcutaneously) 15 min before the scan, which enhances the uptake of the radioisotope by the gastric mucosa. It has been shown, however, that the parietal cells do not specifically accumulate pertechnetate and are not essential for detection purposes. The scan far more useful in children than in adults.

Complications of Meckel's diverticulum in adults include intestinal obstruction, bleeding, acute diverticulitis, or the presence of a diverticulum in a hernia sac (Littre's hernia). Obstruction may be produced by one of two mechanisms. The most common is volvulus or kinking around a band running from the tip of the diverticulum to the umbilicus, abdominal wall, or mesentery. The diverticulum also may cause obstruction by intussusception. Bleeding is the second most common complication and usually is found only when there is heterotopic gastric mucosa within the diverticulum. The bleeding ulcer is found not in the diverticulum but in the ileum adjacent to the diverticulum.

Meckel's diverticulitis, which is clinically indistinguishable from appendicitis, is the third most common complication in adults. The incidence of perforation or peritonitis with Meckel's diverticulitis is about 50 percent.

A Meckel's diverticulum should be considered in the differential diagnosis of patients who present with a mechanical bowel obstruction, with low small- bowel hemorrhage, or with signs and symptoms of inflammation or peritonitis. Treatment is prompt surgical intervention, with resection of the diverticulum or resection of the segment of ileum bearing the diverticulum (Fig. 25-30 I–J). Segmental intestinal resection is required for treatment of patients with bleeding, because the bleeding site usually is in the ileum adjacent to the diverticulum. Recent reports have demonstrated the feasibility and safety of laparoscopic diverticulectomy; long-term outcome with this procedure, however, are lacking.

It is generally recommended that asymptomatic diverticula found in children during laparotomy be resected; however, the treatment of an asymptomatic Meckel's diverticulum found incidentally at laparotomy in the adult patient is controversial. In a landmark paper that has greatly influenced the surgical management of the asymptomatic diverticulum, Soltero and Bill estimated that the likelihood of a Meckel's diverticulum becoming symptomatic in an adult is 2 percent or less and that morbidity from incidental removal (reported to be as high as 12 percent in some studies) far exceeds the potential for prevention of disease. From this study, the authors concluded that an asymptomatic Meckel's diverticulum in the adult should not be removed. This study has been criticized, however, since it was not a population-based analysis. An epidemiologic, population-based study by Cullen and associates has challenged the practice of ignoring an incidentally found Meckel's diverticulum. A 6.4 percent rate of developing complications from the Meckel's diverticulum was calculated to occur over a lifetime; this incidence of complications does not appear to peak during childhood as originally thought. These authors therefore recommended that an incidentally discovered Meckel's diverticulum should be removed at any age up to 80 years, as long as no additional condition (e.g., peritonitis) makes removal hazardous. The rates of short-term and long-term postoperative complications from prophylactic removal are low (approximately 2 percent), and in the Cullen series mortality was related to the primary operation or the general health of the patient and not to the diverticulectomy. Therefore, this study as well as other recent studies suggest that prophylactic diverticulectomy in selected patients may be beneficial and safer than originally reported.

Miscellaneous Problems

Congenital Abnormalities

Although primarily limited to infants and children, developmental anomalies of the small intestine also may present in adulthood. In addition to Meckel's diverticulum, discussed above, intestinal duplications and anomalies of gut rotation and fixation may be manifested in the adult.

The term *duplication* actually is a misnomer, since approximately 75 percent are enteric cysts and not true duplications. The remainder are true tubular duplications that are intimately attached to the adjacent portion of the gastrointestinal tract, possess a gastrointestinal type of mucosal lining, and may or may not communicate with the visceral lumen. Duplications occur on the mesenteric side of the intestine between the leaves of the mesentery and are most often found in the ileum. In rare instances, a duplication from the abdomen extends into the chest. Cystic lesions may present with symptoms of obstruction from extrinsic compression. Communicating tubular duplications often are lined by gastric mucosa, which may ulcerate and present with gastrointestinal hemorrhage or perforation. In addition, cancers have been reported to arise in the mucosal lining of these duplications. Treatment is surgical resection. Small tubular duplications and all cysts are excised along with overlying normal intestine; intestinal continuity is restored by end-to-end anastomosis. Long tubular duplications that would require massive small-bowel resection for complete removal are more problematic and may be treated by mucosal stripping of the duplication.

Various anomalies may occur from defects in gut rotation. Failure of the midgut to rotate results in the duodenum's descending to the right of the midline with the entire small bowel lying in the right half of the abdomen and the colon lying to the left. Patients usually are asymptomatic. Symptoms from malrotation result from the midgut's failing to rotate completely and usually occur in patients 2 months of age or less; however, symptoms of midgut volvulus occur in 10 percent of patients at a later age and present either acutely or

with chronic symptoms of intermittent partial obstruction. Partial obstruction of the duodenum by peritoneal bands (Ladd's bands) may cause bilious vomiting and intermittent cramping abdominal pain. Mesocolic hernias (also referred to as paraduodenal hernias) occur when failure of proper gut fixation results in the small bowel's being trapped within the mesentery of the colon. The most common presentation is that of obstruction. Treatment for anomalies of rotation and fixation include lysis of Ladd's bands (if present), reduction of the volvulus, and repositioning of the intestine to prevent twisting.

Small-Bowel Ulcerations

The majority of ulcerations of the small bowel have definable causes, which include the following: drug-induced (enteric-coated potassium chloride tablets or corticosteroids), vascular (occlusion or vasculitis), Crohn's disease, syphilis, typhoid fever, tuberculosis, lymphoma, heterotopic gastric mucosa (Meckel's diverticulum), and ulcers associated with gastrinoma. This discussion is limited to ulcerations of the small intestine in which no causative agent can be identified.

Patients with discrete isolated ulcers of the small bowel and without any identifiable underlying disease have nonspecific ulcers. Ulcers are more common in the terminal ileum. These appear to be self-limited and do not recur after bowel resection.

These patients usually present with a single ulceration, although multiple ulcers may be present. Indications for operation are for complications of the ulcers, including perforation, bleeding, or stricture. Recurrence of ulceration in the small bowel distal to the duodenum is rare. A review of 59 patients studied from 1956 to 1979 reports the overall incidence of small-bowel ulcerations to be 4 per 100,000 new patients seen at the Mayo Clinic. These investigators noted that the yearly rate fell from 3.6 new cases per year from 1960 to 1969 to 1.2 cases per year from 1970 to 1979. They believe, despite the absence of a documented underlying cause, that the decrease in incidence was directly related to the removal of enteric-coated potassium chloride tablets from the market.

The ulcers are discrete, varying from 0.3 to 5 cm in diameter; they are sharply demarcated, and the surrounding mucosa is perfectly normal. They occur more frequently on the antimesenteric border and may be associated with fibrous scar formation, which produces the obstruction. The characteristic microscopic findings include acute granulation tissue and inflammatory cells at the base of the ulcer, local hyperplasia of the muscularis mucosae, and pyloric metaplasia of the adjacent mucosa. Varying degrees of edema and fibrosis, depending on the chronicity of the ulcer, are noted. There is no evidence of vascular disease associated with the ulcer. With time, the ulcers may increase in size, may become annular, and, with healing, may produce fibrous strictures of the intestine, which may produce obstruction.

Diagnosis is rarely if ever made before operation; the majority of patients present with complications. In the Mayo Clinic series 63 percent of patients had intermittent small-bowel obstruction, 25 percent had bleeding, and 12 percent had symptoms of acute abdominal inflammation caused by perforation. With the increasing use of enteroclysis, the diagnosis of small-bowel ulcer may be made more frequently. An asymptomatic solitary ulcer does not require treatment.

Treatment

The treatment of small-bowel ulcers depends on the complications encountered at the time of diagnosis. Mechanical bowel obstruction and bleeding should be treated by segmental resection. Although excision and primary closure of perforated ulcers has been advocated by some, high recurrence rates have been associated with this technique. The ulcerated segment of bowel should be resected.

Ingested Foreign Bodies

A great variety of objects that are capable of penetrating the wall of the gut are swallowed, usually accidentally, but sometimes intentionally by the mentally deranged. These include glass and metal fragments, pins, needles, cocktail toothpicks, fish bones, coins, whistles, toys, and broken razor blades.

Treatment is observation, since the vast majority pass without difficulty. If the object is radiopaque, progress can be followed by serial plain films. Catharsis is contraindicated.

Sharp, pointed objects such as sewing needles may penetrate the bowel wall. If abdominal pain, tenderness, fever, or leukocytosis occurs, immediate surgical removal of the offending object is indicated. Abscess or granuloma formation is the usual outcome without surgical therapy.

Small-Bowel Fistulas

The vast majority of small-bowel fistulas are a result of operation; less than 2 percent are associated with granulomatous disease of the bowel (Crohn's disease) or trauma. In some patients there are contributing factors, such as preoperative radiotherapy, intestinal obstruction, inflammatory bowel disease, mesenteric vascular disease, and intraabdominal sepsis. But in the majority, surgical misadventures are the primary cause. These include anastomotic leak, injury of bowel or blood supply at operation, laceration of bowel by wire mesh or retention sutures, and retained sponges. In addition, fistulas may result from erosion by suction catheters and by abscesses.

The major complications associated with small-bowel fistulas include sepsis, fluid and electrolyte depletion, necrosis of the skin at the site of external drainage, and malnutrition. Successful management of patients with small-bowel fistulas requires meticulous attention to detail and a logical, stepwise plan of management. One must establish controlled drainage, manage sepsis, prevent fluid and electrolyte depletion, protect the skin, and provide for adequate nutrition.

Mortality for patients with intestinal fistulas remains high (20 percent or greater), even with the use of total parenteral nutrition (TPN). Although TPN has not been shown to reduce mortality significantly, it is the single most important advance in the management of patients with enterocutaneous fistulas. Fluid, electrolyte, and nutritional status may be maintained from the time the fistula becomes apparent and throughout the time required for control of sepsis. The key to successful management of intestinal fistulas is control of sepsis and prevention of malnutrition.

Diagnosis of small-bowel fistula usually is not difficult. When the damaged area of the small bowel breaks down and discharges its contents, dissemination may occur widely in the peritoneal cavity, producing generalized peritonitis. More commonly, however, the process is more or less walled-off in the immediate area of the leak, with formation of an abscess. This usually underlies the operative incision, so that when a few skin sutures are removed to ascertain why the incision is becoming red and tender, contents of the abscess are discharged and the fistula established. The discharge initially may be purulent or bloody, but this is followed—sometimes immediately, sometimes within a day or two—by drainage of obvious small-bowel contents. If the diagnosis is in doubt, confirmation can be obtained by oral administration of a nonabsorbable marker such as charcoal or Congo red.

Small-bowel fistulas are classified according to their location and volume of daily output, since these factors dictate treatment as well as morbidity and mortality rates. In general, the more proximal the fistula in the intestine, the more serious the problem. Proximal fistulas have a greater fluid and electrolyte loss, the drainage has a greater digestive capacity, and an important (distal) segment is not available for food absorption. High-output fistulas are those that discharge 500 mL or more per 24 h. It is important, therefore, as soon as the patient's condition is stabilized, to identify the site of the fistula, to determine the extent of the associated abscess cavity by fistulogram, and to ascertain whether there is distal obstruction, since fistulas will not close in the presence of distal obstruction (Fig. [25-31](#)). Upper gastrointestinal series with small-bowel follow-through and barium enema studies also may provide useful information.

Treatment

Control of sepsis is aided by sump suction, which provides drainage of the associated intraabdominal abscess cavity and prevents accumulation of intestinal contents. Control of fistula output is most easily accomplished by percutaneous intubation of the fistula tract. Protection of the skin around the fistulous opening is important. In the past, frequent applications of zinc oxide, aluminum paste ointment, or karaya powder were required; excoriation and destruction of skin still occurred. The advent of Stomahesive appliances used for colostomy and ileostomy bags greatly improved and facilitated protection of the skin at the site of the fistula. The Stomahesive appliance should be cut so that the opening just fits over the fistulous opening and no unprotected skin remains. The suction catheter can be brought out through the end of the bag, which is fixed firmly about the tube. This allows for collection of all the drainage and accurate quantitation of the lost volume.

The volume depletion that occurs from a proximal small-bowel fistula may present a formidable problem. Volume losses exceeding 5 L/day are not uncommon. Agents that inhibit gut motility (codeine, Lomotil, or loperamide) generally are not helpful. The hormone somatostatin is considered a general "off switch" and inhibits both intestinal secretion and motility. We and others have used a long-acting octapeptide analog of somatostatin (octreotide) in combination with TPN in the management of enterocutaneous fistulas. In most series, the overall fistula closure rate was not altered, but the analog ameliorated the problems associated with massive volume loss. Systemic antibiotics should be administered until sepsis is controlled. TPN should be instituted at the same time, because a prolonged course of inability to use the gut for nutrition is likely.

Several factors may prevent spontaneous closure of fistulas. Fistulas will not close spontaneously if there is high output (> 500 mL/24 h) or severe disruption of intestinal continuity (> 50 percent of the circumference of the bowel involved in the fistula). A fistula will not close spontaneously if it arises from a segment of bowel involved with active granulomatous disease, cancer, or radiation enteritis, if there is distal obstruction, or if there is an undrained abscess cavity. If a foreign body is in the tract, if the fistula tract is less than 2.5 cm in length, or if there is epithelialization of the tract, spontaneous closure will not occur. Radiographic investigation of the fistula by injection of water-soluble contrast material through the fistula tract should be carried out early to delineate the presence and extent of any abscess cavities and to obtain information about the length of the tract and the extent of bowel wall disruption. A diligent search by means of contrast studies for distal obstruction should be performed. CT will often reveal undrained collections of fluid.

When any of the conditions noted above are present, spontaneous closure is unlikely, and therefore management should be directed toward obtaining prompt control of sepsis, maintaining positive nitrogen balance, and early operation.

Conservative treatment for up to 3 months with TPN has been advocated by some to allow spontaneous closure of the fistula. We do not believe that the results support this approach. Fewer than 30 percent of all small-bowel fistulas will close spontaneously. In patients with low-output fistulas, particularly those located in the distal small bowel without any of the conditions that prevent spontaneous closure, a wait of up to 6 weeks may be indicated. The patient usually can wait at home. When we reviewed reported series that advocate conservative therapy for longer than 6 weeks, we found that the majority of fistulas that close spontaneously do so within 3 weeks after their appearance. After 3 weeks, if sepsis has been controlled and adequate nutritional status has been achieved, operative control of the fistula should be carried out promptly. Delay only produces delay. TPN simplifies management of patients, but it does not cure fistulas. The single most important determinant in successful treatment of fistulas is sepsis. If sepsis is not controlled, the patient will die. After sepsis has been controlled, one should not wait endlessly for a fistula to close spontaneously simply because malnutrition can be avoided by use of TPN. The proper role of TPN is prevention or treatment of malnutrition before operative closure of fistulas.

Operation is most easily accomplished by entering the previous abdominal wound. The wound should be reopened with great care to avoid needless reinjury to the bowel. The fistula tract is excised, the bowel should be completely mobilized, and the portion of bowel involved in the fistula is resected. The technique of excision and fistula closure must be precise and accurate, and all rigid or diseased bowel must be resected. Simple closure of the fistula after removing the fistula tract and minimal mobilization of the bowel almost always results in recurrence of the fistula.

If an unexpected abscess is encountered or if the bowel wall is rigid and distended over a large distance, a proximal enterostomy should be performed. Later, resection of the bowel involved in the fistula will be required for successful closure. Side-to-side bypass should not be done.

The overall mortality rate in enterocutaneous fistulas of the small bowel is greater than 20 percent. It is higher in jejunal fistulas and significantly lower in ileal fistulas. Successful treatment of the majority of patients with small-bowel fistulas requires control of sepsis, provision of adequate nutrition, and operative closure.

Pneumatosis Cystoides Intestinalis

This is an uncommon condition manifested by multiple gas-filled cysts of the gastrointestinal tract. The cysts are either submucosal or subserosal and vary in size from microscopic to several centimeters in diameter. The jejunum is most frequently involved, followed by the ileocecal region and the colon; extraintestinal structures such as mesentery, peritoneum, and the falciform ligament also may be involved. Gas cysts are associated with other lesions of the gastrointestinal tract in about 85 percent of cases. These “secondary” causes include inflammatory, obstructive, or infectious conditions of the intestine, iatrogenic conditions such as endoscopy and jejunostomy placement, ischemia, and extraintestinal diseases such as chronic obstructive pulmonary disease, diabetic enteropathy, and collagen vascular diseases. Pneumatosis not associated with other lesions (15 percent of cases) is referred to as primary pneumatosis.

Grossly, the cysts resemble cystic lymphangiomas or hydatid cysts. On section, the involved portion has a honeycomb appearance. The cysts are thin-walled and break easily. Spontaneous rupture gives rise to pneumoperitoneum.

Symptoms are nonspecific and in secondary pneumatosis may be those of the associated disease. Symptoms in primary pneumatosis, when present, resemble those of irritable bowel syndrome. The diagnosis usually is made radiographically by plain abdominal or barium studies (Fig. 25-32). Diagnosis also may be made by CT. No treatment is necessary unless one of the very rare complications supervenes, such as rectal bleeding, cyst- induced volvulus, or tension pneumoperitoneum. Prognosis in most patients is that of the underlying disease. When pneumatosis occurs in infants with necrotizing enterocolitis, it does not make the outlook any worse. The cysts may disappear spontaneously or may persist for prolonged periods without serious symptoms.

Blind Loop Syndrome

This is a rare clinical syndrome manifested by diarrhea, steatorrhea, anemia, weight loss, abdominal pain, multiple vitamin deficiencies, and neurologic disorders. The underlying cause is not a blind loop per se, but bacterial overgrowth in stagnant areas of small bowel produced by stricture, stenosis, fistulas, blind pouch, or diverticula (Table 25-5). The bacterial flora are altered in the stagnant area, both in number and in kind. Bacteria compete successfully for vitamin B 12, producing a systemic deficiency of B 12 and megaloblastic anemia. Steatorrhea also occurs; bacteria in the stagnant area deconjugate bile salts, causing disruption of micellar solubilization of fats. There also may be absorptive defects of other macronutrients and micronutrients, probably caused by direct injury of the mucosal cells.

The syndrome can be confirmed by a series of laboratory investigations. First, a Schilling test (60Co-labeled vitamin B12absorption) is performed; this should reveal a pattern of urinary excretion of vitamin B 12resembling that of pernicious anemia (that is, a urinary loss of 0 to 6 percent of vitamin B 12, compared to the normal of 7 to 25 percent). The test is then repeated with the addition of intrinsic factor. In true pernicious anemia, the excretion should rise to normal; in the blind loop syndrome, the addition of intrinsic factor will not increase the excretion of vitamin B 12. Next, the patient is given a course of tetracycline for 3 to 5 days, and the Schilling test is repeated. With blind loop syndrome, absorption of 60Co-labeled vitamin B 12 returns to normal; this does not occur in the macrocytic anemia due to steatorrhea. Patients with the blind loop syndrome respond to tetracycline and parenteral vitamin B 12therapy. Medical treatment is not definitive but should be employed to prepare patients for operation. Surgical correction of the condition producing stagnation and blind loop syndrome effects a permanent cure and is indicated.

Radiation Enteritis

Radiation is a common adjuvant therapy in the multimodality approach to the treatment of various abdominal and pelvic cancers. Along with the beneficial effects gained by killing tumor cells, surrounding normal tissues such as the small intestine may sustain severe acute and chronic deleterious effects. The intestinal epithelium is the most radiosensitive tissue of the gut. The amount of radiation required to produce clinical signs of enteritis varies with the treatment regimen as well as the patient. Serious morbidity is unusual if the total radiation dosage is less than 4,000 cGy; however, the complication rate increases when doses exceed 5,000 cGy. In addition, previous abdominal operations, preexisting vascular disease, hypertension, diabetes, and treatment with certain chemotherapeutic agents (e.g., 5-fluorouracil, doxorubicin, actinomycin D, and methotrexate) increase the likelihood of enteritis after radiation treatments.

The mucosa and the submucosal vasculature of the intestine are the most sensitive to radiation damage. With the relatively rapid turnover of the intestinal mucosa, radiation damage to this layer tends to be acute and self-limiting, with symptoms consisting mainly of diarrhea, abdominal pain, and malabsorption. Late effects of radiation are the result of damage to the small submucosal vessels, with a progressive obliterative arteritis and submucosal fibrosis, resulting eventually in thrombosis and vascular insufficiency. This injury may produce necrosis and perforation of the involved intestine, but more commonly it leads to strictures, with symptoms of obstruction, or fistula formation.

Radiation enteritis may be minimized by adjusting ports and dosages of radiation to deliver optimal treatment specifically to the tumor and not to surrounding tissues; this could be facilitated by placement of radiopaque markers, if laparotomy is performed, to delineate the area to be irradiated. Prophylactic measures to help decrease the incidence of enteritis include methods to exclude small bowel from the pelvis such as reperitonealization, omental transposition, or placement of absorbable mesh slings.

Treatment of the acute sequelae of radiation injury may be obtained by conservative measures such as the administration of antispasmodics, analgesics, and antidiarrheal agents. Agents that may prove useful in the treatment of acute sequelae include glutamine-enriched enteral formulas and the gut hormone bombesin, which ameliorates methotrexate-mediated enterocolitis in experimental animals.

Operative intervention may be required for symptomatic strictures or fistulas. Caution must be exercised when operating on patients with previously irradiated bowel, since the vascular injury may be widespread and not readily recognizable by gross inspection of the intestine; if resection and reanastomosis are performed, dehiscence of the anastomosis can occur. Extensive adhesiolysis should be avoided if possible. Perforation of the intestine should be treated with resection and anastomosis; when reanastomosis is thought to be unsafe, ostomies should be created. Frozen sections and laser Doppler flowmetry have been used to assist resection and anastomosis; however, the clinical usefulness of these techniques has been debated. Obstruction caused by a rigid, fixed pelvis incorporating small intestinal loops is best treated by bypass.

Radiation enteritis is a relentless disease process reflecting widespread bowel involvement. Almost one-half of patients who survive their first laparotomy for radiation bowel injury require further surgery for ongoing bowel damage. Up to 25 percent of these patients die from radiation enteritis and complications from its management.

Short Bowel Syndrome

In the adult, emergency massive resection of the small bowel must sometimes be done when extensive gangrene precludes revascularization. Mesenteric occlusion, midgut volvulus, and traumatic disruption of the superior mesenteric vessels are the most frequent causes. Short bowel syndrome may result from such massive resections; it also may be produced by several bowel resections in patients with severe recurrent Crohn's disease. In neonates the most common cause of short bowel syndrome is necrotizing enterocolitis.

The short bowel syndrome is a group of signs and symptoms that result from a total small bowel length that is inadequate to support nutrition. The clinical hallmarks of the short bowel syndrome include diarrhea, fluid and electrolyte deficiency, and malnutrition. The small bowel has two primary functions, digestion and absorption of nutrients. Problems that result from extensive resection of the small bowel can be divided into two types: those related to the extent of small-bowel loss, and those related to the specific area of bowel removed.

Although there is considerable individual variation, resection of up to 70 percent of the small bowel usually can be tolerated if the terminal ileum and ileocecal valve are preserved. Length alone, however, is not the only determining factor of complications of small-bowel resection. For example, if the distal two-thirds of the ileum, including the ileocecal valve, is resected, significant abnormalities of absorption of bile salts and vitamin B 12 may occur, although only 25 percent of the total length of the small bowel has been removed. Proximal bowel resection is tolerated much better than distal resection, since the ileum can adapt and increase its absorptive capacity more efficiently than the jejunum.

Digestion and absorption in the small bowel depend on the presence of brush border enzymes, an adequate number of enterocytes for absorption, and normal intestinal motility. With massive resection of the small bowel, there is reduced absorption of all nutrients, including electrolytes, water, carbohydrates, protein, fat, trace elements, and vitamins. The proximal small bowel is the primary site of absorption of iron, folate, and calcium, whereas the distal small bowel is the site of absorption of bile salts and vitamin B 12.

The bowel has an intrinsic capacity to adapt after small-bowel resection, and in many instances this process of intestinal adaptation effectively prevents severe complications resulting from the reduced surface area available for absorption and digestion. Any adaptive mechanism can be overwhelmed; maximum adaptation will be inadequate if too much small bowel is lost. Intestinal adaptation is characterized by an increased absorptive surface area as a result of hyperplasia of the remaining enterocytes. The villi lengthen (but do not increase in number), more cells are produced, and there are increased cell renewal and migration to the villous tip. All this serves to produce an increase in total absorptive surface area. Although there are more cells, individual cells do not increase their life span (they must migrate farther) or their capacity to synthesize digestive enzymes or to increase absorptive processes, so the overall net increase in digestive efficacy is not great (Fig. 25-33).

The mechanisms responsible for intestinal adaptation have been studied widely in animals. Multiple factors are responsible and are required for development of successful intestinal adaptation. For unknown reasons, the ileum exhibits a much greater adaptive response than the jejunum. Luminal nutrients, trophic gut hormones, specific amino acids (e.g., glutamine), and pancreatic and biliary secretions are all required for complete adaptation to occur. In animals maintained on TPN after extensive small-bowel resection, nutrition may be maintained but intestinal adaptation does not occur. Enteral diets containing glutamine, the principal fuel used by the small intestine, have been shown to increase mucosal proliferation and gut regeneration in experimental models. In addition, dietary fiber (e.g., pectin) has been shown to enhance mucosal adaptation, increase stool acidity, and improve colonic water absorption. The trophic gut peptides studied most intensively in small-bowel adaptation are gastrin, CCK, secretin, neurotensin, peptide YY, and bombesin. We now know that, although hypergastrinemia is associated with the short bowel syndrome, gastrin does not play a major role in the adaptive response after resection. CCK and secretin may have direct effects on enterocyte replication; however, their primary importance in intestinal adaptation may be in stimulation of pancreaticobiliary secretions rather than in directly stimulating enterocyte proliferation. The small-bowel mucosa is a complex and highly proliferative tissue with multiple factors regulating growth. The gut hormone neurotensin appears to be one of the most potent enterotrophic factors identified to date. Administration of neurotensin stimulates small-bowel mucosal growth in rats fed a normal diet, prevents gut mucosal hypoplasia induced by feeding rats an elemental diet, and augments intestinal regeneration after small-bowel resection. Recent studies demonstrate a marked mucosal growth response by the gut-derived peptide glucagonlike peptide-2 (GLP-2), which may hold promise for patients with short bowel syndrome. Two other hormones, not derived from the gut, that have been evaluated extensively in various experimental and in limited clinical trials include growth hormone and insulinlike growth factor-1 (IGF-1).

Growth hormone enhances mucosal hyperplasia in both the remnant small bowel and colon. IGF-1, which is regulated by growth hormone, increases the weight and length of the small and large intestines. Results reported recently by Byrne and colleagues using a combination of growth hormone, glutamine, and a modified diet appear promising in allowing for a reduction or elimination of TPN requirements in some refractory patients with severe short bowel syndrome and TPN dependence.

In human beings, the adaptive responses to massive resection have been found to be increased caliber of the remaining small bowel, hypertrophy of the gut wall, increased villous height, and increase numbers of enterocytes. This process often takes weeks or months to complete after small-bowel resection. With time, absorptive function increases. This increase is characterized by decreasing stool losses of water and electrolytes and increased absorption of glucose and vitamin B₁₂.

Hypergastrinemia and gastric hypersecretion occur after massive small-bowel resection and have been widely studied in experimental animals; some information has come from human subjects. Diarrhea associated with gastric hypersecretion is caused by (1) delivery of a massive volume of fluid and electrolytes to the shortened small bowel, (2) steatorrhea from failure of lipolysis by pancreatic lipase, which requires an intraluminal pH greater than 5.0 for activity (pancreatic secretion of lipase is not affected), and (3) acid enteritis. Although acid hypersecretion was at one time thought to be of prime importance in producing diarrhea after extensive small-bowel resection, both hypergastrinemia and hypersecretion of acid are transient. Acid hypersecretion is now easily managed by H₂-receptor antagonists or proton-pump blockers. Control of acid secretion controls diarrhea to a great extent during the early phase. Several operations, including vagotomy with pyloroplasty, or vagotomy with antrectomy, have been employed in treatment of the short bowel syndrome to control acid hypersecretion. Since the problem is self-limited, however, these procedures are not indicated and should not be done.

Resection of specific segments of the small bowel leads to specific problems. Resection of the distal small bowel results in diarrhea, steatorrhea, and malabsorption. Conjugated bile salts, essential for normal fat absorption, are almost totally absorbed in the distal ileum by active transport mechanisms. Resection of the ileum results in disruption of the enterohepatic circulation of bile salts and may lead to two types of diarrhea. When less than 100 cm of small bowel has been resected, excessive amounts of bile salts enter the colon and produce a chemical enteritis; this type of diarrhea has been termed *cholerheic*. The toxic effects of bile acids on colonic epithelial cells are twofold: bile salts inhibit absorption of water and electrolytes in the colon, and the injured colonic cells secrete excessive amounts of water and electrolytes. The response to decreased absorption of bile salts is increased hepatic production of bile salts, and this leads to perpetuation of diarrhea.

When more than 100 cm of ileum has been resected, the loss of bile salts is so great that hepatic synthesis cannot compensate. Furthermore, decreased intraluminal bile acids stimulate CCK release, and CCK stimulates gut motility. In addition to the direct toxic effects of bile salts on the colonic epithelium, fat malabsorption (steatorrhea) occurs. Differentiation of the two types of diarrhea associated with distal resection is important, because treatment is different. Measurement of stool fat content, vitamin B₁₂ absorptive capacity, and fecal bile salt concentrations is important for accurate determination of the deficits produced. For patients who have cholerheic diarrhea, agents that bind bile acids (e.g., cholestyramine) may alleviate diarrhea. If steatorrhea is present, then medium-chain triglycerides that do not require micelle formation for absorption also should be used.

Another factor contributing to diarrhea after ileal resection is loss of the ileocecal valve. The ileocecal valve has two important actions. It prolongs intestinal transit time, and it prevents retrograde passage of colonic bacteria into the small bowel, which, if not prevented, causes bacterial enteritis.

Other complications associated with alteration of enterohepatic circulation of bile acids include gallstones and anemia. The changes in the bile salt pool produce lithogenic bile; the incidence of gallstones in patients with ileal resection is three to four times greater than in the normal population. The ileum is the specific site for transport mechanisms for intrinsic-factor-mediated vitamin B₁₂ absorption, and with total ileal resection, stores of vitamin B₁₂ are depleted and anemia results.

Treatment

The most important principle in the treatment of short bowel syndrome is prevention. This means that at operation, when intestinal viability is questionable, the smallest possible resections should be performed, and “second-look” operations 24 to 48 h later should be carried out to allow the ischemic bowel to demarcate. Delay may prevent unnecessary, extensive resection of bowel. In patients with Crohn's disease, the devastating complications of the short bowel syndrome have led all students of the disease to recognize that only limited resections should be performed.

After massive small-bowel resection, the program for treatment may be properly divided into early and late phases. Early on, treatment is primarily directed at the control of diarrhea, replacement of fluid and electrolytes, and the prompt institution of total parenteral nutrition. Volume losses may exceed 5 L/day, and vigorous monitoring of intake and output with adequate replacement must be carried out. Depletion of fluid volume caused by diarrhea, especially in the early phase, is often a formidable problem. Judicious use of agents that inhibit gut motility (codeine, Lomotil, loperamide) may be helpful. These drugs may cause profound ileus if used excessively, and volume lost through the gut is simply traded for volume lost through nasogastric suction. In addition, prolonged ileus with dilatation and edema of the bowel wall may result.

As intestinal adaptation progresses and gut absorption increases, the stool volume gradually decreases. Once patients have completely adapted to an oral diet, semiformal stools may appear, but these patients will likely never have the normal number or consistency of stools.

As soon as the patient has recovered from the acute phase, enteral nutrition should begin, so that intestinal adaptation may begin early and proceed successfully. The most common types of enteral diets are elemental (Vivonex, Flexical) or polymeric (Isocal, Ensure). Each presents problems with increased osmolality and may contain foodstuffs that may not be absorbed because of enzyme deficiency (for example, lactase deficiency). Milk products should be avoided, and diets should be begun at isoosmolar concentrations and with small volumes (50 mL/h), even though the full nutrient value may not be obtained. As the gut adapts, the osmolality, volume, and caloric content may be increased. As previously noted, the combination of glutamine, growth hormone, and a modified oral diet may prove efficacious at this stage. Gut hormones in combination with dietary modifications may prove to be useful in the future.

Reduction of dietary fat has long been considered to be important in the treatment of patients with the short bowel syndrome. High-carbohydrate, high-protein, low-fat diets have been prescribed. Fat has more than twice as many calories per gram as protein and carbohydrate and is important for maintenance of proper nutrition. Supplementation of the diet with 100 g or more of fat should be carried out. Often this requires the use of medium-chain triglycerides, which may be absorbed in the proximal bowel without micelle formation. Vitamins, especially fat-soluble vitamins, as well as calcium, magnesium, and zinc supplementation, also must be provided. H₂-receptor antagonists or proton-pump blockers may greatly diminish the diarrhea that is largely caused by the early, transient acid hypersecretion. Measurement of intragastric pH can be used to guide the dose of drugs required. Antacids are not useful, because they may aggravate diarrhea or bind essential ions. In no case should gastric resection or vagotomy be used for the treatment of the short bowel syndrome.

Since the dysfunction of massive small-bowel resection is caused by decreased absorptive surface and rapid transit time, most attempts at surgical treatment have been directed toward increasing the absorptive surface or slowing the intestinal transit time. The intestinal tapering and lengthening procedure, originally described by Bianchi, improves intestinal function by correcting the dilatation and ineffective peristalsis of the intestine as well as by prolonging intestinal transit time by doubling the intestinal length while preserving the mucosal surface area. Dissection is performed longitudinally on the mesenteric edge of the bowel to create a space that permits longitudinal division of the bowel with a stapling device. This procedure may be beneficial in selected patients; however, potential complications include necrosis of divided segments and anastomotic leak. Procedures to slow intestinal transit time include reversed intestinal segments, circular loops, colon interposition, and construction of valves (artificial sphincters). These procedures have received limited clinical evaluation; most reports are only anecdotal, and the efficacy of these techniques remains questionable. In fact, some reports actually show a decreased effective functional length and an increased risk of bowel infarction with these procedures. Therapy for the short bowel syndrome may be revolutionized when small-intestine transplantation becomes a less morbid procedure. The greatest obstacles to successful bowel transplantation have been rejection and sepsis.

In summary, the present treatment of the short bowel syndrome is palliative and is directed toward control of diarrhea and prevention of dehydration and malnutrition. In the future, use of glutamine, growth factors, and gastrointestinal hormones may be useful adjuncts in certain patients; however, only with the development of successful allotransplantation of the gut will the short bowel syndrome be cured.

Intestinal Bypass

Morbid Obesity

Surgical procedures to treat morbid obesity (defined as more than 100 lb over ideal weight) have become popular because the long-term success rate of nonsurgical treatment of this condition is only 1 percent. There are two basic approaches: (1) restrict the amount of food entering the gastrointestinal tract (gastric reduction) or (2) reduce the amount of food absorbed (gut shortening). The original procedure designed to create a short-gut malabsorption syndrome, jejunocolostomy, had to be abandoned because of an unacceptable rate of complications. It was succeeded by jejunoileostomy, either end-to-side (Payne procedure) or end-to-end (Scott procedure). Many thousands of these procedures have been done in the United States. These too have been abandoned because of long-term complications, which included persistent diarrhea, profound electrolyte abnormalities, arthralgias, neurologic symptoms, enteropathies, cholelithiasis, renal disease, and hepatic failure. In addition, the long-term weight control was poor. An alternative method of operative therapy of obesity is the gastric bypass or partition. This method limits food intake by reducing the reservoir capacity of the stomach to 5 to 10 percent of normal. After a Consensus Development Conference at the National Institutes of Health in March 1991, the only procedures currently recommended for evaluation are gastric reductions.

Hyperlipidemia

Surgical bypass of a portion of the small intestine is a useful method of treating hypercholesterolemia and hypertriglyceridemia. The operation, designed by Buchwald and Varco, bypasses either the distal 200 cm or the distal one-third of the small intestine, whichever is greater (Fig. 25-34). This operation, though occasionally associated with diarrhea, does not cause significant weight loss and is not associated with the undesirable side effects of the jejunoleal bypass.

This procedure lowers serum cholesterol level through two mechanisms: the absorption of cholesterol is reduced by bypassing the usual site of absorption, and cholesterol and bile acid excretion is increased, which accelerates cholesterol turnover.

Clinical metabolic studies have demonstrated a 60 percent decrease in cholesterol absorption, a 40 percent reduction in serum cholesterol levels, and a reduction of more than 50 percent in plasma triglyceride levels. About 70 percent of patients with angina have had improvement or total remission of symptoms after this operation.

Results have been reported from the long-term follow-up of the first group of patients studied as well as from the Program on the Surgical Control of the Hyperlipidemias (POSCH), a prospective, randomized, multicenter trial. Of the original 57 patients, partial ileal bypass produced significant sustained (longer than 20 years) reduction in total plasma cholesterol levels. Only 3.5 percent of patients required reversal of the bypass; however, 40 percent developed nephrolithiasis. These findings were confirmed in the POSCH trial. The POSCH trial data also have shown an apparent reversal of coronary artery atherosclerosis and reduction of mortality rates in some subgroups of patients. The response of the 78 women in the POSCH trial was similar to that of the group as a whole, although small numbers made statistical significance difficult to achieve. Thus, partial ileal bypass, when employed for the correction of hyperlipidemia, appears to be an effective method of lipid reduction and may result in a decrease of mortality in certain subgroups of patients.

ANATOMIC CONSIDERATIONS

Embryology

The primitive gut, which is divided into the foregut, the midgut, and the hindgut, develops during the fourth week of gestation. The midgut develops into the small intestine (beginning at the entrance of the common bile duct) and the large intestine proximal to the midtransverse colon. This intestinal segment receives blood from the *superior mesenteric artery*. The hindgut develops into the large bowel distal to the midtransverse colon as well as the proximal anus and the lower urogenital tract and receives its main blood supply from the *inferior mesenteric artery*. The distal anal canal receives blood from branches of the internal pudendal artery and is ectodermal in origin (Fig. 26-1).

The developing midgut migrates out of the abdominal cavity during the sixth week of pregnancy. During the ensuing 4 weeks, the midgut rotates 270° in a counterclockwise direction about the superior mesenteric artery before assuming its final anatomic position in the abdominal cavity.

The developing hindgut is terminated by the *cloaca*, which during the sixth week of development is partitioned by the anorectal septum into the ventral urogenital sinus and the dorsal rectum. The anal canal is completely formed by the end of the eighth week when the thin anal membrane ruptures. The *dentate line* in the lower anal canal marks the transition from endodermal hindgut to ectodermal tissue.

Anatomy

Colon

The colon, approximately 3 to 5 feet in length, extends from the ileum to the rectum. The terminal ileum joins the cecum on its posteromedial border at the ileocecal valve. The fold of Treves (the only antimesenteric fatty appendage on the small bowel) is located on the distal ileum just proximal to the ileocecal valve. The *cecum* projects from the antimesenteric side of the ascending colon and is a large blind pouch with no mesentery. The cecum is approximately 7.5 to 8.5 cm in diameter and is the widest portion of the colon. The colon progressively diminishes in size to the *sigmoid* colon, its narrowest portion, which is approximately 2.5 cm in diameter. This size discrepancy accounts for the frequent observation that cecal tumors can grow to be large and bulky before the onset of symptoms, whereas sigmoid tumors are symptomatic at smaller sizes. The cecum, because of its relatively large diameter, is also the most common site of colonic rupture caused by distal obstruction. This is explained by Laplace's law: Tension is directly proportional to the radius of a sphere ($T = PR$, where T is tension in the wall of the bowel, P is internal pressure, and R is the radius of the bowel).

The layers of the colon wall include mucosa, submucosa, inner circular muscle, outer longitudinal muscle, and serosa (Fig. 26-2). The longitudinal muscle is separated into three distinct bands called *teniae coli* and positioned 120° apart about the circumference of the colon. The teniae converge proximally at the appendix and disappear as distinct bands at the proximal rectum at the level of the sacral promontory. *Haustra coli* are sacculations between the teniae and are separated by crescent-shaped folds called *plicae semilunares*. *Appendices epiploicae* are fatty appendages attached to teniae.

The *omentum* is attached to the transverse colon on its anterosuperior edge. The ascending colon, descending colon, and posterior surface of the hepatic and splenic flexures are usually retroperitoneal, whereas the cecum, transverse colon, and sigmoid colon are intraperitoneal in location. Although volvulus is most common in the sigmoid colon, the cecum and, rarely, the transverse colon also might twist about their mesenteries because of their intraperitoneal location and relative lack of fixation.

Arterial Supply

The *superior mesenteric artery* arises from the ventral surface of the aorta just below the celiac axis (see Fig. 26-1). It passes downward behind the pancreas and crosses in front of the third portion of the duodenum. It supplies the cecum, ascending colon, and transverse colon via its ileocolic and middle colic branches. Cadaver studies have shown that the right colic artery arises from the superior mesenteric artery in fewer than 15 percent of patients. It arises from the ileocolic in 85 percent of patients. *The inferior mesenteric artery* arises from the infrarenal aorta and supplies the descending colon, sigmoid colon, and upper rectum via its left colic, sigmoidal, and superior rectal branches.

Collaterals exist between the superior and inferior mesenteric arteries in the region of the splenic flexure. The arcades of the ileocolic, right, middle, and left colic arteries are peripherally connected by a series of anastomosing vessels commonly referred to as the *marginal artery of Drummond*. The marginal artery of Drummond runs along the mesenteric border of the colon and provides the vasa recta to the colon. The *arc of Riolan* is located closer to the mesenteric root. It is an inconstant vessel that exists between the left colic branch of the inferior mesenteric artery and the middle colic branch of the superior mesenteric artery. It is frequently referred to as the *meandering mesenteric artery* because of its tortuous course, and it is best visualized when there is an occlusion of either the inferior or superior mesenteric artery.

Venous Drainage

Except for the inferior mesenteric vein, which lies adjacent to the ascending branch of the left colic artery, the veins draining the colon follow the same course as the corresponding arteries. The *inferior mesenteric vein* drains the descending colon, sigmoid colon, and proximal rectum. It runs in a retroperitoneal location to the left of the ligament of Treitz, continues behind the body of the pancreas, and enters the splenic vein. The *superior mesenteric vein* drains the cecum, ascending colon, and transverse colon and joins the splenic vein to form the portal vein.

Lymphatic Drainage

The colon is encircled by lymphatic channels located in the submucosa and the muscularis mucosae. The mucosa has rich vascular plexi but no lymphatics. For this reason, superficial cancers that do not penetrate the muscularis mucosae cannot metastasize via the lymphatic route. This segmental architecture limits longitudinal intramural extension of tumors. Circumferential extension into submucosal and serosal zones results in annular lesions. Lymphatic vessels follow the arterial supply of the colon. Lymph nodes are located on the bowel wall (epicolic), along the inner margin of the bowel (paracolic), around the named mesenteric arteries (intermediate), and about the origin of the superior and inferior arteries (main).

Nerve Supply

Sympathetic nerves inhibit and *parasympathetic* nerves stimulate peristalsis. Sympathetic fibers to the right colon originate in the lower six thoracic segments of the spinal cord. They travel in the thoracic splanchnic nerves to the celiac plexus and then to the superior mesenteric plexus. The parasympathetic supply to the right side of the transverse colon is presumed to come from the right vagus nerve.

Sympathetic innervation of the left colon and rectum originates in the first three lumbar segments. These nerves join the preaortic plexus and become the inferior mesenteric plexus below the bifurcation of the aorta. The parasympathetic nerves to the left colon arise from the sacral nerves to form the nervi erigentes on either side of the rectum. Extensions of the sacral parasympathetics ascend through the hypogastric plexus to the area of the splenic flexure.

Rectum and Anal Canal General Anatomy

The rectal wall consists of mucosa, submucosa, and two complete muscular layers: inner circular and outer longitudinal (Fig. 26-3). The rectum is approximately 12 to 15 cm in length and extends from the sigmoid colon to the anal canal following the curve of the sacrum (Fig. 26-4). The anterior *peritoneal reflection* is about 5 to 7.5 cm above the anus in females and 7 to 9cm above the anus in males. The posterior peritoneal reflection is usually 12 to 15 cm above the anus. The upper third of the rectum is covered by peritoneum on its anterior and lateral surfaces. The middle third of the rectum is covered by peritoneum only on its anterior surface, and the lower third of the rectum is below the peritoneal reflection. The proximal rectum is identified as the level at which the teniae coli of the colon coalesce to form a complete layer of longitudinal muscle at approximately the level of the sacral promontory.

The rectum contains three distinct curves: The proximal and distal curves are convex to the right, whereas the middle curve is convex to the left. These folds project into the lumen as the *valves of Houston*. These mucosal infoldings present some difficulty for proctoscopic examination, but they are excellent targets for mucosal biopsy because they do not contain all layers of the muscular rectal wall and the risk of perforation is therefore diminished. The middle valve of Houston roughly correlates with the level of the anterior peritoneal reflection.

Waldeyer's fascia is a dense rectosacral fascia that begins at the level of the fourth sacral body and extends anteriorly to the rectum, covering the sacrum and overlying the vessels and nerves (see Fig. 26-86 E). Anterior to the extraperitoneal rectum is *Denonvilliers' fascia*, which is the rectovesical septum in men and the rectovaginal septum in women. The *lateral ligaments* of endopelvic fascia support the lower rectum but do not usually contain major blood vessels, as previously believed. Division of the lateral ligaments is thus possible without impairing the blood supply to the rectum or encountering a significant bleeding. Accessory middle hemorrhoidal arteries can be located in the lateral ligaments but are not critical to the blood supply of the rectum.

The *pelvic floor* is a musculotendinous sheet formed by the levator ani muscle and is innervated by the fourth sacral nerve (Fig. 26-5). The pubococcygeus, iliococcygeus, and puborectalis muscles make up the levator ani muscle. These are paired muscles that intertwine and act as a single unit. The line of decussation is called the *anococcygeal raphe*. The rectum, vagina, urethra, and the dorsal vein of the penis pass through the levator hiatus in the pubococcygeal portion of the levator ani. During defecation, the puborectalis relaxes and the levator ani contracts, widening the levator hiatus.

The *anal canal* starts at the pelvic diaphragm and ends at the anal verge (see Fig. 26-4). It is approximately 4 cm long and normally exists as a collapsed anteroposterior slit. The *anatomic anal canal* extends from the anal verge to the dentate line. For practical purposes, however, surgeons usually define the *surgical anal canal* as extending from the anal verge to the anorectal ring, which is the circular lower (see Fig. 26-3) border of the puborectalis that is palpable by digital rectal examination. The anorectal ring is 1 to 1.5 cm above the dentate line.

The *anal verge* is the junction between anoderm and perianal skin. The anoderm is a specialized epithelium rich in nerves but devoid of secondary skin appendages (hair follicles, sebaceous glands, or sweat glands). The *dentate line* is a true mucocutaneous junction located 1 to 1.5 cm above the anal verge (see Fig. [26-3](#)). A 6- to 12-mm transitional zone exists above the dentate line over which the squamous epithelium of the anoderm becomes cuboidal and then columnar epithelium.

The anal canal is surrounded by an internal and external sphincter, which together constitute the *anal sphincter mechanism* (see Fig. [26-5](#)). The *internal sphincter* is a specialized continuation of the inner circular smooth muscle of the rectum. It is an involuntary muscle and is normally contracted at rest. The intersphincteric plane represents the fibrous continuation of the longitudinal smooth muscle layer of the rectum.

The *external sphincter* is a voluntary, striated muscle divided into three U- shaped loops (subcutaneous, superficial, and deep) acting as a single functional unit. It is a specialized continuation of the levator muscles of the pelvic floor, specifically of the puborectalis muscle. The *puborectalis* originates at the pubis and joins posterior to the rectum. It is normally contracted, causing an 80° angulation of the anorectal junction.

The *columns of Morgagni* consist of 8 to 14 longitudinal mucosal folds located just above the dentate line and forming the anal crypts at their distal end (see Fig. [26-3](#)). Small rudimentary glands open into some of these crypts. The ducts of these glands penetrate the internal sphincter, and the body of the gland resides in the intersphincteric plane.

Arterial Supply

The terminal branch of the inferior mesenteric artery becomes the *superior rectal artery* as it crosses the left common iliac artery (Fig. [26-6A](#)). It descends in the sigmoid mesocolon and bifurcates at the level of the third sacral body. The left and right branches of the superior rectal artery supply the upper and middle rectum.

The middle and inferior rectal arteries supply the lower third of the rectum. The *middle rectal arteries* arise from the internal iliac arteries, run through Denonvilliers' fascia, and enter the anterolateral aspect of the rectal wall at the level of the anorectal ring. Collaterals exist between the middle and superior rectal arteries. Preservation of the middle rectal arteries is necessary to maintain viability of the remaining rectum after proximal ligation of the inferior mesenteric artery.

The *inferior rectal arteries* are branches of the internal pudendal arteries. They traverse Alcock's canal and enter the posterolateral aspect of the ischiorectal fossa. They supply the internal and external sphincters and the lining of the anal canal and do not form collaterals with the other rectal arteries. The *middle sacral artery* arises just proximal to the aortic bifurcation and provides very little blood supply to the rectum.

Venous Drainage

The venous drainage of the rectum parallels the arterial supply and empties into both the portal and the systemic (caval) systems. The upper and middle rectum are drained by the *superior rectal vein*, which enters the portal system via the inferior mesenteric vein (see Fig. [26-6 B](#)). The lower rectum and upper anal canal are drained by the *middle rectal veins*, which empty into the internal iliac veins and then into the caval system. The *inferior rectal veins* drain the lower anal canal and empty into the pudendal veins, which drain into the caval system via the internal iliac veins. Low rectal tumors can thus metastasize through venous channels into both the portal and systemic venous systems.

There are three submucosal *internal hemorrhoidal complexes* located above the dentate line (see Fig. [26-3](#)). The left lateral, right posterolateral, and right anterolateral internal hemorrhoidal veins drain into the superior rectal vein. Below the dentate line the *external hemorrhoidal veins* drain into the pudendal veins. There is communication between the internal and external plexi.

Lymphatic Drainage

The rectal lymphatic flow is segmental and circumferential and follows the same distribution as the arterial blood supply (Fig. [26-7](#)). Lymph from the upper and middle rectum drains into the inferior mesenteric nodes. The lower rectum is drained primarily by lymphatics that follow the superior rectal artery and enter the inferior mesenteric nodes. Lymph from the lower rectum also can flow laterally along the middle and inferior rectal arteries, posteriorly along the middle sacral artery, or anteriorly through channels in the rectovesical or rectovaginal septum. These channels drain to the iliac nodes and subsequently to periaortic lymph nodes.

Lymphatics from the anal canal above the dentate line drain via the superior rectal lymphatics to the inferior mesenteric lymph nodes or laterally to the internal iliac lymph nodes. Below the dentate line, the lymphatics drain primarily to the inguinal nodes but can drain to the inferior or superior rectal lymph nodes as well.

Nerve Supply

The innervation of the rectum is shared with the urogenital organs of the pelvis and consists of both sympathetic and parasympathetic nerves (Fig. [26-8](#)). *Sympathetic* nerves from thoracolumbar segments unite below the inferior mesenteric artery to form the *inferior mesenteric plexus*. These purely sympathetic nerves descend to the *superior hypogastric plexus* located below the aortic bifurcation. They then bifurcate and descend in the pelvis as the *hypogastric nerves*. The lower rectum, bladder, and sexual organs in both men and women receive sympathetic innervation via the hypogastric nerve. Injury to the inferior mesenteric plexus can result during ligation of the inferior mesenteric artery at its origin.

Parasympathetic fibers from the second, third, and fourth sacral roots (the *nervi erigentes*) unite with the hypogastric nerves anterior and lateral to the rectum forming the *pelvic plexus*, which runs laterally in the pelvis. The periprostatic plexus arises from the pelvic plexus. Mixed fibers from these plexi innervate the rectum, internal anal sphincter, prostate, bladder, and penis. The *pudendal nerve* (S2, S3, S4) mediates sensory stimuli from the penis and clitoris via the dorsal nerve.

Both sympathetic and parasympathetic fibers are essential for penile erection. The parasympathetic fibers cause vasodilation and increased blood flow in the corpus cavernosum, resulting in an erection. The sympathetic fibers cause vasoconstriction of the penile veins and thus sustain the erection. Sympathetic nerves cause contraction of the ejaculatory ducts, seminal vesicles, and prostate and are necessary for ejaculation. Damage to the periprostatic plexus might occur during surgical dissection of the rectum. Injury to the pelvic autonomic nerves may result in bladder dysfunction, impotence, or both.

The *internal anal sphincter* is innervated by both sympathetic and parasympathetic nerves, and both are inhibitory to the sphincter. The internal sphincter has a continuous tone that decreases as rectal pressure increases. Once the rectum empties, the internal sphincter tone rises again. The *external anal sphincter* and *levator ani muscles* are innervated by the inferior rectal branch of the internal pudendal nerve (S2, S3, S4) and the perineal branch of the fourth sacral nerve. Any distention of the rectum results in relaxation of the internal sphincter. The external sphincter can be contracted voluntarily and kept in that state for approximately 1 minute.

Below the dentate line, cutaneous sensations of heat, cold, pain, and touch are conveyed by afferent fibers of the inferior rectal and perineal branches of the pudendal nerve. Above the dentate line, a poorly defined dull sensation, experienced when the mucosa is pinched or when internal hemorrhoids are ligated, is probably mediated by parasympathetic fibers.

Resection of the sacrum with sacrifice of *sacral nerves* occasionally may be required for total resection of pelvic tumors. Sacrifice of the lower sacral nerves will lead to saddle anesthesia and possible motor weakness in the lower extremities. Preservation of at least one of the third sacral nerves is required to maintain acceptable anal continence. Near-normal continence will be maintained if the upper three sacral roots on one side are preserved along with the upper two sacral roots on the contralateral side. If all the sacral roots are destroyed unilaterally but the contralateral nerves are preserved, the patient should maintain continence. If both S3 roots are destroyed, the patient will be incontinent. The upper half of S1 is needed for stability of the spine and pelvis.

DISTURBANCES OF PHYSIOLOGY

Normal Colonic Function

The colon is much more than a receptacle and conduit for the end products of digestion. This organ absorbs water, sodium, and chloride and secretes potassium, bicarbonate, and mucus; it is the site of digestion of certain carbohydrates and proteins and provides the environment for the bacterial production of vitamin K.

Water and Electrolyte Exchanges

The major absorptive function of the colon is the final regulation of water and electrolyte balance in the intestine. The colon reduces the volume of enteric contents by absorbing greater than 90 percent of the water and electrolytes presented to it. This accounts for 1 to 2 liters of fluid and 200 meq of sodium and chloride per day on average. During a 24-h period, 8 liters of fluid enters the jejunum. In healthy individuals, the small bowel absorbs about 6.5 liters and the colon 1.4 liters, leaving 0.1 liter of normal fecal water content. Under maximum conditions, the colon can absorb 5 to 6 liters of fluid a day. Only if small bowel absorption is reduced to less than 2 liters a day is colonic salvage overwhelmed, and the resulting increase in fecal water content is manifested as diarrhea.

Sodium and Potassium

In healthy persons, the colon absorbs water, sodium, and chloride while secreting potassium and bicarbonate. The colon is able to absorb sodium against very high concentration gradients, especially in the distal colon, which shares many basic cellular mechanisms of sodium and water transport with the distal convoluted tubule of the kidney (Fig. [26-9](#)). The colon has the capacity to absorb up to 400 meq of sodium per day, and the colonic response to aldosterone stimulation may be an important compensatory mechanism during dehydration. A patient with an ileostomy loses this absorptive capacity and cannot tolerate increased sodium losses or decreased sodium intake.

Potassium transport in the colon is mainly passive, along an electrochemical gradient generated by the active transport of sodium. Potassium continues to be secreted into the lumen as long as the luminal concentration is less than 15 meq/L; however, at concentrations below this level, potassium secretion ceases and potassium absorption occurs.

Chloride and Bicarbonate

Chloride, like sodium, is actively absorbed across the colonic mucosa against a concentration gradient. Chloride and bicarbonate are exchanged at the luminal border. Chloride absorption is facilitated by an acidotic environment, and the secretion of bicarbonate is enhanced by increased concentration of luminal chloride. This becomes clinically important in patients with ureterosigmoidostomy, who may develop hyperchloremia and metabolic acidosis due to the absorption of urinary chloride accompanied by the secretion of bicarbonate into the colon.

Short-Chain Fatty Acids

Although active absorption of nutrients is minimal, the colon can passively absorb short-chain fatty acids (SCFAs) formed by intraluminal bacterial fermentation of unabsorbed

carbohydrates, particularly fiber. This can account for up to 540 kcal/day of assimilated calories. The absorbed SCFAs butyrate, acetate, and propionate are the major fuel sources of the colonic epithelium. They provide the energy required for active sodium transport, and altered SCFA metabolism or SCFA deficiency may result in impaired colonic sodium absorption.

There is evidence that SCFA metabolism is impaired in patients with ulcerative colitis and that intraluminal infusion of SCFAs can be of benefit in patients with colitis. SCFAs also have been shown to be effective in treating diversion colitis (which can occur after a diverting ileostomy or colostomy), implicating colonocyte nutritional deficiency as the cause of this disorder. Elemental diets, which lack fiber, are associated with colonic mucosal atrophy.

Ammonia

Colonic bacteria degrade protein and urea to produce ammonia. Ammonium ions react with bicarbonate to form nonionized ammonia and carbon dioxide. The nonionized ammonia diffuses across the colonic mucosa and is carried to the liver through the portal vein. This absorptive process depends on bacterial degradation of protein and intraluminal pH. As the pH in the colonic lumen falls, ammonia absorption decreases.

Ammonia absorption becomes a problem in patients with severe liver disease, who are unable to metabolize ammonium. The administration of poorly absorbed broad-spectrum antibiotics, coupled with cathartics and enemas, diminishes the colonic bacterial population and decreases ammonia production. Lactulose can be administered with the rationale that its metabolism to organic acids lowers the colonic luminal pH and decreases the absorption of ammonia, and it also reduces bacterial numbers by its purgative action because it causes an osmotic diarrhea.

Diarrhea

A number of agents can stimulate fluid and electrolyte secretion in the colon, including bacteria, enterotoxins, hormones, neurotransmitters, and laxatives. The diarrhea associated with *Shigella* and *Salmonella* infection is caused by diminished absorption or increased secretion of water, sodium, and chloride. Gut hormones, particularly vasoactive intestinal polypeptide, have been shown to have significant effects on colonic absorption and secretion. Prostaglandins play a role in the pathogenesis of diarrhea associated with ulcerative colitis and several laxatives. Any sort of irritation to the colon also can cause increased secretion, such as bile salt malabsorption after terminal ileal resection and long-chain fatty acid malabsorption in steatorrhea. The induced colonic mucus and fluid are high in potassium and may result in potassium depletion in chronic cases.

Motility

Colonic motility is more difficult to study than small bowel motility because of the great regional heterogeneity in the colon and because of the intermittent and unpredictable nature of colonic contractile waves. Even the normal pattern of colonic motility remains the subject of debate. In the first decade of the twentieth century, radiologists observed three patterns of colonic contractions: retrograde movements, segmental contractions, and mass movements. More recently, electrophysiologic and manometric measurements appear to correlate with observed colonic motor contractions; however, much more research is required before the complexities of colonic motility are satisfactorily understood.

Retrograde movements were identified initially as contractile waves originating in the transverse colon and traveling toward the cecum. These contractions appear to delay the transit of material from the right colon, prolonging the exposure of luminal contents to the mucosa and thus increasing the absorption of fluid and electrolytes.

Segmental contractions are the most commonly observed motility pattern. These are localized simultaneous contractions of longitudinal and circular colonic musculature that isolate short segments of the colon. These contractions occur more frequently on the right side of the colon, but their occurrence in the sigmoid colon has been hypothesized to play a role in the formation of diverticula. This contractile activity is decreased by anticholinergic drugs and increased by food and cholinergic drugs.

The third and most infrequent type of colonic activity is the *mass movement*. This pattern is characterized by an antegrade propulsive contractile wave involving a long segment of colon. The contraction propels the colonic contents forward at the rate of 0.5 to 1.0 cm/s. These contractions are 20 to 30 s in duration and generate intracolonic pressures of 100 to 200 mmHg. They occur three or four times a day, often after arising in the morning or in the late postprandial period. Mass movements in the right colon move colonic contents to the more distal colon. A mass movement in the sigmoid colon may occur at the time of defecation.

Many factors affect colonic motility. Emotions such as hostility, anger, and resentment are associated with hypermotility, whereas anxiety and fear are associated with hypomotility. Exercise has been shown to increase segmental and peristaltic colonic activity; sleep is a colonic motility depressant. Mechanical colonic distention stimulates motility and is the basis for the effect of bulk laxatives. Nondigestible polysaccharides and cellulose derivatives absorb water and increase fecal mass, thus stimulating colonic propulsion. Fatty meals appear to have a greater stimulatory effect on colonic motility than carbohydrate or protein meals. Colonic motility is influenced by certain hormones. Glucagon and somatostatin have inhibitory effects. Cholecystokinin increases colonic motor activity and is thought to be responsible for the gastrocolic reflex (increased colonic motility during and after meals).

Neurogenic Control

Colonic motility is regulated by complex and poorly understood extrinsic and intrinsic neuronal systems. The extrinsic system consists of preganglionic parasympathetic neurons from the vagus nerve or the pelvic plexus (S2, S3, S4) and the postganglionic sympathetic neurons (T11–L2). The intrinsic (enteric) nervous system is composed of neurons residing within the colon wall. These intramural neurons communicate through extensive interconnecting plexuses. The enteric plexuses are identified by their location within the colon wall: subserosal, myenteric (Auerbach's plexus), submucosal (Meissner's plexus), and mucosal.

The enteric neurons also may be classified by function: sensory, associative, or motor. The complex interaction between these neurons can be demonstrated by a localized radial distention of the colon that activates sensory neurons. These neurons communicate through associative neurons to proximal and distal motor neurons, resulting in contraction of the colon proximal to the stimulus and simultaneous distal relaxation.

Motor neurons of the enteric nervous system may be excitatory or inhibitory. Excitatory neurons are mainly postganglionic parasympathetic cells that are located in the myenteric or submucosal plexus. Acetylcholine is the most important excitatory neurotransmitter, and its action can be blocked by atropine or scopolamine. Noncholinergic agents, such as substance P, may be released by enteric neurons and appear to have an excitatory action.

Inhibitory motor neurons of the enteric nervous system reside mainly in the myenteric plexus. These cells are noncholinergic and nonadrenergic. There is evidence that purine nucleotides such as adenosine triphosphate may be the neurotransmitters of these cells. Vasoactive inhibitory peptide (VIP) is also a very important inhibitory substance. The inhibitory neurons are involved in the coordinated propagation of colonic propulsive movements such as the mass movement.

Colonic Microflora

The human colon is sterile at birth, but within a matter of hours the intestine is colonized from the environment in an oral to anal direction. *Bacteroides*, destined to be the dominant bacteria in the colon, is first noted at about 10 days after birth. By 3 to 4 weeks after birth, the characteristic stool flora is established and persists into adult life. The large intestine harbors a dense microbial population, with bacteria accounting for approximately one-third of the dry weight of feces. Each gram of feces contains 10^{11} to 10^{12} bacteria, with anaerobic bacteria outnumbering aerobic organisms by a factor of 10^2 to 10^4 . *Bacteroides* species are the most common colonic organisms, present in concentrations of 10^{11} to 10^{12} organisms per milliliter of feces. *Escherichia coli*, by comparison, is present in concentrations of 10^8 to 10^{10} organisms per milliliter.

The complex symbiotic relationship between human beings and colonic bacteria is poorly understood, but it is recognized that endogenous colonic bacteria suppress the emergence of pathogenic microorganisms, play an important role in the breakdown of carbohydrates and proteins that escape digestion in the small bowel, participate in the metabolism of numerous substances that are salvaged by the enterohepatic circulation (including bilirubin, bile acids, estrogen, and cholesterol), and produce certain beneficial elements such as vitamin K.

Colonic Gas

Nitrogen, oxygen, carbon dioxide, hydrogen, and methane make up 99 percent of all the gas in the gut. Nitrogen and oxygen are found in the atmosphere and appear in the colon via swallowing air. Hydrogen, methane, and carbon dioxide are produced by bacterial fermentation of carbohydrates and proteins in the colon. An eminent flatologist, Levitt, has shown that most patients who complain of excessive flatus have high concentrations of hydrogen and carbon dioxide in their intestinal gas. Because carbon dioxide is an end product of bacterial fermentation, therapy consists of diet manipulation to decrease the amount of ingested carbohydrate, especially lactose, wheat, and potatoes. In addition, various vegetables (particularly beans) contain undigestible carbohydrates that serve as a substrate for colonic bacterial fermentation and should be avoided by these patients.

Normal humans pass approximately 600 mL of flatus daily (ranging from 200 to 2000 mL/day). There is normally about 200 mL of gas in the intestinal tract, and the amount of detectable gas is seldom increased in patients who complain of bloating and distention. Most complaints of increased intestinal gas probably represent motility disorders instead of actual excessive production of gas.

The five predominant colonic gases (N_2 , O_2 , CO_2 , H_2 , CH_4) are odorless. Trace substances such as dimethyl sulfide and methanethiol appear to be responsible for the odor of human feces. Hydrogen and methane are combustible gases and can explode if present in the colon when electrocautery is used for polypectomy or biopsy. Adequate bowel cleansing is necessary before the use of intracolonic electrocautery. Mannitol is an inappropriate purgative under such circumstances because it is a substrate for colonic bacterial fermentation. Polyethylene glycol purgatives are not metabolized by intestinal bacteria and have not been associated with intracolonic explosions.

Disorders of Colonic Physiology

Irritable Bowel Syndrome

Irritable bowel syndrome is a disorder manifested by altered bowel habits and abdominal pain in the absence of other pathology. Patients with the diagnosis of irritable bowel syndrome have been shown to have increased slow-wave activity (3 cycles per minute) in the rectosigmoid, corresponding to increased contractile activity at the same frequency. A similar motility pattern has been noted in patients with diverticular disease, and some authors have suggested that uncoordinated smooth muscle activity followed by increased intraluminal pressure may be the underlying mechanism producing the irritable bowel syndrome and colonic diverticuli. Irritable bowel syndrome is a diagnosis of exclusion and has many different presentations. It is important to exclude organic colonic disease by the appropriate diagnostic tests. Irritable bowel syndrome is not amenable to surgical treatment.

Delayed Transit

Constipation is a symptom with numerous and diverse causes. It is difficult to formulate a precise definition of constipation, but one that is generally accepted is fewer than three stools per week while following a high-residue diet (30 g dietary fiber daily). The causes of constipation are multiple and include metabolic and endocrine disorders (hypothyroidism and hypercalcemia), faulty diet (principally inadequate intake of fiber and fluid), neurologic abnormalities (Parkinson's disease, multiple sclerosis), Hirschsprung's disease,

medications (codeine, antidepressants, anticholinergics), colonic inertia, and lack of exercise. Abnormalities of pelvic floor function, such as nonrelaxation of the puborectalis muscle and intussusception of the rectum, have been implicated as important causes of constipation.

A change in bowel habits is a common presenting symptom for colorectal tumors; thus the evaluation of a patient with new-onset constipation should include colonoscopy or contrast enema plus proctoscopy. If no obstructing lesion is present, a trial of fiber supplementation and increased fluid intake relieves constipation symptoms in the majority of patients. If unsuccessful, colonic transit time can be measured. A standardized test has not been generally accepted, but the techniques used by most institutions rely on observation of the movement of ingested radiopaque markers through the intestinal tract. The patient ingests a high-fiber diet (30 g/day) and abstains from all laxatives and enemas for 48 h before and during the investigation. The markers, which are commercially available, are ingested before breakfast on the first day and then followed by radiographs, usually at days 3 and 5. If all markers are still present on the radiograph by day 3, intestinal transit time is slower than normal. Normally, at least 80 percent of markers should have passed by day 5 after ingestion, and all markers should pass by day 7. The abdominal location of the markers indicates the segment of the colon involved with the motility disorder. If a significant number of markers remain in the proximal colon for several days, total colonic inertia should be suspected; if the markers accumulate in the rectosigmoid, anorectal outlet obstruction is the likely cause of the delayed transit.

Anorectal outlet obstruction is evaluated with a variety of techniques. Defecography can demonstrate rectal intussusception and nonrelaxation of the puborectalis muscle. Cinefluoroscopy is used to obtain video images of the rectum from the lateral view during attempts to evacuate barium paste. Rectocele (anterior displacement of the posterior wall of the vagina) and enterocele (inferior displacement of the small bowel on the vagina) also can be demonstrated. Anal manometry can demonstrate absence of the normal rectoanal inhibitory reflex (relaxation of the internal anal sphincter and brief contraction of the external anal sphincter with distention of the rectum), which is suggestive of Hirschsprung's disease, and may be used as an adjunct to rectal biopsy to make this diagnosis. Inability to expel a saline- filled balloon from the rectum suggests failure of the puborectalis muscle to relax during defecation.

Slow-transit constipation (colonic inertia) is a poorly understood disorder of chronic intestinal stasis that afflicts predominantly women. This disorder is sometimes referred to as *Arbuthnot Lane's disease*, after the British surgeon who, at the beginning of the century, recommended colectomy with ileorectal anastomosis as the treatment for chronic constipation. An extreme form of colonic inertia presents as acquired megacolon, which has been seen in association with neurologic disorders and in institutionalized and psychiatric patients. These patients present with frequent fecal impaction, volvulus, and episodes of abdominal distention mimicking large bowel obstruction. The colon can attain immense proportions, filled with gas or stool. Sigmoidoscopy is often performed in these patients in an effort to reduce what appears to be a sigmoid volvulus. The instrument slips easily into the rectum, decompressing it somewhat, but significant decompression is not achieved. A water-soluble contrast enema is often diagnostic and therapeutic. Patients with chronic megacolon do not have evidence of obstruction, and the impaction may be relieved after the study. Complete evaluation includes colonic transit studies to rule out colonic inertia and defecography and anal manometry to rule out pelvic floor abnormalities.

The medical treatment of colonic inertia consists of eliminating obvious sources of constipation, encouraging proper exercise, and ensuring appropriate intake of liquids and dietary fiber. A diet containing 30 g of dietary fiber daily should be prescribed (the average American adult consumes 13 to 19g of fiber per day). Laxatives and enemas should be avoided if possible. While laxatives are useful for occasional relief of constipation, their chronic use is counterproductive and leads to increased motility abnormalities. Medications known to cause constipation should be reduced or eliminated whenever possible.

The exact role of surgery in the treatment of colonic inertia is not clearly defined. If transit studies demonstrate total colonic inertia and appropriate medical treatment is not successful, abdominal colectomy with ileorectal anastomosis has been beneficial. Such patients are relatively rare and must be carefully selected. If the motility disorder is caused by anorectal outlet obstruction, abdominal colectomy is inappropriate; treatment should be directed toward correction of the primary problem, as described in a later section of this chapter. In rare cases where the individual is incapacitated by chronic megacolon, the only relief of symptoms may be total colectomy with construction of an ileostomy.

Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

Intestinal pseudo-obstruction, a profound ileus without evidence of mechanical obstruction, was first described by Ingelfinger in 1943. The first description of the colonic variant of pseudo-obstruction is thought to be Sir Heneage Ogilvie's 1948 report of two cases associated with malignant infiltration of the celiac plexus. Colonic pseudo-obstruction is associated with neuroleptic medications, opiates, malignancy, severe metabolic illness, or any acute severe illness. Excess sympathetic tone has been postulated as the common mechanism. This concept is supported by anecdotal reports of success with epidural anesthesia, which paralyzes the sympathetic afferent and efferent nerve fibers to the colon and with neostigmine, which increases parasympathetic tone by its anticholinesterase effect.

The diagnosis of colonic pseudo-obstruction is one of exclusion; a water- soluble contrast enema or colonoscopy should be performed to exclude mechanical obstruction. Initial treatment maneuvers include nasogastric decompression, rectal tube placement, correction of metabolic disorders, and discontinuation of medications that decrease colonic motility (e.g., narcotics and anticholinergics). Evidence of rapid cecal dilatation or a cecal diameter greater than 11 to 12 cm on abdominal x-ray should prompt more aggressive intervention because of the risk of cecal ischemia, necrosis, and perforation. Colonoscopic decompression is successful initially in 70 to 90 percent of patients, with a recurrence rate of 10 to 30 percent. The majority of patients will respond to a second colonoscopic decompression. The use of long colonic tubes has not been uniformly successful. Operation is reserved for patients with persistent colonic dilatation despite colonoscopic decompression and patients with peritonitis. Cecostomy or loop colostomy are effective in relieving distention; laparotomy should be performed in patients with peritonitis, and nonviable bowel should be resected.

Volvulus

Volvulus is a twisting of an air-filled segment of bowel about its narrow mesentery, causing an obstruction that can lead to strangulation and gangrene (Fig. [26-10](#)). Volvulus almost never occurs when the colon is filled with solid stool. The condition is classified and treated according to its location in the colon. Sigmoid, cecal, and transverse colon are the most common sites. Volvulus causes less than 10 percent of intestinal obstructions in the United States, but it has been reported as the cause of 55 percent of intestinal obstructions in parts of Iran and Russia.

Sigmoid Volvulus

Sigmoid volvulus accounts for about 90 percent of all volvulus seen in the United States. It usually occurs in older or institutionalized patients and in patients with a variety of neurologic disorders. A redundant sigmoid colon with a narrow-based mesocolon is the factor necessary for sigmoid volvulus.

Diagnosis

Patients present with complaints of abdominal pain, cramping, distention, and obstipation. Many patients give a history of previous episodes of abdominal pain and distention. Elevated white blood cell count, fever, or evidence of peritoneal irritation on physical examination suggests the presence of gangrenous bowel.

Plain abdominal radiographs may be diagnostic (Fig. [26-11](#)). The inflated sigmoid appears as an inverted U-shaped, sausage-like loop. A dense line is often seen running downward to the point of torsion. Water-soluble contrast enema may be diagnostic but should not be performed on patients with suspected gangrene. The column of barium stops at the obstruction and tapers to a point ("bird's beak" deformity) (Fig. [26-12](#)). Reduction of the volvulus may occur during the examination.

Treatment

If gangrene is suspected, or if the patient has signs of peritoneal irritation, reduction should not be attempted, and the patient should undergo emergency operation. If peritonitis is not present, rigid sigmoidoscopy should be performed. An attempt to reduce the volvulus by inserting a soft rectal tube through the sigmoidoscope past the point of volvulus usually results in dramatic decompression. The tube is left in place to further decompression. Flexible sigmoidoscopy or colonoscopy has been used to reduce volvulus beyond the limits of the rigid sigmoidoscope. Unsuccessful detorsion, bloody discharge, or evidence of mucosal ischemia indicates strangulation or gangrene. If this is found, sigmoidoscopy should be terminated, and the patient should undergo an emergency operation.

Recurrence rates following nonoperative reduction can be as high as 40 percent. If the volvulus is reduced successfully, the patient should be stabilized and undergo mechanical bowel preparation, followed by elective sigmoid resection. Resection with primary anastomosis is the recommended surgical treatment for sigmoid volvulus in a patient who is adequately prepared. Resection of the sigmoid colon with construction of a colostomy and Hartmann pouch is usually necessary if emergent operation is performed on unprepared bowel. All nonviable bowel must be resected, and mortality is related to the presence of gangrenous bowel.

Cecal Volvulus

Cecal volvulus is generally seen in younger patients and accounts for less than 20 percent of colonic volvulus. It is thought to be due to anomalous fixation of the right colon to the retroperitoneum, leading to a freely mobile cecum.

Diagnosis

Abdominal pain is the most common symptom of cecal volvulus. Nausea and vomiting, obstipation, and diarrhea are also common symptoms. Clinically, the patient appears to have a small bowel obstruction, and many patients give a history of chronic intermittent symptoms.

Ninety percent of patients with cecal volvulus have a full axial volvulus; 10 percent have a cecal bascule (cecum folded on itself in an anterior cephalad direction). A plain abdominal radiograph may be diagnostic. Cecal volvulus is seen as a kidney-shaped, air-filled structure in the left upper quadrant. The convexity of the loop faces the left upper quadrant. Water-soluble contrast enema may show obstruction of the column of contrast material at the level of the volvulus. The tapered edge of the contrast material points toward the site of the torsion.

Treatment

Resection, with ileostomy and mucous fistula, is indicated if there is gangrenous bowel. The operative treatment of nongangrenous cecal volvulus is controversial. Right hemicolectomy, cecopexy, tube cecostomy, and simple detorsion have been recommended. Resection has the lowest recurrence rates (essentially zero), and primary anastomosis often can be performed safely. Suture of the right colon to the lateral peritoneal surface (cecopexy) risks the sutures pulling through the thin-walled, distended cecum and has had variable recurrence rates. Cecostomy has been associated with abdominal wall and wound complications and persistent fecal fistula in up to 50 percent of patients and recurrence of volvulus in up to 15 percent of patients. Logic dictates that detorsion alone without fixation should lead to high recurrence rates; however, only 7 to 15 percent of patients have been reported to have recurrent volvulus. Regardless, few authors have recommended simple detorsion as adequate treatment for cecal volvulus.

Transverse Colon Volvulus

Volvulus of the transverse colon is rare because the transverse colon is normally prevented from rotation by a broad-based, short mesentery. Failure of the mesenteries to fix

normally or narrowing of the mesenteric attachments, allowing a short, fixed point of attachment, may predispose the transverse colon to volvulus. Patients present with a clinical picture similar to sigmoid volvulus. Barium enema is diagnostic and reveals the point of obstruction. Successful attempts at colonoscopic detorsion have been reported. Most patients require operative detorsion with resection of the redundant transverse colon.

Diverticular Disease General Considerations

The word *diverticulum* is used to describe an abnormal sac or pouch protruding from the wall of a hollow organ such as the colon. The term *true diverticulum* implies that the pouch is composed of all layers of the intestinal wall (true diverticula are rare), whereas a *false diverticulum* lacks a portion of the normal bowel wall. Specifically, the commonly observed diverticula of the colon consist of protrusions of mucosa through the muscular layers of the wall and are devoid of a muscular coat and thus are false diverticula.

Diverticular disease and *diverticulosis* are terms used to indicate the presence of colonic diverticula (Fig. 26-13), a condition that is rare before age 30, becomes more common with increasing age, and is present in approximately 75 percent of Americans over age 80. The variation in incidence by sex varies among reports, and a review of large series of patients fails to indicate that either men or women are more susceptible to the development of diverticula.

Diverticular disease seems to be a phenomenon of the industrial revolution and Western society. The marked increase in the prevalence of diverticulosis in England after 1910 has been attributed to the process introduced approximately 30 years earlier of roller-milling wheat flour. This advance resulted in a decreased consumption of unprocessed cereals and was accompanied by an increased consumption of sugar and meat. In the past half century, the amount of fiber consumed by individuals in North America and western Europe has declined, while the prevalence of diverticular disease has increased dramatically. Further evidence of reduced intake of fiber as a cause of diverticulosis is provided by the observation that the disease is almost unknown in sub-Saharan African blacks who consume a high level of dietary fiber; however, blacks in Johannesburg who consume a low-fiber diet have the same high incidence of diverticular disease as South African whites.

Etiology

The precise cause of diverticulosis is not known. Anatomic studies have demonstrated that diverticula are actually herniations of mucosa through the colon at sites where arterioles penetrate the muscular wall. These sites are located predominantly on the mesenteric side of the antimesenteric teniae. A lesser number of protrusions can occur between the antimesenteric teniae (Fig. 26-14). In some cases the artery divides, with one branch penetrating the wall at the site of a diverticulum and the other branch passing external to the muscular coat and sometimes actually being displaced over the dome of the diverticulum. This intimate association between the artery and the diverticulum is responsible for the massive hemorrhage that occasionally can complicate diverticulosis.

Another striking anatomic abnormality associated with diverticulosis is marked thickening of the affected colonic wall. This muscular abnormality seems to precede the appearance of diverticula and occurs predominantly in the sigmoid colon. Diverticula occur most often in the sigmoid, with the abnormalities being confined to the sigmoid in over half the patients with diverticular disease; other colonic segments (usually the descending colon) are also involved in about another 40 percent of affected patients, and the entire colon is involved in approximately 5 to 10 percent of patients.

A low-fiber diet appears to be associated with a narrow sigmoid colon. The small lumen permits segmental contractions to isolate small regions of the colon into compartments that are subjected to high pressures. Normally, the colonic pressure is only slightly above atmospheric pressure, but pressures as high as 90 mmHg can be generated in the narrow sigmoid by segmental contraction. It is presumed that repeated high-pressure contractions produce the herniation of mucosa through the colonic wall resulting in diverticula.

Diverticulitis denotes infection associated with diverticula. This term is somewhat a misnomer because the infectious process commonly associated with diverticular disease is pericolic in nature and predominantly involves the surrounding soft tissues such as mesentery or adjacent organs, in addition to the serosal surface of the colon.

Peridiverticulitis would be a more accurate descriptive term for this disease. It should be recognized that the infection is the result of a perforation of a diverticulum, leading to extravasation of feces from the lumen to the serosal surface of the colon. In most instances, the amount of fecal contamination is minute, and the body's natural defenses confine the infection. If the contamination is significant, or if the patient's response to infection is compromised, the local peritoneal defenses may be overwhelmed, and abscess formation or even generalized peritonitis can occur. Whether the perforation of the diverticulum is the result of increased colonic pressure, obstruction of the neck of the diverticulum by inspissated feces, or ischemia of the protruded mucosal sac, the end result, pericolic infection, is the same. Recognition that the cause of the abdominal infection is a perforation of a diverticulum provides a basis for understanding the signs and symptoms of the disease as well as the rationale for determining appropriate diagnostic tests and treatment.

Patients with *acute diverticulitis* usually complain of pain in the left lower abdomen. The pain may radiate to the suprapubic area, left groin, or back. An alteration in bowel habit, usually constipation or occasionally diarrhea, may be noted. Fever and chills are not unusual, and urgency or frequency of urination may be present if the inflammation is adjacent to the bladder. Rectal bleeding is distinctly unusual in the presence of diverticulitis.

The physical findings depend on the severity of the infection. The most common finding is tenderness over the left lower abdomen. If considerable inflammation is present, abdominal palpation may reveal a poorly circumscribed area of induration. A tender mass in the left lower quadrant is suggestive of a localized phlegmon or, more likely, an abscess. Occasionally, abdominal distention is caused by ileus or by partial obstruction of small bowel involved in the inflammatory process. Rectal examination may demonstrate pelvic tenderness, and a tender pelvic abscess may be palpated by rectal or vaginal examination.

A limited sigmoidoscopic examination occasionally is indicated to rule out a rectal cancer. If diverticulitis is suspected, air should not be insufflated through the sigmoidoscope because this will only distend the colon and may increase the inflammation by forcing more feces through a perforated diverticulum. Usually the sigmoidoscope cannot be advanced beyond 12 cm without undue discomfort to the patient. Fiberoptic endoscopy offers little information in the evaluation of suspected diverticulitis and carries significant risk of increasing the pericolic contamination.

Often the diagnosis of diverticulitis can be reasonably ensured based on the history and physical examination. If the diagnosis is in doubt, however, three diagnostic tests can be considered: computed tomography (CT) of the abdomen, ultrasound, and the contrast enema. The abdominal CT and ultrasound are noninvasive tests, and both can demonstrate thickened colonic wall and an associated abscess.

The CT is usually the test of choice to confirm the suspected diagnosis of diverticulitis. It reliably detects the location of the inflammation and provides valuable ancillary information such as the presence of an abscess, ureteral obstruction, or a fistula between the colon and urinary bladder (by demonstrating air in the bladder) (Fig. 26-15 A). If an abscess is present, percutaneous drainage under CT guidance is a valuable therapeutic procedure.

The need for contrast enema in the evaluation of acute diverticulitis has diminished considerably since the introduction of CT scanning and ultrasound. Instilling contrast material under pressure into the colon carries the risk of spreading infection by extravasation through the perforated diverticulum. If the infection has not been well contained by the peritoneal defenses, a localized infection may be converted to generalized peritonitis. For this reason, the use of barium should be avoided; barium combined with feces produces a more severe peritonitis than either agent as an isolated contaminant. Water-soluble contrast enemas do not carry the risk of barium-fecal peritonitis but still may result in extravasation of contrast material from the colon and spreading peritonitis. Colonic wall thickening, diverticula, fistula formation, or displacement of the colon by an abscess may be detected by contrast study. However, these findings generally can be demonstrated more safely by abdominal CT scan.

Treatment

Uncomplicated Diverticulitis

The treatment of diverticulitis depends on the severity of the disease. Patients with minimal symptoms or signs of inflammation can be treated on an outpatient basis with a clear liquid diet and broad-spectrum antibiotics. The antibiotics are continued for 7 to 10 days. Pain medications should be avoided. If the inflammation is so severe as to warrant analgesic administration, the patient should be hospitalized and given intravenous antibiotics. The use of morphine especially should be avoided because it increases intracolonic pressure and can aggravate the inflammatory process. Meperidine decreases intraluminal pressure and is a more appropriate analgesic.

Patients with significant signs of inflammation should be hospitalized for bowel rest, intravenous fluids, and intravenous broad-spectrum antibiotics. Nasogastric suction is usually not necessary unless the inflammation is accompanied by ileus or obstruction.

The patient's symptoms usually respond promptly to nonoperative treatment, with noticeable improvement occurring within 48 h. As the clinical situation permits, diet is resumed and investigative studies may be performed after 3 weeks. A colonoscopic examination is usually indicated, after the inflammation resolves, to evaluate the extent of diverticulosis and to rule out the presence of a cancer. A barium enema may demonstrate the extent of diverticulosis, but this is a less accurate test for identifying small polyps or malignant growths in the presence of numerous diverticula.

When a patient recovers from a simple, uncomplicated episode of diverticulitis, a high-fiber diet is recommended. Surgery is seldom indicated in such circumstances because 70 percent of patients who have recovered from one uncomplicated episode of diverticulitis will have no recurrence. However, if the patient suffers recurrent attacks of diverticulitis, surgical treatment should be considered. The chance of a subsequent attack following a second episode of diverticulitis is greater than 50 percent. Such attacks are treated similarly to the initial episode, and elective resection of the diseased colon is scheduled after the inflammation has resolved, usually 4 to 6 weeks later.

Generalized Peritonitis

Spreading generalized peritonitis may occur if the infection originating from the perforated diverticulum is not immediately localized by the normal peritoneal defenses. If the perforation remains unsealed, the entire peritoneal cavity can be contaminated, with resulting generalized fecal peritonitis. This complication is rare, but immediate surgical intervention is mandatory. Patients complain of severe abdominal pain, and there is voluntary and involuntary guarding in all abdominal quadrants. Intraperitoneal free air may be detected by abdominal x-rays, but the absence of free air does not exclude the diagnosis. Leukocytosis with a left shift is generally observed; however, leukopenia may accompany instances of severe sepsis. Urgent celiotomy is required to control the infection. If the peritonitis is not so severe as to prohibit intestinal resection, the diseased segment of bowel containing the perforation should be resected. The distal segment of bowel should be closed or exteriorized as a mucous fistula, and the bowel proximal to the resected segment is used to construct a colostomy. Since the great majority of diverticular perforations occur in the sigmoid colon, there is seldom sufficient length of distal bowel to reach the abdominal wall as a mucous fistula. Therefore, it is usually necessary to suture or staple the distal bowel (proximal rectum) closed. This operation is frequently called *Hartmann's operation* (see Fig. 26-81) after the French surgeon, Henri Hartmann, who described it as a treatment for proximal rectal cancer in 1921. Hartmann's operation is the most common operation for the emergent treatment of diverticulitis.

If the peritonitis is so severe that resection of the perforated segment cannot be accomplished, then diversion of feces with a completely diverting colostomy constructed proximal to

the perforation should be considered. This is a far less satisfactory procedure and should be avoided because the site of contamination remains in the peritoneal cavity.

Diversion of the fecal stream of the source of infection, accompanied by appropriate antibiotics and nutritional support, should permit resolution of the peritonitis. When the patient has recovered completely, usually over a period of no less than 10 weeks, the colostomy can be taken down and intestinal continuity restored with an anastomosis between the descending colon and the rectum.

Diverticulitis with Abscess

An important advance in the treatment of diverticulitis has been the development of percutaneous drainage of abdominal abscesses. A patient with an abscess that has resulted from a perforation of a diverticulum usually has pain localized to the left lower abdomen. A tender abdominal mass may be palpable, and if the abscess resides low in the pelvis, it may be palpable by digital rectal examination. Abdominal CT scan will confirm the diagnosis (see Fig. 26-15 B). Either of these modalities also permits guided placement of a drain through the abdominal wall into the abscess, allowing evacuation of the purulent material. If the abscess is located low in the pelvis and cannot be approached safely through the abdominal wall, it can be drained safely into the rectum through a transanal or transvaginal approach.

These approaches are immeasurably preferable to a celiotomy, during which the abscess contents potentially could contaminate other areas of the peritoneal cavity. In such circumstances, it is usually necessary to perform Hartmann's operation, requiring the patient to have a temporary colostomy. Another option is resection of the diseased segment with primary anastomosis and proximal diverting colostomy. Percutaneous drainage of the abscess provides safe control of the infection, and an elective resection can be anticipated. At the time of elective surgery, it is usually possible to resect the diseased sigmoid colon and construct an anastomosis between the descending colon and rectum, thus avoiding a colostomy. It is mandatory to excise all abnormally thickened colon and to extend the resection to incorporate normal rectal wall. It is felt that a major cause of recurrent diverticulitis following sigmoidectomy is the failure to completely resect the abnormally thickened muscular wall at the rectosigmoid junction. It is seldom necessary to mobilize the rectum distally beyond 2 cm below the sacral promontory to obtain normal bowel for a satisfactory anastomosis. Although diverticula may be present throughout the colon, it is not necessary to incorporate all of them in the resected specimen. Only the colon with a thickened, brittle wall needs to be excised.

Diverticulitis with Fistula

A fistula between the sigmoid colon and other organs, including bladder, vagina, small intestine, and skin, is a relatively frequent complication of diverticulitis. Diverticulitis is a more common cause of sigmoid-vesical fistula than cancer or Crohn's disease. A fistula is usually formed by an abscess that drains into an organ, establishing a tract between the source of the abscess (the perforated sigmoid diverticulum) and the secondarily involved organ. Fistulas between the sigmoid colon and the bladder are more common in men than in women because the uterus lies between the sigmoid colon and bladder in women. Women with fistulas between the sigmoid colon and bladder or vagina usually have had a previous hysterectomy. A fistula from the sigmoid colon to the skin may result from percutaneous drainage of an abscess caused by diverticulitis.

A fistula between the colon and the urinary bladder presents with recurring urinary tract infections, fecaluria, or pneumaturia. In the presence of distal urinary tract obstruction (prostatic hypertrophy in men), a sigmoid-vesical fistula may be complicated by ascending urinary tract infection and sepsis. CT most accurately confirms the fistula by demonstrating air in the bladder. A barium enema will demonstrate the presence of a fistula in fewer than 50 percent of patients, and intravenous pyelography is even less rewarding. Cystoscopy usually reveals cystitis and bullous edema in the area of the fistula.

The presence of a fistula caused by diverticulitis is seldom a cause for emergency surgical treatment. The formation of a fistula often results in improvement in the patient's condition, since it allows natural drainage of an abdominal abscess. Initial treatment should be directed toward control of any associated sepsis. Sepsis in a patient with a sigmoid-vesical fistula and distal urinary tract obstruction should be treated by relief of the obstruction (with a Foley catheter or suprapubic cystostomy) and appropriate intravenous antibiotics.

Before definitive surgical treatment, the cause of the fistula should be confirmed. The second most common cause of fistula between the sigmoid colon and the bladder is sigmoid carcinoma. Colonoscopy should be used to directly visualize the sigmoid mucosa and to exclude carcinoma, for the curative surgical treatment of sigmoid-vesical fistula caused by cancer involves obtaining wider margins of surgical resection than would be reasonable for a patient whose primary disease is diverticulitis.

After diverticulitis has been established as the cause of the fistula and sepsis has been controlled, treatment is directed toward resolution of the localized inflammation in the region of the fistula. This often can be accomplished by antibiotics administered on an outpatient basis for several weeks. Total parenteral nutrition and bowel rest, concomitant with intravenous antibiotics, have been used in some patients to permit more rapid resolution of inflammation in preparation for surgery.

The surgical treatment of a fistula caused by diverticulitis is excision of the diseased segment of the colon containing the site of perforation. We have found it helpful to place stents in the ureters by means of cystoscopy immediately prior to celiotomy. This technique facilitates identification of the ureter in an area in which the normal anatomy may be distorted or difficult to evaluate because of inflammation. Usually the fistulous tract can be interrupted surgically by blunt dissection. If the fistula involves the bladder, the defect in the bladder can be closed primarily, but unless the defect is large, this is seldom necessary. Providing adequate drainage of the bladder with a Foley catheter or suprapubic cystostomy for a week to 10 days will allow the bladder defect to heal. If the local inflammation is not severe, a one-stage operation usually can be accomplished by sigmoidectomy and anastomosis between the descending colon and rectum. If inflammation is too extensive to permit a primary anastomosis, it may be prudent to perform Hartmann's operation, as discussed previously. On some occasions it may be possible to fashion an anastomosis between the colon and rectum, but adjacent inflammation in the pelvis may be unfavorable, causing the risk of anastomotic leak to be unacceptable. In such instances, the anastomosis can be protected by a proximal transverse colostomy or ileostomy. After the patient has recovered and evaluation reveals the anastomosis to have healed satisfactorily, the proximal stoma can be closed.

On rare occasions, the infection will be so severe that sepsis cannot be controlled with the measures outlined above, and the extent of inflammation will not permit a bowel resection to be accomplished safely. In such instances, fecal diversion is mandatory, with a colostomy constructed proximal to the area of perforation and fistula.

Acquired Vascular Abnormalities

Acute lower gastrointestinal hemorrhage most commonly affects older patients. Although most episodes of bleeding stop spontaneously, between 10 and 25 percent of patients eventually will require surgery to control bleeding. The two most common causes of hemorrhage from the colon are *diverticulosis* and *angiodysplasia*. Both these disorders appear to be acquired, are rare in the young but appear with increasing frequency after age 50, and may occur simultaneously in the same individual.

Hemorrhage from Diverticular Disease

Colonic diverticula are formed at the location where the colonic arterioles penetrate the muscular wall of the bowel, and thus there is an intimate association between the arteriole and the diverticulum (Fig. 26-16). In some instances the artery is displaced over the dome of the diverticulum. With the passage of time, structural changes occur in the wall of the affected blood vessel; there are thickening of the intima and simultaneous focal attenuation of the media. These pathologic changes in arterial structure have been demonstrated in the arterioles associated with diverticula that have been observed to have been the source of hemorrhage. It appears that the vessel is prone to disruption at two sites: the dome of the diverticulum or its neck at the antimesenteric margin. Arterial disruption at either site can result in massive lower gastrointestinal hemorrhage; it is rare that diverticulosis is the cause of significant chronic bleeding. It is curious that the vascular disruption almost always occurs on the mucosal side of the artery, and the bleeding is virtually always into the colonic lumen instead of into the peritoneal cavity.

Hemorrhage from Angiodysplasia

Before the 1970s it was assumed that the great majority of cases of colonic hemorrhage were caused by bleeding from diverticula. Unexplained by this assumption was the fact that the bleeding site, when localized, was in the proximal colon most commonly, whereas diverticula are predominately located in the sigmoid colon. Furthermore, a significant number of patients with colonic hemorrhage had no identifiable colonic diverticula. The introduction of mesenteric arteriography provided a method of identifying the site of hemorrhage and demonstrated that a significant number of cases of colonic hemorrhage were associated not with an arteriole adjacent to a diverticulum but with a different type of vascular abnormality. Various names have been applied to this lesion, including *angiodysplasia*, *vascular ectasia*, *arteriovenous malformation*, and *angiectasia*.

It is apparently an acquired lesion, occurring more commonly with increasing age. It is rarely present in individuals under 40 years of age but becomes increasingly common after age 50, the same age group in which colonic diverticula are found. It has been suggested that the cause of colonic angiectasia is chronic, intermittent obstruction of the submucosal veins (Fig. 26-17). This is apparently caused by repeated muscular contractions of the colon that result in obstruction of the venous system. The lesions are located most commonly in the cecum; according to Laplace's law, the tension generated in the spherical cecum is greater than the tension in the remaining cylindrical colon. The lesions are not confined to the proximal colon; as many as 20 percent are found in the descending and sigmoid colon.

With the passage of time, the venules become dilated; eventually, the process extends to the precapillary sphincters, which become incompetent, forming small arterial-venous communications. Angiographic studies of this pathologic process have correlated the earliest stage of the lesion with a slowly emptying vein or a vein that contains contrast material after the dye has cleared from the normal veins during the venous phase of the mesenteric angiogram. When the process becomes more advanced, dilation of a submucosal vein, a *vascular tuft*, may be recognizable by angiography. If the precapillary sphincters have become incompetent and small arterial-venous communications have developed, the angiogram will reveal the presence of an early-filling vein: a colonic vein that fills within 5 s following the injection of arterial contrast material (Fig. 26-18).

The more advanced lesion of dysplasia also can be identified by colonoscopy as a distinct red mucosal patch. These lesions vary in size from 2 mm to over 2 cm. Histologic study reveals tortuous, dilated capillaries in the submucosa.

Management of Massive Lower Gastrointestinal Hemorrhage

Massive lower gastrointestinal hemorrhage can be defined as bleeding distal to the ligament of Treitz that requires transfusion of more than 3 units of blood over 24 h. The causes of such bleeding are numerous, but diverticular disease and angiodysplasia are the most common causes of life-threatening colonic hemorrhage. The exact incidence of each cause is uncertain. Other causes of lower gastrointestinal hemorrhage include inflammatory bowel disease, ischemic colitis, and tumors. Anticoagulant therapy can also cause gastrointestinal bleeding. While these latter conditions are associated with some blood loss, life-threatening hemorrhage is rare. It is important to remember that gastroduodenal hemorrhage is a frequent cause of rectal bleeding, and this source should be excluded immediately by passing a nasogastric tube into the stomach and confirming the absence of blood in the stomach.

The management of the patient with lower gastrointestinal hemorrhage consists of simultaneously restoring the intravascular volume and identifying the site of the hemorrhage so that appropriate treatment can be given (Fig. 26-19). It is more important to identify the location of the bleeding point than to obtain an immediate diagnosis as to the cause of the bleeding. Lower gastrointestinal bleeding occurs most commonly in elderly patients in whom both angiodysplastic lesions and diverticula may be present. Colonic bleeding will stop spontaneously in 85 percent of patients, and the site of bleeding may be impossible to identify once the hemorrhage has stopped. Celiotomy for massive gastrointestinal hemorrhage of uncertain origin should be avoided except in the most extreme circumstances, for it is rare that the site of hemorrhage cannot be otherwise identified, and even the

extreme operation of total colectomy carries the risk of leaving an unrecognized angiodysplastic lesion in the small intestine.

Blood transfusions should be administered as indicated by the clinical situation, and proctoscopy should be performed to exclude an anorectal cause. The sequence of the next diagnostic step varies somewhat among institutions but consists of nuclear imaging, mesenteric angiography, or colonoscopy. These tests are not mutually exclusive, each has advantages and disadvantages, and all depend on the expertise of the examiner.

Bleeding Scans (Scintigraphy)

Nuclear scintigraphy has been reported by some investigators to be very useful in identifying a lower intestinal bleeding site, whereas others have found this approach to be unreliable and do not recommend it as a preferential test. There are two categories of nuclear scans; the first type uses substances that are cleared from the blood after being injected, whereas the second type employs nondiffusible intravascular indicators (autologous red blood cells labeled with technetium-99m). The technetium- sulfur colloid scan has the advantage of immediate availability and excellent sensitivity. Intestinal bleeding at a rate as low as 0.5 mL/min can be identified by accumulation of the isotope in the intestine at the bleeding site. The patient must be bleeding at the time the isotope is administered intravenously, however, for the label is removed from the circulatory system in about 12 min, accumulating in the liver and spleen. These sites of accumulation also may obscure a bleeding site in the region of the hepatic flexure. The autologous labeled red blood cell (RBC) scan is the scintigraphic test most commonly used in the evaluation of gastrointestinal bleeding (Fig. 26-20 A). The patient's labeled RBCs remain in the circulation for as long as 24 h, permitting monitoring when the bleeding occurs intermittently. In as many as half the patients with the bleeding site identified by this technique, the location does not become evident until more than 6 h after the isotope is introduced. The labeled RBC scan can demonstrate bleeding at a rate of approximately 1 mL/min.

Mesenteric Angiography

Selective mesenteric angiography should be performed once the patient's condition is stable and hydration is adequate. A catheter is placed into the mesenteric circulation using a percutaneous approach, usually the femoral artery, and contrast material is introduced. This approach has the advantage of accurately identifying the bleeding site by visualizing the extravasation of contrast material, but bleeding must be at a rate of at least 1 mL/min for this technique to be successful (see Fig. 26-20 B). Mesenteric angiography carries the distinct advantage of therapeutic options: Vasopressin can be infused through a specific mesenteric artery in an attempt to stop the bleeding by the arterial constriction and muscular contraction of the colonic wall induced by the drug. This approach will stop the bleeding in greater than 85 percent of patients in whom the bleeding site is identified. Vasopressin should not be used in patients with a history of myocardial ischemia. A variety of materials also can be introduced through the mesenteric catheter to embolize the area of bleeding. While success has been reported with this approach, intestinal ischemia is obviously a potential complication. Finally, angiographic study of the bowel may demonstrate the presence of angiodysplastic lesions. Unfortunately, these lesions are relatively common, and the mere presence of such vascular lesions, in the absence of extravasation of vascular contrast material, does not reliably indicate the source of the hemorrhage.

As implied earlier, scintigraphy and angiography are not mutually exclusive tests. If the general location of the bleeding site can be determined by scintigraphy, percutaneous arteriography can be immediately directed toward the correct vessel (superior mesenteric artery for lesions of the ascending or transverse colon, inferior mesenteric artery for sigmoid lesions), and vasopressin can be administered into the appropriate mesenteric artery.

Emergent Colonoscopy

A relatively recent approach to the patient with massive lower gastrointestinal hemorrhage has been the use of colonoscopy. The introduction of orally administered electrolyte lavage permits adequate cleansing of the colon within 2 h, and an experienced colonoscopist can reach the cecum in more than 90 percent of the patients. Colonoscopy has the advantage of providing therapeutic options if the bleeding point is identified. Vasoconstricting agents such as epinephrine can be injected at the bleeding site; vasodestructive agents such as alcohol, morrhuate sodium, or sodium tetradecyl sulfate may eradicate the lesion. Finally, thermal modalities such as laser photocoagulation, electrocoagulation, or heater probe coagulation may control the bleeding source via the colonoscope.

Celiotomy

The approaches discussed above are used to avoid an abdominal operation to control intestinal bleeding from a site that cannot be identified. Every reasonable effort should be made to identify and control the bleeding with nonoperative techniques. There will seldom be any signs that will reliably identify the cause of bleeding at the time of celiotomy. Intraoperative colonoscopy rarely may be beneficial in such circumstances, but usually the bleeding rate is too high to permit adequate visualization of the colonic lumen if emergency celiotomy has been required. In such circumstances, the small bowel should be examined carefully to exclude an obvious source of bleeding, such as lymphoma or Crohn's disease. If no specific lesion can be identified, the treatment of choice is abdominal colectomy. The decision to fashion an ileorectal anastomosis or ileostomy should be based on the patient's overall condition. The incidence of recurrent bleeding after abdominal colectomy is less than 10 percent, but the mortality of such bleeding is significant, with reports ranging from 20 to 40 percent.

Ischemic Colitis

Localized ischemia of the intestine occurs most often in the colon. It may be the result of occlusion of a major mesenteric vessel by thrombosis, embolization, or iatrogenic ligation (after aortic aneurysm resection). Ischemic colitis also has been reported in patients with thromboangiitis obliterans or periarteritis nodosa. In the majority of patients, however, no specific vascular disease or underlying cause can be identified and presumably related to low blood flow. The disease occurs most commonly in the elderly, but it occasionally afflicts young adults. It has been reported to occur in women taking birth control pills.

The pathogenesis of the disease that occurs in the absence of mesenteric arterial occlusion is not well understood. The colonic mucosa becomes edematous, and colonoscopy may reveal dark, hemorrhagic mucosa with patchy ulceration. In mild cases the serosal surface of the colon appears normal, but severe cases of transmural ischemia can cause obvious gangrene of the bowel.

The disease usually presents as mild lower abdominal pain accompanied by the passage of bright red blood per rectum. Physical examination often reveals only mild abdominal tenderness, and proctoscopy reveals normal rectal mucosa with blood coming from above. The diagnosis can be made by contrast enema, which reveals submucosal hemorrhage and edema, or "thumbprinting" of the involved colonic segment. Arteriography usually does not demonstrate specific vascular abnormalities, suggesting that this is a disease of the microscopic vasculature of the bowel. The region of the splenic flexure is most commonly involved, perhaps because this is the area at the periphery of both superior and inferior mesenteric arterial blood supply; however, any area of the large intestine can be affected.

Treatment depends on the severity of the ischemia, as manifested by the patient's signs and symptoms. Patients with mild abdominal pain, minimal leukocytosis, and minimal fever should be observed closely, with the anticipation of recovery within 2 or 3 days. Follow-up colonoscopy or barium enema a few weeks later is usually normal. In some patients, however, the ischemia is more severe, with more marked abdominal pain, fever, and leukocytosis. These patients should be observed closely and treated with intravenous antibiotics. Occasionally the ischemic segment will heal with stricture formation, which may be resected electively if it causes obstructive symptoms.

A small number of patients have severe ischemia involving the full thickness of the colonic wall. This condition is characterized by signs of bowel necrosis with severe abdominal pain, peritonitis, and systemic toxicity. Immediate celiotomy is required, with resection of the ischemic intestine and proximal colostomy or ileostomy. The morbidity and mortality are high in this group of patients.

Radiation Proctocolitis

Radiation injury to the intestine is most commonly associated with pelvic irradiation for uterine or cervical cancer, but in recent years high radiation doses have been used for the treatment of prostatic and bladder cancer, as well as adjuvant or even primary treatment for selected cases of rectal malignancy. The new high-energy radiation sources deliver large doses of radiation to the viscera with sparing of the skin; thus the treating physician may not be warned of prior intestinal radiation injury.

Individual responses to radiation vary considerably, but there is a rough correlation of bowel injury with the dosage of radiation. Tissue doses of less than 4000 cGy are seldom associated with intestinal damage. Most patients will exhibit some degree of intestinal injury after exposure to 5000 cGy, and exposure to radiation in excess of 6000 cGy is associated with symptoms of radiation enterocolitis in the vast majority of patients. Factors that increase the likelihood of intestinal complications related to radiation include arteriosclerotic vascular disease, diabetes, hypertension, advanced age, and adhesions from previous abdominal operations that fix the bowel in the pelvis.

Radiation injury to the intestine is manifested in early and late stages. During radiation therapy the proliferating intestinal epithelial cells are affected, and the mucosa becomes edematous and hyperemic. Acute ulceration may occur if reepithelialization is significantly impaired. After therapy is completed, the mucosa usually heals, although the villi are shortened. Patients having radiation to the intestine often have nausea and vomiting, cramping abdominal pain, and diarrhea during the course of treatment. Tenesmus and rectal bleeding may occur during high levels of pelvic irradiation. Usually these symptoms can be managed symptomatically, but sometimes the radiation dosage must be decreased or treatment interrupted until the symptoms subside.

The late stages of intestinal radiation injury occur from weeks to years following completion of radiation therapy and are the manifestations of a progressive vasculitis affecting the arterioles of the submucosa. This radiation arteritis is characterized by thickening of the arteriole wall with subsequent microvascular thrombosis. This chronic ischemic process is associated with thickening and fibrosis of the intestinal wall and ulceration of the mucosa. Progressive ischemia can result in stricture formation, intestinal perforation, or abscess and fistula formation. The rectum is by far the most common site of involvement because of its location in close proximity to the uterus, cervix, and prostate.

Radiation proctitis is associated with tenesmus and bleeding. These symptoms may occur from months to years after completion of therapy and are the result of mucosal ulceration secondary to radiation endarteritis and ischemia. The symptoms often can be managed symptomatically with stool softeners, topical 5-aminosalicylic acid preparations, and occasionally, corticosteroid enemas. Should these measures fail, topical application of 10% formalin to the affected mucosa has been very efficacious. On rare occasions, a proximal colostomy is required for severe tenesmus or bleeding. It is extremely rare for proctectomy to be necessary to control symptoms.

Rectal stricture following pelvic radiation may cause symptoms of colonic obstruction. Recurrent cancer should be excluded by careful endoscopic evaluation and biopsies of suspected radiation-induced rectal strictures. If gentle dilation does not relieve the obstructive symptoms, diverting colostomy may be necessary.

Radiation-induced rectovaginal fistula most commonly occurs in women who have been treated for carcinoma of the uterine cervix. The fistula usually occurs within 2 years after completion of radiation therapy, but it may occur decades later. Patients usually note bleeding and rectal pain in the weeks preceding the passage of stool and gas through the vagina. A rectal stricture is often associated with the rectovaginal fistula, and occasionally there is also a concomitant fistula between the urinary bladder and vagina.

A proximal colostomy is invariably required to relieve the symptoms of radiation-induced rectovaginal fistula. It is mandatory to exclude recurrent carcinoma as the cause of the fistula, a diagnosis that is at times difficult and may require examination under anesthesia. If cancer is excluded and the patient's health is satisfactory, consideration should be

given to treating the fistula by resecting the involved rectum and restoring continuity by low colorectal anastomosis or, more commonly, by coloanal anastomosis. Local excision and closure of the fistula are rarely successful, even when preceded by a diverting colostomy. Bricker has advocated repair of rectovaginal fistula caused by radiation using a technique of reconstructing the anterior rectal wall with nonirradiated sigmoid colon brought down as a fold-over patch graft. All these approaches to repair a complicated radiation-induced fistula require protection by a temporary colostomy or ileostomy. Often the entire pelvis is “frozen” with radiation- injured structures, including multiple loops of small intestine. In this situation, complete fecal diversion with a colostomy should be the definitive treatment, avoiding injury to the irradiated small intestine, which has limited healing capability.

Normal Function of Anorectum

The rectum functions mostly as a storage capacitance vessel. The rectum has very little peristaltic function of its own and relies on external pressure to empty. The outer longitudinal muscle is thick and has some contractility but has lost the organization of the teniae found on the colon. The rectum has a normal manometric resting pressure of approximately 10 mmHg, mostly due to intraperitoneal pressure and resting muscle tone. Conditions such as Crohn's disease or radiation injury cause the rectum to lose its natural compliance. This loss of compliance and capacitance is occasionally incapacitating to the patient.

The normal rectum can hold 650 to 1200 mL of liquid. A rectum that holds more than 1500 mL can be classified as a megarectum. The normal daily volume of stool eliminated by the rectum ranges from 250 to 750 mL of formed feces.

The anal sphincter mechanism is the other component of defecation and continence. Its anatomy and innervation have been described previously (see Fig. 26-5). The external sphincter fibers are responsible for 20 percent of the resting pressure and 100 percent of generated squeeze pressure. The internal sphincter provides 80 percent of anal resting pressure. Both the internal and external sphincter muscles are contracted at rest.

Defecation and continence are coordinated mechanisms. *Continence* can be described as controlled elimination of the rectal contents at a socially acceptable time and place. The coordination of rectal emptying and sphincter contraction and relaxation is very complex, and there are numerous abnormalities that occur.

Defecation can be divided into four components. The first is movement of feces into the rectal vault or capacitance organ. A mass peristaltic wave in the proximal colon and sigmoid colon occurs two or three times per day to pass solid substance into the rectum. The gastrocolic reflex is a well-known phenomenon that results in colonic mass peristaltic movement after distention of the stomach, probably hormonally mediated.

The second component of defecation is the *rectal-anal inhibitory reflex* or *sampling reflex*. Distention of the rectum results in involuntary relaxation of the internal anal sphincter and allows sensation of the rectal contents at the transitional zone. The sampling reflex has been shown by ambulatory manometry to occur frequently throughout the day and night.

The third component of defecation is voluntary relaxation of the external sphincter mechanism. Voluntary relaxation of the pelvic floor, puborectalis muscle, and external sphincter allows the rectal contents to be pushed farther into the anal canal and expelled. The relaxation of the sphincter mechanism is actually a failure to contract rather than an active relaxation, because the mechanism is paradoxically contracted when the rest of the individual is relaxed, yet continent (Fig. 26-21).

The fourth component of defecation is the voluntary increase of intraabdominal pressure, using the diaphragm and abdominal wall muscles. This increase in pressure serves to propel the rectal contents through the anal canal and accomplish defecation.

The passage of flatus also requires coordination of multiple factors. The sensation of gas at the transitional zone and in the anoderm informs the individual that gas is present to be eliminated. If the situation is such that full evacuation of the rectum is not possible but elimination of gas is desired, a voluntary contraction of the pelvic floor including the puborectalis and external sphincter muscles occurs to prevent loss of solid rectal contents. With an increase in abdominal pressure and a coordinated relaxation of some of the external sphincter, selective passage of flatus may be accomplished. During defecation, the gaseous contents of the rectum will be expelled with the solid contents without discrimination. This mechanism of discrimination appears to be learned. Patients eventually can pass flatus selectively even after the rectum has been removed and replaced by a reservoir of ileum for diseases such as ulcerative colitis and familial adenomatous polyposis.

Continence, or the control of rectal contents, requires an adequate rectal capacity and normal compliance. It may be difficult to retain rectal contents in conditions such as Crohn's disease, in which the rectum becomes a rigid tube rather than a soft distensible bag, even if the external and internal sphincter mechanisms work properly. Adequate sensation at the transitional cell zone is required to coordinate pelvic pressure and sphincter tone during the sampling reflex. The external sphincter is most responsible for the fine control of solid, liquid, and gas. The puborectalis muscle has been proposed as the mainstay of the sphincter mechanism and is probably responsible for the control of solid stool. The internal sphincter may be responsible for fine control of gas on the basis of the sampling reflex and constantly provides resting pressure to prevent release of flatus. The pudendal nerves provide both the sensory afferents of the anal canal and the motor efferents to the voluntary muscles of the anal canal.

Dysfunction of Anorectum

Incontinence

Anal incontinence can be defined as the inability to control elimination of rectal contents. Incontinence can be categorized as either constant or intermittent. It also can be characterized by the type of material that the anal canal is unable to control. Incontinence to solid, liquid, and gas is complete incontinence. Incontinence to liquid and gas and incontinence to gas only represent degrees of partial incontinence.

Etiology

Anal incontinence can be caused by mechanical or neurogenic defects in the anal sphincter mechanism. *Mechanical defects* result from trauma to the anal sphincter mechanism. The most common cause of sphincter trauma is obstetric injury during vaginal delivery. The true incidence of anal incontinence after vaginal delivery is unknown, but there is an increased likelihood of incontinence after a midline episiotomy or a perineal tear that extends into the rectum (fourth degree), after multiple vaginal deliveries with midline episiotomies, after infection of an episiotomy repair, and after prolonged labor followed by traumatic vaginal delivery.

The treatment of cryptogenic abscess/fistula disease of the anal canal by fistulotomy also can cause anal incontinence. A fistulotomy performed through a significant amount of external sphincter, in the anterior quadrant, often causes incontinence. This is especially true in women because continence depends on one thin band of anterior external sphincter muscle.

Some systemic diseases also can cause mechanical malfunction of the anal sphincter and result in incontinence. Scleroderma, for example, produces a progressive sclerosis and fibrosis of the muscle and nerve endings and prevents normal function. The internal sphincter is known to become dense, spastic, and occasionally stenotic. The external sphincter may fail to function voluntarily, resulting in total incontinence.

Neurogenic causes for anal incontinence include isolated pudendal nerve injury as well as systemic neurologic disease. Stretch or trauma to the pudendal nerve during prolonged labor at childbirth has been documented to cause partially reversible pudendal nerve injury. Lifelong straining to have a bowel movement has only recently been recognized as a cause of pudendal nerve injury. The pudendal nerve is stretched over the ischial spine as the perineum descends during straining to eliminate the rectal contents. This form of neurogenic incontinence occurs most commonly in elderly women and has been called *idiopathic fecal incontinence*. Systemic diseases may affect selected nerves (e.g., multiple sclerosis) or may cause diffuse damage that affects all nerves and eventually causes incontinence by its effect on the pudendal system (e.g., diabetic neuropathy).

Other causes of anal incontinence that are unrelated to anal sphincter malfunction include severe diarrhea, fecal impaction with overflow incontinence, irritable bowel syndrome, radiation proctitis and fibrosis, inflammatory bowel disease of the rectum, and tumors of the distal colon and rectum.

Physiologic Evaluation of Disordered Anorectal Function

The visual and digital rectal examination remains very important in the evaluation of a patient with anal incontinence. The perineal body is often thin in the setting of incontinence after obstetric trauma. There is usually a scar present when this is the source of the injury. Occasionally fistulous tracts or fistulotomy scars will be evident. An estimate of the resting tone and squeeze pressure can be obtained from the digital rectal examination.

Anal manometry measures the resting pressure, the squeeze pressure, the sphincter length, and the minimal sensory volume of the rectum. Maximal rectal tolerance also can be measured. There are various techniques for performing anal manometry. Normal resting pressure is usually reported as 40 to 80 mmHg. The maximal squeeze pressure generated by the external sphincter is 80 to 160 mmHg, which is twice the normal resting pressure. The average sphincter length of 3 cm is based on measurement of the high-pressure zone of the anal canal. The sphincter is shorter anteriorly where the puborectalis muscle does not complete the circle of fibers at the upper extent of the anal canal. The entire sphincter mechanism is shorter in women than in men. Normal minimal sensory volume is less than 10 mL of air instilled into a latex balloon placed within the rectum just above the anal canal. Resting *rectal* pressure is normally 10 mmHg (Fig. 26-22).

The measurement of the pudendal nerve *terminal motor latency* uses a stimulating electrode on the tip of a gloved finger that is placed over the ischial spine to stimulate the pudendal nerve. The resulting contraction of the external sphincter muscle is detected by means of a recording electrode at the base of the same finger. Normal pudendal nerve terminal motor latency is 2.0 ms, and it has been shown to increase with age, after childbirth, after prolonged excessive straining with perineal descent, and in systemic diseases such as diabetes and multiple sclerosis.

Nerve injury to the sphincter mechanism also can be determined by the electromyographic measurement of single-fiber density of the external sphincter muscle. This uses a thin bipolar needle with a 250-mm recording surface on the side of the needle. Motor unit potentials from a bundle of muscles innervated by a single terminal branch of the pudendal nerve are recorded. The external sphincter and puborectalis muscle maintain a constant resting tone, with spontaneous motor unit potentials documented in the muscle at rest. Injury to a terminal branch of a nerve is demonstrated by a multiphasic reinnervation pattern. As more muscle bundles are reinnervated, the average fiber density in numerous samplings may increase beyond the normal limits, also indicating nerve injury. Surgical correction of a mechanical defect in the muscle will not be successful if the innervation is severely impaired. Electromyographic techniques are also used to “map” the anal sphincter for viable, contracting motor units to document the extent and site of mechanical injury.

Transrectal ultrasound is as accurate as needle electromyography for sphincter mapping and is better tolerated by patients. A 360° 10-mHz probe can image the puborectalis, external anal sphincter, and internal anal sphincter and identify defects in these muscles.

Surgical Correction

If a patient has a minor defect demonstrated by anal manometry or has not responded completely to anal sphincter reconstruction, muscle/sensory retraining may be helpful using biofeedback techniques to improve anal continence. The majority of mechanical problems in the anal sphincter can be corrected by restoring the circular integrity of the sphincter mechanism. The technique most commonly used is the overlapping muscle repair (Fig. 26-23). In a patient with a defect in the circular fibers of the external and internal sphincters, the muscle can be mobilized and the ends of the scar and muscle brought together, in overlapping or end-to-end configuration, to complete the circular ring of the anal sphincter. The normal sphincter length is restored in the anterior quadrant, which may in itself provide a barrier to leakage of liquid and gas.

Extensive injury to the muscles and nerves of the anal sphincter may preclude simple muscle repair. In such cases, some success has been reported from use of the gracilis or gluteal muscle to create an encirclement of the anus; the degree of true continence that this provides is still questioned. Studies are evaluating the use of implantable pacemakers to drive the denervated external sphincter muscle or a transferred muscle, such as the gracilis or gluteus. These techniques are usually reserved for complete denervation of the anal canal or for severe mechanical injury in a patient who wishes to avoid a colostomy. The complicated process of diagnosing and treating anal incontinence is summarized in Fig. 26-24.

Obstructed Defecation

Obstructed defecation or pelvic floor outlet obstruction is a disorder of the anorectum resulting from nonrelaxation of the puborectalis muscle, or internal intussusception of the rectum, these disorders being the major components of a spectrum of disturbances known as *pelvic floor abnormalities*, the end stage of which is complete rectal prolapse.

Anal stenosis is a rare cause of obstructed defecation that results in thin, frequent stools, abdominal bloating, and dilatation of the large intestine. The most common cause of anal stenosis is scarring after anal operation such as an improperly performed circumferential Whitehead hemorrhoidectomy. Other causes of anal stenosis include chronic laxative abuse (particularly mineral oil), radiation injury, recurrent anal ulcer, Crohn's disease, trauma, and anal tumors. Occasionally anal stenosis will respond to dilation. The so-called Whitehead deformity includes a scarred stenosis of the anal canal and an ectropion of mucosa that is pulled from the rectum onto the perineal skin. Both anal ectropion and stenosis can be corrected by advancing a full-thickness pedicled flap of skin into the circumferential scar (Fig. 26-25). The success of this procedure depends on the presence of normal tissue surrounding the obstructing scar.

Nonrelaxation of the puborectalis muscle is a functional disorder in which a normal muscle displays abnormal function or control. Patients complain of straining, incomplete evacuation, need for digital maneuvers to eliminate the rectal content, and anal or pelvic pain. The diagnosis of nonrelaxing puborectalis muscle as a cause of constipation symptoms relies on the documentation of normal colonic transit to the rectum. A persistent image of the puborectalis muscle distorting the posterior rectum is seen on defecography (Fig. 26-26). Defecography is accomplished by instilling methylcellulose-thickened barium into the rectum. Video cinefluoroscopy is used to record a lateral image of the rectum while the patient strains in the sitting position. The inability to expel an air-filled latex balloon from the rectum while sitting on a toilet may be a more accurate means of documenting nonrelaxation (or paradoxical contraction) of the puborectalis. The treatment of this problem is nonoperative. Biofeedback is the most effective method for teaching the patient the cognitive aspects of defecation.

Internal intussusception (or internal prolapse of the rectum) is another cause of outlet obstruction. This condition accompanies laxity of the rectal fixation at the sacrum (Fig. 26-27) and will be discussed in more detail later. The intestine telescoping into itself causes partial obstruction to defecation while simultaneously contributing to a feeling of rectal fullness and a need to defecate.

Other Associated Problems

Proctalgia fugax, or the *levator muscle syndrome*, is spasm of the anal sphincter, which causes pain, often at night. The puborectalis muscle goes into spasm and typically awakens the patient. The pain usually lasts only a few minutes and can be relieved by heat, dilation, or muscle relaxants. It may be stress-related and has been associated with the irritable bowel syndrome or a past history of migraine headaches. Other causes of anal pain such as abscess, foreign body, or cancer should be excluded before this diagnosis can be confirmed.

Fecal impaction and *stercoral ulceration* are occasionally seen in patients with outlet obstruction due to nonrelaxing puborectalis or internal intussusception. The symptoms of bleeding and rectal fullness are treated by regulation of the bowel habits and periodic emptying of the rectum with a bowel regimen consisting of enemas, increased fiber, and stool softeners.

Descending perineum syndrome was in the past thought to be a primary process. It is now known to be the result of chronic straining at defecation. The primary process is, therefore, chronic constipation, disordered defecation, or intussusception. Descending perineum syndrome causes stretching of the pudendal nerve, which leads to neurogenic weakening of the external sphincter and puborectalis muscle, which eventually can lead to anal incontinence.

Rectocele is the result of weakened muscle and soft tissue between the rectum and the vagina after years of straining to defecate. The bulge, or rectocele (see Fig. 26-26 B), occurs in the posterior vaginal wall and in severe cases may even cause protrusion of tissue through the vagina. Symptoms are similar to those of other types of obstructed defecation, and the patient may need to put a finger in the vagina and push the rectum posteriorly in order for it to empty. A rectocele is a signal that a basic problem exists in the rectum or mechanism of defecation. Repair of a rectocele without correction of internal intussusception or outlet obstruction is seldom successful, and recurrence is common in such circumstances.

Psychological Profile of an Outlet Obstruction Patient

Psychological abnormality has never been clearly documented as the cause of disordered defecation, but many patients with constipation have been found by psychological evaluation to have depression, somatization disorder, and an extreme need to control. Patients with nonrelaxing puborectalis have similar findings. These patients also seem to exhibit a cancer fear, which is alleviated when they find that their work-up is normal. It is prudent to obtain a psychological profile on these patients before considering biofeedback or surgery.

Physiologic Evaluation of Disordered Defecation (Pelvic Floor Abnormality)

Disordered defecation or pelvic floor abnormality is a complex problem. An overlap in symptoms between causes may result in a diagnostic dilemma unless a well-planned evaluation has been performed (Fig. 26-28). *Defecography* uses cinefluoroscopy from a lateral position as the patient attempts to empty thickened barium while sitting on a commode. The features of a *normal defecogram* include fixation of the posterior rectum to the curve of the sacrum, rapid rectal emptying with straining, and appropriate relaxation of the puborectalis muscle. Abnormal findings are observed when the rectum moves from the sacrum during straining, when it displays excessive mobility from the sacral curve, and when it forms a funnel configuration (complete intussusception) (Fig. 26-29).

Complete rectal prolapse also can be documented by defecography. Obstructed defecation is suggested if the puborectalis does not relax during attempted defecation (see Fig. 26-26 A).

Colonic *transit time*, as described previously, is important in differentiating colonic from anorectal malfunction in patients with disordered defecation. Outlet obstruction may exist with normal colonic transit to the rectum. Colonic transit studies will show markers within the rectum after the fifth day because the rectum does not empty normally.

Anal manometry rarely has a role in the evaluation of disordered defecation. Its main use in this context is to document the presence of a normal rectal-anal inhibitory reflex to rule out Hirschsprung's disease as the cause of constipation. *Megarectum* is an acquired problem thought to be a result of failure to respond to the normal signals for defecation and can result in an abnormal rectoanal inhibitory reflex. Manometry also shows an increase in the maximal tolerable rectal volume in patients with megarectum.

Balloon expulsion recently has been found to be helpful in establishing the diagnosis of nonrelaxing puborectalis muscle as the cause for disordered defecation. Defecography often reveals a persistent puborectalis shadow and poor relaxation of the sphincter during efforts to evacuate the rectum; however, many of these patients are able to empty their rectum at other times. The overdiagnosis of nonrelaxing puborectalis muscle can be avoided by performing a balloon expulsion test. The inability to pass a 60- mL inflated latex balloon in a private bathroom, sitting on a toilet, seems to be an accurate means of documenting the absence of the normal coordination of muscle function required for defecation.

Therapeutic Options for the Treatment of Disordered Defecation

Nonrelaxation of the puborectalis muscle has been treated with limited transection of the puborectalis muscle itself, an approach that initially was reported to cause improvement in some patients with outlet obstruction; long-term follow-up revealed that almost all patients treated with the operation develop incontinence with very little improvement in symptoms. The most consistent improvement in patients with nonrelaxing puborectalis muscle has come via the use of biofeedback. Several series have now documented a long-term improvement using behavioral modification techniques to retrain the patient to relax the pelvic floor during straining to defecate.

The anatomic abnormalities associated with internal intussusception can be corrected surgically. Retrorectal sacral fixation straightens the rectum and fixes the bowel to the sacrum, eliminating the abnormal mobility (Fig. 26-30 A). Unfortunately, this operation often fails to relieve the symptoms of disordered defecation. Success has been reported with low anterior resection of the rectum (Fig. 26-30 B), but more data concerning long-term results are needed. Most of the patients with internal intussusception as a cause of outlet obstruction respond well to medical management, once the cause of symptoms has been clearly diagnosed. Only those with the most severe problems and impending pudendal nerve damage should be considered for operative correction. It is important to remember that if an outlet obstruction is not corrected before other causes of constipation are treated, the method of treating the constipation will fail. Even the use of abdominal colectomy for severe constipation due to colonic inertia has failed if outlet obstruction is a major component of the problem.

Abnormal Rectal Fixation Internal Intussusception

Internal intussusception has already been described as a cause of outlet obstruction. It is also possible that a nonrelaxing puborectalis muscle induces internal intussusception from prolonged, aberrant straining at defecation. It is further thought that internal intussusception is a precursor to complete rectal prolapse. There seems to be an increased incidence of intussusception of the rectum with aging, connective tissue disorders, and irritable bowel syndrome. Internal intussusception is also now known to be the cause of the *solitary rectal ulcer*. The ulcer develops as the lead point of the intussuscepting tissue becomes chronically ischemic and traumatized. If the ulcer heals, glands may be trapped in the deep tissues, causing the lesion of *colitis cystica profunda*, large glandular lakes within the mucosal and submucosal tissue in the area of the solitary rectal ulcer. Colitis cystica profunda is characterized by the presence of localized or diffuse submucosal cysts and may be mistaken for rectal cancer, resulting in inappropriate resection. It may be found in association with several different clinical conditions, including radiation injury, postoperative changes, adenomatous polyps, malignant growth, or inflammatory bowel disease. Patients may have symptoms of mucous discharge, rectal bleeding, or tenesmus. Feelings of rectal fullness or incomplete evacuation are common patient complaints. Colonoscopy or barium

enema should be performed to rule out malignant growth, and the patient should be evaluated for rectal prolapse or intussusception by defecography. Spontaneous resolution can occur but is rare. Colitis cystica profunda associated with rectal prolapse is treated by correcting the rectal prolapse.

The majority of patients with internal intussusception respond to increased bulk in their diet, stool softeners, and glycerine suppositories or small enemas to stimulate rectal emptying. Indications for surgical correction of internal intussusception include symptoms severe enough to change the patient's life despite maximal medical and psychological therapy, chronic bleeding from a solitary rectal ulcer, or impending anal incontinence because of the descending perineum and subsequent stretch injury to the pudendal nerve.

Rectal Prolapse

Rectal prolapse is the protrusion of the full thickness of rectum and occasionally sigmoid through the anus. Rectal prolapse may be the long- term result of outlet obstruction or internal intussusception of the rectum. There is an increased incidence in elderly women and institutionalized patients treated with constipating psychotropic drugs. There is also an increased incidence of prolapse in women who have had hysterectomy and in spinal cord–injured patients who require routine use of laxatives to maintain bowel function. Surprisingly, there is not an increased incidence of rectal prolapse in women who have had multiple vaginal deliveries.

The symptoms of rectal prolapse include anorectal pain, bleeding, mucous discharge, and incontinence. Some patients will be hesitant to describe the large bolus of protruding tissue and will instead present with symptoms of mucous discharge or progressive incontinence. As the condition progresses, spontaneous reduction may not occur, and manual replacement of the prolapsed rectum becomes necessary. In severe instances, the prolapsed tissue becomes too edematous to replace, and necrosis of the prolapsed segment may occur. Sometimes the patient is unable to demonstrate the prolapse in the physician's office, and defecography is required to reveal increased mobility from the sacrum, marked intussusception, and finally protrusion of the rectum through the anal canal. Occasionally, a solitary rectal ulcer is seen at the lead point of the prolapse. It is important to differentiate rectal prolapse from prolapsing internal and mixed hemorrhoids. In hemorrhoidal disease, there will be a deep groove between the areas of prolapsing tissue as opposed to the concentric rings on the mucosa seen on the rectal prolapse. It is a significant mistake to perform a hemorrhoidectomy when the problem is really complete rectal prolapse.

Complete evaluation of the patient with rectal prolapse should include colonoscopy or air-contrast barium enema to fully evaluate the colon and rule out the presence of a malignant growth that might be serving as the lead point for the prolapse. Anal manometry and electromyography are helpful in evaluating sphincter function in patients with rectal prolapse in order to choose the appropriate corrective procedure.

Therapeutic options in the treatment of rectal prolapse can be divided into three groups (see Fig. 26-30). The first group, patients with full rectal prolapse and normal sphincter function, should be considered for a low anterior resection or retrorectal sacral fixation. If constipation is a significant factor, or if the patient is found to have a very redundant sigmoid colon, low anterior resection with fixation of the lateral rectal ligaments is probably a better choice of procedure. Any operation for rectal prolapse must include full mobilization of the rectum, preceding fixation of the rectum, to prevent forward motion and avoid distal prolapse. Excellent functional results should be anticipated for this group of patients.

The second group of patients has full rectal prolapse and incontinence. Most patients recover sphincter function after repair of the prolapse (60 to 70 percent), but it is difficult to predict which of these patients would tolerate a low resection of the rectum. These patients should be treated by retrorectal sacral rectopexy using a synthetic sling via an abdominal approach or by a perineal proctectomy combined with rectopexy and a posterior sphincter-enhancing procedure (see Fig. 26-30 C). Of patients having surgical correction of rectal prolapse, 30 percent will not recover fecal continence. This is true especially in patients with documented neurogenic incontinence who have prolonged pudendal nerve latency. These patients may be helped by the "posterior repair" of the anal canal using the technique described by Sir Alan Parks. The external sphincter and puborectalis sling are brought together posteriorly to elongate the anal canal, to decrease the anal opening, and to add bulk to the posterior aspect of the canal. In some cases continence is further improved by reconstruction of the anterior aspect of the sphincter as well as posteriorly. This technique has been combined with a perineal proctectomy to correct rectal prolapse and associated anal incontinence.

The third group of patients consists of those at extremely high operative risk or elderly individuals with incontinence and prolapse who have a very short life expectancy. These patients may be considered for an anal encircling procedure (see Fig. 26-30 D). The original procedure used a silver wire (Thiersch procedure) placed in the ischiorectal fat around the external sphincter mechanism. The wire served to cause obstruction of the anal outlet and to compress the sphincter mechanism. Currently, the encircling procedure is performed with a band of soft synthetic mesh, a silicone tube, or a gracilis muscle graft to the anal canal. The majority of these patients require laxatives or enemas to avoid fecal impaction. The complications of this procedure include erosion of the encircling band and infection. This is obviously not the first choice of treatment for rectal prolapse and is used less frequently because the combined perineal proctectomy procedure is available for use in elderly patients under spinal or epidural anesthesia.

Hemorrhoids Pathophysiology

Hemorrhoidal tissue is normally found at the distal end of the rectum within the anal canal (Fig. 26-31 A). These vascular and connective tissue cushions are usually found in the right anterolateral and posterolateral positions and the left lateral position. Internal hemorrhoids are above the dentate line (see Fig. 26-31 B); external hemorrhoids are the vascular complexes under the anoderm of the anal canal (see Fig. 26-31 C).

The pathophysiology of symptomatic hemorrhoids is related to engorgement of the vascular pedicles in the hemorrhoidal complexes, which then dilate, stretch, and cause the cushions to enlarge. The vascular complexes engorge as pressure is applied to the pelvic floor during straining, lifting, or standing. Bleeding occurs from local trauma to the hemorrhoidal complex, usually during defecation. Hard stools, prolonged straining, increased abdominal pressure, and prolonged lack of support to the pelvic floor all combine to increase the likelihood that abnormal hemorrhoidal tissue will develop.

Internal hemorrhoids, which are covered by mucosa, typically bleed or prolapse but do not cause pain. Patients complain of rectal fullness, mucous discharge, and bright red blood dripping into the toilet or on the toilet paper. Occasionally, internal hemorrhoids will incarcerate within the outer ring of the anal canal and develop thrombosis and necrosis. Internal hemorrhoids can be classified as follows: First-degree hemorrhoids bleed; second-degree hemorrhoids bleed and prolapse but reduce spontaneously; third-degree hemorrhoids bleed and prolapse and require manual reduction; and fourth-degree hemorrhoids bleed and incarcerate and cannot be reduced.

External hemorrhoids beneath the anal skin can become enlarged over time as a result of dilatation or repeated thrombosis. The overlying skin may stretch to develop a skin tag, which prevents adequate hygiene. Occasionally, a clot within an external hemorrhoid will cause severe pain and may bleed if the clot erodes through the overlying skin. It is rare for an internal hemorrhoid to cause pain unless it becomes incarcerated and thrombosed. External hemorrhoids usually cause pain even after a small thrombosis because they are beneath richly innervated skin.

The symptoms of hemorrhoids are limited, and caution must be used not to misdiagnose other anorectal problems as hemorrhoids (Table 26-1). Defecography is helpful when symptoms of rectal prolapse or obstructed defecation exist, and sigmoidoscopy, colonoscopy, or contrast enema identifies malignant growths or inflammatory bowel disease.

Treatment

Medical Therapy

The majority of bleeding first- and second-degree hemorrhoids respond to the addition of dietary fiber (e.g., psyllium) or stool softeners and avoidance of straining or prolonged sitting on the commode. It is important to counsel the patient to ingest an appropriate amount of water with the fiber. The goal is to produce soft stool that is easy to pass. Failure of medical therapy is an indication for mechanical intervention, e.g., elastic ligation, excision, etc. of second-degree hemorrhoids. Surgery rarely is indicated for the bleeding of first-degree hemorrhoids.

Elastic Ligation

Elastic ligation of second- and third-degree internal hemorrhoids, 1 to 2 cm above the dentate line, is very effective for control of bleeding and prolapse. The tissue is grasped and pulled into the cylinder of a rubber-band applier, and the rubber bands are placed at the base of the hemorrhoidal tissue (Fig. 26-32). The tissue necroses, sloughs, and leaves a scar in the area of the vascular pedicle, which prevents further prolapse of tissue or bleeding. Care is taken to avoid placement of the bands on the transitional zone or anoderm, both of which are richly innervated with pain fibers. One also must avoid placement of the rubber bands on the deep internal sphincter muscle, since symptoms of spasm may become so severe that urinary retention may result. The majority of patients can tolerate a single- quadrant ligation in the office every 2 weeks. If symptoms are severe or the patient has significant external hemorrhoids and other anorectal problems, three quadrants may be banded in the operating room under local anesthesia.

Severe sepsis has been reported after ligation of hemorrhoids in immunocompromised patients or patients with pelvic floor abnormalities in whom the full thickness of the distal prolapsing rectum has been ligated. This life-threatening complication is heralded by inordinate pain, fever, and urinary retention within 12 h of ligation. The incidence of urinary retention after a single ligation should be less than 1 percent. Urinary retention after multiple ligations may be as high as 10 to 20 percent. The septic patient requires intravenous antibiotic coverage for gram-negative and anaerobic organisms, removal of the rubber bands, and hospitalization.

Normally, the rubber bands fall off with the necrotic tissue after 7 to 10 days. Bleeding may occur, but it is usually minimal. One percent of patients develops significant hemorrhage, which may require cautery or suture ligation of the bleeding site. Nonsteroidal anti-inflammatory drugs or aspirin taken during the 7 to 10 days after banding may increase the incidence of bleeding when the bands and tissue slough.

Photocoagulation

This is a very simple technique by which heat causes necrosis fibrosis of the vascular pedicle in several areas within the anal canal to achieve the same result as elastic ligation on smaller pedicles, but larger hemorrhoids require another form of treatment.

Sclerosis

A mixture of 5% phenol and almond oil developed at St. Mark's Hospital in London may be used to stop bleeding from first- and second-degree hemorrhoids. The mixture is injected through a spinal needle into the submucosa at the base of each hemorrhoid to raise a bleb of mucosa. The depth and amount of sclerosing agent are critical to avoid slough of the entire anal mucosa. Minimizing the amount of IV fluids given during an operation decreases the rate of this complication. Other complications include allergic reaction, local infection, and prostatitis. Many surgeons believe that if tissue can be treated by sclerosis, it probably should not have surgical treatment at all.

Cryosurgery and Direct-Current Coagulation

Hemorrhoidal tissue can be coagulated by freezing with liquid N₂ or a CO₂ probe. Because frozen tissue undergoes liquefaction necrosis and there is poor control of the depth of

freezing, the majority of surgeons avoid using this technique. Patients also complain of profuse, foul-smelling seropurulent discharge.

Direct-current coagulation requires approximately 10 min per site to coagulate the hemorrhoidal cushion. The resulting scar prevents prolapse and further bleeding of first-, second-, and some third-degree internal hemorrhoids. The technique is simply another means of treating internal hemorrhoids in the outpatient or office setting.

Excisional Hemorrhoidectomy

The excision of hemorrhoids should be limited to large third- and fourth- degree hemorrhoids that cannot be treated on an outpatient basis, mixed hemorrhoids with an external anoderm component that are not amenable to ligation, and acutely thrombosed, incarcerated hemorrhoids with severe pain and impending gangrene. Patients on anticoagulant medication are also better treated with closed, excisional hemorrhoidectomy rather than elastic ligation because of the risk of excessive bleeding when the necrotic tissue sloughs. There are numerous techniques for excising hemorrhoids. All of them are best done with the patient in the prone, flexed position. The closed technique uses either a laser, scalpel, scissors, or cautery to elliptically incise the pedicles of the hemorrhoid cushion, including the external and internal components (Fig. 26-33). The incision avoids the underlying internal sphincter muscle as the vascular cushion is dissected from the surface of the muscle. The mucosal defect is then closed after the vascular pedicle is secured with the suture.

Urinary retention is the most common complication after excisional hemorrhoidectomy and has been reported in 10 to 50 percent of patients. Minimizing the amount of IV fluids given during an operation decreases the rate of this complication. Other complications include bleeding, infection, fecal impaction, and sphincter injury. Many of the complications can be prevented by proper use of analgesia to avoid pain and straining to urinate or defecate in the immediate postoperative period. Significant bleeding after hemorrhoidectomy must be managed by complete visualization of the operative site and cautery or suture ligation of the bleeding tissue. This requires adequate anesthesia, usually a spinal or epidural. Anal stenosis is a long-term complication following circumferential excision of the anoderm and dentate line during an improperly performed Whitehead procedure. Excision of the dentate line and anoderm causes circumferential scarring at the new mucocutaneous junction. The result is eversion of rectal mucosa to form ectropion and stenosis of the anal canal. This *Whitehead deformity* often requires an island advancement flap procedure in which normal skin is inserted into the anal canal to relieve the ectropion and the stenosis (see Fig. 26-25).

Acute thrombosis and incarceration of mixed hemorrhoids can be treated conservatively with bed rest and stool softeners or with excisional hemorrhoidectomy after injecting local anesthesia and reducing the edematous rectal tissue. Epinephrine and sometimes hyaluronidase may be added to the local anesthetic agent to decrease swelling and allow the tissue to reduce. A standard three-quadrant excisional hemorrhoidectomy is safe in this setting and should not cause anal stricture and sphincter injury if performed carefully.

Excision of Thrombosed External Hemorrhoid

A patient seen in the office or emergency department with an acutely thrombosed external hemorrhoid may obtain relief by excision of the acutely thrombosed tissue. This is performed with local anesthesia, and the wound is usually left open. Merely incising the hemorrhoid and expressing the clot carries a significant risk of recurrence of the thrombosis and bleeding. The patient who is seen more than 48 h after thrombosis of a hemorrhoid is best treated conservatively with warm soaks, an increase in fiber in the diet, and stool-softening agents.

Prevention

The majority of hemorrhoids occur because of a patient's poor bowel habits. It is important to stress the use of fiber and water in the diet, the avoidance of straining, and the cessation of sitting on the toilet for long periods of time. Symptomatic hemorrhoids can recur despite surgical treatment if these instructions are disregarded.

Anal Fissure/Anal Ulcer General Principles

The very common problem of anal fissure was first described in 1829 by Recamier, who recommended stretching the anal sphincter to treat the condition. An *anal fissure* is a split in the anoderm, usually in either the posterior or anterior midline just distal to the dentate line (Fig. 26-34A). Ninety percent of all fissures occur posteriorly and 10 percent anteriorly. Less than 1 percent of patients will be found to have a fissure in both the anterior and posterior positions. The very characteristic symptoms of the fissure or ulcer include tearing pain on defecation, blood on the toilet paper or stool, and, rarely, blood in the toilet bowl. Patients also may complain of a perineal or perirectal ache or spasm for several hours after defecation.

The cause of the anal fissure has been postulated to be a hard bowel movement or prolonged diarrhea with stretching of the anal canal to cause a split in the anoderm. Increased anal sphincter pressure has been documented on anal manometry in patients with an anal fissure. However, patients in the general population with increased anal pressure have not been found to be at high risk for developing an anal fissure. Fissures may result from ischemia, since anodermal blood flow in the posterior midline less than in other segments of the anal canal, and increased anal pressure correlates with reduced blood flow to this area. The pain and irritation of the fissure result in spasm of the underlying internal sphincter muscle, which then fails to relax during defecation, resulting in further tearing of the anoderm and deepening of the fissure to form an anal ulcer. The presence of this anal ulcer implies a chronic fissure and is accompanied by an external skin tag and a hypertrophied anal papilla in its most mature form (see Fig. 26-34 B). The white fibers of the internal sphincter are found at the base of the ulcer.

Crohn's disease or tuberculosis of the anal canal should be suspected when the fissure or ulcer is in an atypical position. Anal disease is the first manifestation in 10 percent of patients with Crohn's disease. Patients with anal tuberculosis will have a prior history of pulmonary tuberculosis or a concomitant infection. Anal cancer may present as a painless ulcer, but it is usually associated with a mass and persists despite treatment. It is important to biopsy all nonhealing ulcers for this reason. Occasionally, abscess/fistula disease, cytomegalovirus, herpes, or *Chlamydia* infection, or syphilis will mimic some of the features of fissure and ulcer disease.

Diagnosis and Management

The diagnosis is made by visual inspection to identify either the fissure or the ulcer complex at the dentate line. Digital examination can be very painful but, if possible, will reveal not only the ulcer but also the characteristic spasm and hypertrophy of the underlying internal sphincter muscle. Medical treatment of the fissure and ulcer relies primarily on stool softeners and the addition of bulk to the diet. Almost 90 percent of simple anal fissures will heal with simple medical therapy. Stool softeners and bulk, as well as warm sitz baths, will relieve symptoms and produce healing in 60 to 80 percent of patients with a second episode. Topical nitroglycerin 0.2% to 0.5% (a nitric oxide donor) has been used to relax the anal sphincter and has achieved healing of anal fissures in 80 percent of a small series of patients. Botulin toxin injection also has been used to effect transient paralysis of the anal sphincter and promote healing in some patients with anal fissure. Only after the fissure has been shown to be chronic is operation considered.

Surgical Management

The surgical methods of treating fissure and ulcer disease include stretching or dividing the internal sphincter. The four-finger stretch produces uncontrolled fracturing of the internal sphincter even though it may give initial relief of symptoms. Approximately 40 percent of patients treated this way develop recurrence, and a significant proportion are partially incontinent. The lateral internal anal sphincterotomy is considered the procedure of choice by most surgeons. A success rate of 90 to 95 percent is reported after lateral sphincterotomy for a chronic anal fissure or ulcer. Recurrence rates usually are below 10 percent, and minor incontinence, such as leakage of mucus and gas, is reported in less than 10 percent of the patients. The sphincterotomy is usually performed in the posterior lateral anus. The distal third of the internal sphincter is hypertrophied and presents a distinct, palpable band. If this hypertrophied band is not present, another cause of the ulcer should be considered. An open or closed sphincterotomy will give similar results, and each has its proponents (Fig. 26-35). The procedure is performed with the patient in the prone, flexed position, usually with local anesthesia; it is almost always performed on an outpatient basis.

INFECTIONS

Colitis

Pseudomembranous Colitis

Pseudomembranous colitis presents as an acute diarrheal syndrome in patients who are undergoing or have recently completed antibiotic therapy. Antibiotics alter the normal colonic bacterial population, permitting an overgrowth of the pathogen *Clostridium difficile*. This bacterium elaborates two separate exotoxins, a cytopathic toxin and an enteropathic toxin. The cytopathic toxin can be fortuitously neutralized by a cross-reaction with the antitoxin to *C. sordellii*, providing the basis for the tissue culture assay to detect the presence of *C. difficile*. If the cytopathic effects of *C. difficile* can be demonstrated by tissue culture and that effect is eliminated by culture with *C. sordellii* antitoxin, the diagnosis of *C. difficile* infection is presumed. A latex fixation test has been reported to successfully detect the cytopathic toxin. The assay should be performed within 24 h of collection of the stool. The toxin is moderately heat labile and deteriorates rapidly.

C. difficile colitis is usually preceded by the administration of antibiotics, and in as many as one-fourth of the patients the antibiotic has been discontinued before the development of diarrhea. Symptoms may appear as long as 6 weeks after antibiotic therapy. Virtually all antibiotics have been associated with the subsequent development of *C. difficile* colitis, but clindamycin, ampicillin, and the cephalosporins are most commonly implicated. There also is a contagious risk to this disease, with cross- infection occurring in hospitals and nursing homes. For this reason, isolation precautions should be used for patients with *C. difficile* colitis.

The clinical syndrome of this infection varies widely from mild, self-limited diarrhea to severe, invasive colitis associated with megacolon and perforation. When the disease is suspected, the implicated antibiotic should be stopped immediately. Proctoscopy or colonoscopy is a useful measure to detect pseudomembranes, and stool should be sent for toxin assay. Usually mild disease is self-limited. For more severe symptoms, including abdominal pain, fever, and leukocytosis, the patient should be admitted to the hospital for observation and intravenous hydration. Metronidazole is the antibiotic of choice and is usually prescribed in a dosage of 250 to 500 mg orally four times a day for 10 days. Vancomycin (125 mg orally four times a day for 10 days) is also effective, but it is much more expensive. In patients in whom oral therapy is not possible, intravenous metronidazole may be used. Intravenous vancomycin does not achieve therapeutic concentrations in the colon, however, and has no role in this setting. Cholestyramine has been recommended because it binds the toxin and renders it ineffective; however, the resin also may bind the therapeutic antibiotic, rendering it ineffective.

Most patients respond rapidly to the aforementioned treatment. Unfortunately, the recurrence rate is at least 20 percent, but these patients generally respond well to retreatment. Rarely, the disease becomes fulminant and fails to respond to appropriate antibiotic treatment; should the disease progress to a fulminant stage with toxic dilatation of the colon, abdominal colectomy with ileostomy may be necessary.

Amebic Colitis

Amebiasis is an infectious disease caused by the protozoan *Entamoeba histolytica* that infects primarily the colon but may involve other organs (usually the liver) secondarily. In the United States, amebiasis is usually thought to be a tropical disease, to be considered only if the patient has traveled abroad. However, it has been estimated that at least 5 percent of the untraveled population of the United States is infected with *E. histolytica*. The disease is transmitted by the fecal-oral route, which may include sexual contact, contamination of

the water supply, and fecal soilage in day-care centers or institutions for the retarded.

E. histolytica exists in the human colon in two forms: the trophozoite and the cyst. The latter is the infective form that is ingested, causing colonization. The majority of patients infected with the protozoa remain asymptomatic carriers. However, the cysts may transform to invasive *trophozoites* at any time, and the contributing factors leading to the emergence of virulence are not understood. The pathologic lesions of invasive amebiasis are small ulcers that may occur throughout the colon but most commonly affect the cecum. The ulcers may be covered with a yellow exudate. As the disease progresses, the ulcers may grow to more than 2 cm in diameter, with edges of undermined mucosa and necrotic tissue filling the ulcer base. The intervening mucosa may appear completely normal. In rare circumstances the ulcer may perforate, causing fulminant peritonitis. On histologic section, the amebae can be detected at the edge of the ulcer.

The clinical spectrum of amebiasis varies greatly from asymptomatic carriers to acute illness with bloody diarrhea resembling fulminant ulcerative colitis. On rare occasions the disease can cause toxic dilatation of the colon, and emergency colectomy is lifesaving. It is important to distinguish this disease from ulcerative colitis or Crohn's disease; the steroids often prescribed for the latter diseases are contraindicated in patients with amebiasis because immunologic suppression can lead to lethal dissemination of the disease. Microscopic examination of fresh stool specimens will reveal trophozoites in 90 percent of patients with symptomatic invasive amebiasis. Sigmoidoscopy is occasionally helpful if the ulcers are located in the distal bowel; however, these lesions more commonly occur in the cecum. Appropriate stool cultures should be taken to distinguish this disease from infectious bacterial colitis.

Metronidazole is the recommended treatment for invasive amebiasis. This medication, however, might be ineffective against organisms within the bowel lumen and in carriers. Iodoquinol (diiodohydroxyquin) is recommended as an accompanying medication to eliminate luminal organisms.

An uncommon complication of amebic infection that is of interest to surgeons is the *ameboma*, a mass of inflammatory tissue that may cause colonic narrowing and be confused with a carcinoma (Fig. 26-36). Colonoscopy may help in establishing the exact nature of the lesion. This lesion occurs most commonly in the cecum and is difficult to diagnose because the parasite is usually not present in the stools. The indirect hemagglutination test is usually positive in patients with an ameboma, and this test should be done if a lesion is suspicious or if there is a history of previous amebic infection. If the diagnosis is established, these patients should be treated with the antibiotics previously described. If the lesion does not resolve with antibiotic treatment, operation should be performed under cover of antiamebic therapy.

Actinomycosis

Actinomycosis is an uncommon bacterial infection caused by the gram- positive anaerobic or microaerophilic bacterium *Actinomyces israelii*. This organism formerly was misclassified as a fungus; but the species is closer to a bacterium than it is to a fungus. Clinical disease is characterized by chronic inflammatory induration and sinus formation. The organism is a normal resident of the mouth, and the cervicofacial area is the most frequently involved site, followed by thoracic and abdominal involvement.

Abdominal infection most frequently involves the cecal area, usually following appendectomy. An indurated, firm pericecal mass may develop, and, if untreated, the condition progresses to formation of indolent sinuses extending to the abdominal skin.

The diagnosis of actinomycosis should be suspected if an indolent mass or chronic sinus follows an appendectomy. The organisms make *sulfur granules*, which are actually tiny bacterial colonies consisting of a central core of intertwined branching filaments, with club-shaped bodies at the periphery, held together by a polysaccharide protein. These colonies create a sunburst pattern recognized microscopically, from which the organism derives its name. While sulfur granules are highly suggestive of *Actinomyces*, they are neither a consistent finding nor pathognomonic; *Nocardia*, *Streptomyces*, *Actinobacillus*, and *Staphylococcus* may form similar granules. Diagnosis can be confirmed by aerobic and anaerobic cultures. The microbiology laboratory should be alerted to the possible diagnosis of actinomycosis, since it often takes up to a week to isolate the organism in anaerobic culture.

Treatment consists of adequate surgical drainage and antibiotics. Penicillin and tetracycline are both effective; antifungal agents are not effective.

Neutropenic Enterocolitis

Neutropenic enterocolitis occurs most often in patients with acute myelogenous leukemia receiving high-dose cytosine arabinoside chemotherapy, but it may be seen in patients with other types of leukemia or in association with other types of chemotherapy. The syndrome is characterized by sepsis, abdominal pain and tenderness, and neutropenia. High fever, watery or bloody diarrhea, and abdominal distention are common. Tenderness is often localized to the right lower abdominal quadrant, and abdominal x-rays may show partial small bowel obstruction, thickened irregular mucosal folds, a dilated cecum, and air within the bowel wall. CT examination may reveal an edematous cecum with inflammation of the adjacent soft tissues and air in the cecal wall.

The pathogenesis of the syndrome and its proclivity to affect the cecum are not clear. It has been suggested that leukemic infiltrates in the colonic wall become necrotic after chemotherapy, resulting in ulceration of the mucosa and sepsis. Other theories include mucosal hemorrhage accompanying thrombocytopenia causing mucosal disruption and subsequent sepsis or ischemia caused by stasis of the enteric vessels resulting in mucosal necrosis and ulceration.

Treatment consists of complete bowel rest with total parenteral nutrition and intravenous broad-spectrum antibiotics. If the sepsis cannot be controlled, or if colonic perforation occurs, operative intervention will be necessary. In such circumstances, all necrotic bowel must be removed, and the viable limbs of the bowel must be exteriorized as an ileostomy and mucous fistula. It has been suggested that elective right hemicolectomy may be indicated to prevent recurrence in patients who have recovered from neutropenic colitis and require additional chemotherapy.

Cytomegalovirus Colitis

Cytomegalovirus (CMV) infects approximately 90 percent of patients with the acquired immune deficiency syndrome (AIDS) during the course of their illness. It appears to be more commonly associated with homosexuals infected with the human immunodeficiency virus (HIV I). The infection can involve numerous organs, including the lungs, eyes, brain, liver, adrenal glands, intestinal tract, and anus. CMV colitis may occur in up to 10 percent of patients with AIDS and is the most common reason for emergency abdominal operations in this group of patients.

The virus causes mucosal ulceration and submucosal hemorrhage, and symptoms include diarrhea, rectal bleeding, fever, and weight loss. Biopsy will reveal CMV inclusions and inflammation.

Dihydroxypropoxymethyl guanine (DHPG, or ganciclovir) is the drug of choice. If the disease progresses to toxic megacolon or perforation, emergency colectomy is mandatory. Emergency colectomy also might be required for massive colonic hemorrhage. Anastomosis is seldom advisable under such circumstances, and ileostomy is almost always necessary. The prognosis is very poor; fewer than half of patients are alive at 6 months.

Chagas' Disease

Chagas' disease is endemic in Central and South America and is a frequent cause of acquired megacolon in these regions. Infection with the protozoan *Trypanosoma cruzi* results in destruction of Auerbach's myenteric plexus followed by intramural fibrosis. Although various lengths of colon may be affected, the rectum is the site most frequently involved. Loss of normal propulsive ability causes a functional obstruction and results in a proximal megacolon.

Conservative therapy may be possible in patients with mild symptoms. Complications of severe constipation, fecal impaction, or volvulus require resection of the involved colon and rectum. Sigmoidectomy, left colectomy, and subtotal colectomy all have high recurrence rates because the dyskinetic rectum is preserved. Abdominoperineal endoanal pull-through resection with delayed colorectal anastomosis or the Duhamel procedure are the techniques of choice.

Infections of Anorectum

Anorectal Abscess and Fistula Cryptoglandular Abscess

There are several potential spaces around the anorectum that are ordinarily filled with fat and areolar tissue (Fig. 26-37).

Pathophysiology

The *perianal space* surrounds the anus and becomes continuous with the fat of the buttocks. The *intersphincteric space* separates the internal and external sphincters. It is continuous with the perianal space and extends cephalad into the rectal wall. Lateral and posterior to the anus is the pyramidal *ischiorectal space*. It is found below the levator ani and bound medially by the external sphincter, laterally by the ischium, and inferiorly by the transverse septum. This space contains the inferior rectal vessels and lymphatics. The two ischiorectal fossae connect posteriorly above the external sphincter forming the *deep postanal space* between the levator ani and the anococcygeal ligament. An abscess in one ischiorectal fossa can infect the other via the deep postanal space, creating a "horseshoe" abscess. The *supralevator spaces* lie above the levator ani on either side of the rectum. These spaces communicate with each other posteriorly.

The majority of anorectal suppurative disease results from infections of the anal glands (cryptoglandular) (Fig. 26-38) and is usually due to a mixture of fecal and cutaneous flora. The glands are found in the intersphincteric plane, traverse the internal sphincter, and empty into the anal crypts in the anal canal at the level of the dentate line. Not all crypts contain glandular openings. These common infections should not be confused with anorectal manifestations of Crohn's disease, pilonidal disease, hidradenitis suppurativa, or the rarer tuberculosis or actinomycosis. The *acute* phase of cryptoglandular disease results in formation of an abscess. If the abscess drains and an infected tract persists, the process enters the *chronic* phase of fistula-in-ano.

Diagnosis

Severe anal pain is the most frequent presenting complaint. Walking, coughing, or straining can aggravate the pain. A palpable mass is often detected by inspection of the perianal area or by digital examination of the rectum. Occasionally patients present with fever, urinary retention, or life- threatening sepsis.

Infection of an anal gland initially results in the formation of an abscess in the intersphincteric plane (Fig. 26-39). As the abscess enlarges, it spreads in one of several directions. A *perianal abscess* is the most common manifestation. It forms when pus spreads downward between the two sphincters and presents as a tender, erythematous bulge at the anal verge. If the pus penetrates the external sphincter below the level of the puborectalis and expands into the ischiorectal fossa, an *ischiorectal abscess* is formed. A *supralevator abscess* is formed when an intersphincteric or ischiorectal abscess expands upward. Pus is found above the levators, lateral to the rectum, and below the peritoneal reflection.

These abscesses can become quite large, are seldom visible, and are palpated by digital rectal examination as a bulge above the puborectalis. These abscesses are uncommon, accounting for less than 5 percent of patients with anorectal abscesses.

Treatment

Perirectal abscesses should be treated by drainage as soon as a diagnosis is established. It is not necessary to delay operation to allow erythema or purulence to develop. Antibiotics are not indicated unless there is extensive cellulitis or the patient is immunocompromised, has diabetes, or has valvular heart disease. In this group of patients, expeditious treatment is critical, because the infection can spread rapidly and become life-threatening. Usually the abscess can be localized by digital examination. If an indurated area is all that is found, examination under anesthesia and needle localization are indicated. Once adequate anesthesia has been obtained, proctosigmoidoscopy should be performed to rule out other anorectal disease.

An *intersphincteric abscess* is treated by an internal sphincterotomy. The sphincterotomy drains the abscess and destroys the infected crypt. *Perianal* and *ischiorectal abscesses* are treated by drainage through an incision in the perianal skin overlying the abscess. The abscess must be drained completely, either by excising an adequate amount of overlying skin or by inserting a mushroom catheter into the abscess cavity. After the acute phase has resolved, the mushroom catheter may be injected with dilute methylene blue or povidone-iodine. If there is no evidence of a fistula (the presence of an internal opening), the catheter is removed. If a fistula is present, it should be treated as described below. *Supralelevator abscesses* should be drained transanally by incising the rectal wall overlying the abscess. A supralelevator abscess should not be drained externally or through the ischiorectal fossa; this may cause a supralelevator fistula that will seldom heal without a colostomy for diversion of feces (Fig. 26-40).

Drainage alone results in cure for 50 percent of patients. The other 50 percent develop an anal fistula with persistent symptoms of local infection. If only skin pathogens are cultured from an anorectal abscess, there is a decreased incidence of fistula formation. This is probably because such an abscess originates from the skin instead of from an anal crypt. The majority of the recurrences are in patients with ischiorectal abscesses. Although an argument can be made to do a primary fistulotomy at the time of incision and drainage, it is not always possible to find the internal opening in the setting of acute inflammation. Unless the internal opening can be clearly identified, it is probably preferable to treat ischiorectal abscesses by incision and drainage, because a complicated fistulotomy may result in injury to the anal sphincter.

The immunocompromised patient may present with anal pain but no evidence of a fluctuant mass because of the paucity of white blood cells. These patients should be examined under anesthesia. In such circumstances, a painful indurated area should be drained even if no purulence is found. The tissue should be biopsied (to exclude a leukemic infiltrate) and cultured (to aid in selection of antibiotics).

Necrotizing Anorectal Infections

Pathophysiology

Necrotizing anorectal infections (nonclostridial and streptococcal cellulitis, clostridial gangrene, and Fournier's gangrene) are perianal and perineal infections caused by either a monobacterial or mixed synergistic flora. The source of infection may be anorectal or urogenital.

Diagnosis

Examination of the perineum may reveal only limited necrosis of skin overlying crepitant tissue, but extensive tissue necrosis may be rapidly progressing in the deeper tissue. Many patients present with systemic toxicity. Most patients have an underlying chronic systemic disease. Cultures may reveal the causative organism, but surgical therapy should not be delayed while waiting for results.

Treatment

Early recognition and aggressive surgical debridement are important. Excision of all nonviable perineal and perianal tissue is required. Antibiotics are an adjunct to adequate surgical therapy. Orchiectomy is seldom necessary because the blood supply to the testicles is different from that to the scrotum and penile skin. Colostomy may be required to decrease fecal contamination or if the anal sphincters are destroyed by the infective process. Hyperbaric oxygen has been used for clostridial infections but should not interfere with or delay adequate debridement of devitalized tissue. Early diagnosis and treatment are necessary for a successful outcome; the mortality is approximately 50 percent.

Fistula-in-Ano

Pathophysiology

Acute infection of the anal crypt leads to an anorectal abscess; an anal fistula represents the chronic form of this infection (Fig. 26-41). The fistula consists of the infected crypt and a tract extending to the site of drainage. It is therefore important to drain an abscess as close to the anus as possible to avoid the formation of a long fistulous tract. Fistulas also may be secondary to infections due to trauma, fissures, tuberculosis, Crohn's disease, carcinoma, radiation, actinomycosis, and *Chlamydia* infection.

Diagnosis

Patients present with persistent purulent drainage from the external and internal openings of the fistula. An indurated tract is often palpable. The internal opening is usually detectable by anoscope examination. Goodsall's rule can be used as a guide in determining the location of the internal opening (Fig. 26-42). It states that if the anus is bisected by a transverse line, external openings anterior to the line will connect to an internal opening by a short, direct fistulous tract. External openings posterior to this line join tracts that curve toward an internal opening in the posterior midline. An exception to this rule occurs if an anterior external opening is greater than 3 cm from the anal margin. These fistulas are more likely to have an internal opening in the posterior midline.

Treatment

The mainstay of treatment for anal fistula is eradication of sepsis with preservation of anorectal function. A simple fistula is treated by *fistulotomy* (opening the fistulous tract), curettage or cautery of the tract, and healing by secondary intention. *Fistulectomy* (complete excision of the fistulous tract) is not indicated because the magnitude of tissue loss associated with the procedure increases the risk of compromise to sphincter function.

An anal fistula that results from a drained ischiorectal abscess is usually a *transsphincteric fistula*, crossing both the internal and external sphincters. Incising the tract results in an internal sphincterotomy as well as division of a portion of the external sphincter. Continence usually will be maintained if the puborectalis muscle is not divided.

Horseshoe fistulas usually have an internal opening in the posterior midline of the anus and may extend anteriorly and laterally to one or both ischiorectal spaces by way of the deep postanal space (see Fig. 26-37). Incision and drainage of horseshoe abscesses are associated with a high recurrence rate. Adequate treatment of a horseshoe abscess requires incision and drainage of the postanal space and counterdrainage of the lateral ischiorectal spaces through separate incisions (Fig. 26-43). Counterdrainage is maintained until the incision over the deep postanal space is healed. This method is preferable to a fisulotomy, which would require a long skin incision to unroof the entire tract. High, complicated fistulas should not be treated by fistulotomy because of the risk of significant sphincter damage. A *seton* (see Fig. 26-57) used in this situation acts as a drain for the primary tract, but use of the seton to transect the muscle carries a significant risk of incontinence. Primary drainage followed by an endorectal sliding flap has been used to treat complicated anterior fistulas without impairment of the sphincter. This method, a modification of the technique used to treat rectovaginal fistulas (Fig. 26-44), removes the involved crypt and closes the internal opening with a sliding endorectal flap. The fistulous tract is counterdrained, and the drain is removed after the endorectal flap has healed.

Untreated fistulas may cause chronic intermittent infections, episodes of sepsis, rare cases of carcinoma, and, occasionally, death. The use of a seton is associated with an incontinence rate of 17 percent, which is increased to 39 to 63 percent after the tract is laid open at a second stage. Therefore, our technique has been to establish drainage of the primary abscess to control the sepsis. Anorectal function is preserved, and an endorectal sliding flap is used to close the internal opening. The technique is the same as will be described for rectovaginal fistula, except for the perineal counterdrain.

Rectovaginal Fistula Pathophysiology

A *rectovaginal fistula* is a communication between the rectum, proximal to the dentate line, and the vagina. These fistulas are classified by their location. The rectal opening in a *low rectovaginal fistula* is close to the dentate line with the vaginal opening just inside the fourchette. The vaginal opening in a *high rectovaginal fistula* is near the cervix, and the opening of a *midrectovaginal fistula* is between the high and low locations.

The cause varies with the location of the fistula. Low rectovaginal fistulas are commonly caused by obstetric injuries (especially midline episiotomies that become infected), foreign body penetration of the rectum, or Crohn's disease. Midrectovaginal fistulas may result from extension of an undrained ischiorectal abscess. Crohn's disease, surgical excision or fulguration of an anterior rectal tumor, radiation injury, or extensive childbirth trauma. High rectovaginal fistulas are caused by Crohn's disease, radiation injury, operative injury, and diverticulitis. These septic processes are more prone to occur through the vaginal cuff after hysterectomy. Diverticulitis may cause a colovaginal fistula. Carcinoma of the rectum, cervix, or vagina also may result in a rectovaginal fistula at any level.

Diagnosis

Patients describe the very characteristic symptoms of passing gas and stool through the vagina and report varying degrees of continence. Diagnosis is usually evident on anoscopic or vaginal examination. A barium enema or vaginogram may reveal the fistula. Sometimes the history is characteristic, but the site cannot be identified. In such circumstances, administration of a dilute methylene blue enema may stain a tampon placed in the vagina, confirming the presence of a fistula.

Treatment

The treatment of a rectovaginal fistula depends on its cause, location, and the condition of the adjacent tissue. If the fistula is caused by a cryptoglandular abscess, appropriate drainage of the infection may result in spontaneous closure of the fistula. Fistulas resulting from obstetric injury may heal spontaneously, and it is wise to wait at least 3 months before attempting surgical repair. This also allows the acute inflammatory reaction to resolve.

Low and midrectovaginal fistulas are best treated by an endorectal advancement flap (see Fig. 26-44). If a sphincter injury is also present, it may be repaired simultaneously. A protecting colostomy is not necessary, but full bowel preparation and systemic antibiotics are important, because infection is the major source of failure of the repair. Treatment of a high rectovaginal fistula requires a transabdominal approach, allowing resection of the diseased tissue that caused the fistula.

Fistulas caused by Crohn's disease, radiation injury, or cancer almost never heal spontaneously. Intensive medical treatment and conservative local drainage procedures establish adequate drainage of abscesses and preserve the anal sphincter in patients with perianal Crohn's disease. Local sliding endorectal flaps for Crohn's fistulas in which the sepsis has been controlled and the disease is in remission have been used with good results, as will be described in the section on Crohn's disease. Proctectomy may be required for patients

with severe perineal Crohn's disease unresponsive to local anorectal surgical procedures or for patients with extensive destruction of the rectum.

Rectovaginal fistulas due to pelvic radiation are seldom amenable to transanal repair because the tissue is permanently damaged. Tissue repairs constructed with irradiated bowel are doomed to fail. Biopsy of the fistulous tract is mandatory in patients with a history of cancer or radiation therapy. It is sometimes very difficult to clinically differentiate radiation injury from recurrent cancer.

Pilonidal Disease Pathophysiology

Pilonidal disease consists of a hair-containing sinus or abscess that involves the skin and subcutaneous tissues in the postsacral intergluteal region. The cause of the disease is not clear; it may be a congenital or an acquired condition. Most investigators believe that the condition is due to ingrown hair. Pilonidal disease can occur in any age group but is most prevalent from adolescence to the third decade, with a male predominance. The sinus is superficial to the periosteum of the sacrum and may be single or have multiple extensions. An external orifice is not always visible but is usually in the midline approximately 5 cm from the anus. The soft tissues surrounding the sinus exhibit acute and chronic inflammation. Patients present with complaints of pain, swelling, and purulent drainage when these sinuses become acutely infected. Once an acute episode has resolved, the patient rarely remains asymptomatic; recurrent infections are common.

Diagnosis

Pilonidal disease is confirmed as the cause of an abscess when the typical midline pits are identified in association with the inflammatory process. Adequate anal examination should rule out an anal fistula as the source of the abscess.

Treatment

There are numerous treatments reported in the literature, all with imperfect results. Incision, drainage, and curettage with secondary healing constitute the simplest method of treatment and are used for acute abscesses and chronic sinus tracts. This method often can be performed with local anesthesia on an outpatient basis. All hair must be removed, and the wound must be kept clean and shaved until complete healing occurs. Complete excision and secondary healing leave a large open wound and are associated with a prolonged healing time. Excision and primary closure are often successful for small sinuses but are complicated in extensive disease. Excision of the sinus followed by a Z-plasty to obliterate the intergluteal cleft has been used in some centers with low recurrence rates. The Z-plasty also serves to eliminate complicated recurrent pilonidal disease.

Hidradenitis Suppurativa

Hidradenitis suppurativa is an infection of the cutaneous apocrine sweat glands. Infected glands rupture and form subcutaneous sinus tracts. The infection spreads by direct extension and can spread to the perineum, labia, and scrotum. The perianal skin can become a network of superficial abscesses and sinuses. This infection may mimic complicated anal fistula disease but stops at the anal verge because there are no apocrine glands in the anal canal.

The diagnosis is made by clinical appearance. The glands are destroyed by the inflammation resulting from their rupture; thus there are no specific histologic identifying features. Abscesses are initially treated by wide incision, including resection of the severely indurated, infected skin that overlies the infected tracts. A colostomy is almost never indicated. Recurrence is frequent, and any recurrent infections are best incised early in the process.

Pruritus Ani Diagnosis and Pathophysiology

Pruritus ani (severe perianal itching) is a symptom complex that may be caused by a number of factors but often must be classified as idiopathic because a specific etiologic agent cannot be discovered.

Patients complain of perianal itching that is often worse at night. Many have tried numerous over-the-counter medications to relieve their discomfort. A special problem occurs when products containing local anesthetic agents cause contact dermatitis and magnification of the original symptoms. A careful history and physical examination should identify any obvious causes.

The appearance of the perianal skin varies. The skin may appear normal, or it may be erythematous and weeping serum from numerous excoriations. Chronic pruritus ani is characterized by thickened, leathery, white skin.

Pinworms (*Enterobius vermicularis*) are the most common cause of perianal itching in children and may be transmitted to other family members. The worms come out of the anus at night and deposit eggs on the perianal skin, causing intense nocturnal pruritus. The diagnosis is confirmed by swabbing the perianal skin with cellophane tape and examining it under the microscope to identify the *Enterobius* eggs.

Common anal lesions (prolapsing hemorrhoids, villous tumors of the rectum, and rectal prolapse) often cause excessive moisture in the perianal region. This moisture causes irritation and itching of the perianal skin.

Dietary habits, cleansing habits, or a combination of the two are common causes of pruritus. Overzealous, as well as careless, cleaning of the perianal skin can lead to itching. Frequent application of topical ointments keeps the area moist, causing further irritation.

Treatment

The treatment of pruritus ani is directed at the cause. Hemorrhoids, villous adenomas, and rectal prolapse should be specifically treated as discussed in this chapter. Piperazine citrate is the curative treatment for pinworms. Patients must be instructed that frequent washing and topical ointments should be avoided. The perianal area should be kept as dry as possible, and scratching should be avoided. Short term course of topical steroids is likely to provide symptomatic relief. Coffee, tea, cola, beer, chocolate, and tomatoes all can induce perianal itching, and abstaining from these foods, as well as use of proper anal hygiene, for about 2 weeks should alleviate most of the symptoms. It is, however, very common for the symptoms to recur and require reinstitution of the treatment regimen.

Proctitis

Proctitis and *anusitis* are nonspecific entities characterized by inflammation of various degrees within the anus or rectum. The differential diagnosis can be complex and includes infection, inflammatory bowel disease, and various forms of trauma.

Inflammatory Proctitis

Ulcerative colitis always involves the rectum as well as variable amounts of colon. There is a specific, mild form that involves only the rectum and is referred to as *ulcerative proctitis*. Ninety percent of these patients respond to medical management and never go on to have involvement of the colon. Patients with Crohn's disease also may have isolated rectal involvement, making the differentiation between the two difficult at times.

Diagnosis

The diagnosis may be suggested by a good history. Rectal bleeding or discharge, diarrhea, and tenesmus are common presenting symptoms. Endoscopy reveals an inflamed and friable rectal mucosa and biopsy will verify the diagnosis. The remainder of the colonic mucosa may have a normal appearance.

Treatment

The initial treatment consists of steroid retention enemas given over a course of 2 weeks. A short course of oral steroids may be considered in patients who do not respond to the enemas, with the dose being tapered over 4 to 6 weeks. Sulfasalazine may be given orally or its active ingredient, 5-aminosalicylic acid (5-ASA), may be administered as retention enemas or suppositories. Dietary measures to decrease the frequency of bowel movements, such as avoidance of milk, fruit, and fiber, and the addition of bulk-forming agents such as psyllium products may be beneficial, as well as antimotility agents such as loperamide.

Radiation Proctitis

Another cause of proctitis is radiation injury. An accurate history usually reveals the diagnosis. Early symptoms are diarrhea, rectal bleeding or discharge, tenesmus, rectal pain, and incontinence. Late symptoms appear several months to years after irradiation. Bleeding is the most common late symptom, but rectal strictures and fistulas to the bladder or vagina can develop. Examination reveals telangiectasia and friable mucosa.

Treatment

Bulk-forming agents, antispasmodics, and antidiarrheal medications are used initially. Steroid or 5-ASA retention enemas or suppositories may be helpful. Laser coagulation of bleeding telangiectasias may be required to control bleeding. Topical application of 10% formalin may be helpful in patients with persistent bleeding. Rarely, the rectum will be so badly injured that intestinal diversion is necessary.

Sexually Transmitted Disease

The differential diagnosis of proctitis and especially anusitis must include the spectrum of sexually transmitted diseases are common in individuals who practice anal intercourse.

Gonococcal Proctitis

Anorectal gonorrhea is caused by *Neisseria gonorrhoeae*, an intracellular gram-negative diplococcus. It is associated with anal intercourse, and vaginal discharge can transfer the disease to the rectum in women. Initially, patients are asymptomatic or present with rectal bleeding or discharge. Perianal excoriation, painful defecation, and fistulas also may occur. Proctoscopy reveals edematous and friable mucosa and a purulent exudate. The diagnosis should be established by cultures of anus, vagina, urethra, and pharynx, since these areas are also frequently infected.

Intramuscular procaine penicillin G with oral probenecid is the treatment of choice. Penicillinase-producing *N. gonorrhoeae* requires treatment with spectinomycin or ceftriaxone and tetracycline. Follow-up examination and cultures are necessary to avoid inadequate treatment. Sexual partners also should be evaluated.

Anorectal Syphilis

There is a rising incidence of syphilis in the Western Hemisphere. The causative organism is the spirochete *Treponema pallidum*. After an incubation period of up to 8 weeks, the primary lesion (chancre) is found at the site of inoculation. Syphilitic chancres are usually asymptomatic and can easily go unrecognized. Ulcers, proctitis, pseudotumors, and

condylomata lata also may be found. Condylomata lata are the lesions of secondary syphilis and are highly contagious. They are hypertrophic papules found in areas of warmth, moisture, and friction.

Dark-field examination of exudate may reveal the spirochetes. The rapid plasma reagin (RPR) test and Venereal Disease Research Laboratory (VDRL) slide test are nonspecific screening tests that become positive 1 to 3 weeks after the appearance of the primary chancre. These tests are positive in 75 percent of patients with primary syphilis. Both the RPR and VDRL tests remain positive for long periods even after treatment. The fluorescent treponemal antibody-absorption test (FTA-ABS) is more specific and sensitive but is also more expensive. Syphilis is treated with benzathine penicillin G or erythromycin.

Chlamydia trachomatis

Chlamydia trachomatis is an obligate intracellular parasite that causes chlamydial proctitis and lymphogranuloma venereum (LGV). Chlamydial proctitis is associated with anal intercourse or may spread via the lymphatics in the rectovaginal septum in women. The infection may be asymptomatic, or the patient may complain of anal pain, pruritus, rectal bleeding, or rectal discharge.

The primary lesion of LGV is a small shallow ulcer that often is not noticeable. Inguinal adenopathy develops and can form large matted nodes. If left untreated, the patient could develop hemorrhagic proctitis and late rectal strictures. The LGV complement fixation test or the microimmunofluorescent antibody titer confirm the diagnosis. Tissue cultures can be used to isolate the organism.

Tetracycline (or doxycycline) is the treatment of choice, but erythromycin may be used as an alternative. Antibiotics should be continued for 14 to 21 days. Rectal strictures may be dilated early in the disease. Complete obstruction is rare and requires colostomy.

Chancroid

Chancroid, caused by *Haemophilus ducreyi*, is a disease manifested by soft, multiple lesions that are very painful and bleed easily. Multiple lesions may develop as a result of autoinoculation and are often seen in the perineum and around the anus. Inguinal adenopathy is a common finding. Lymph nodes become fluctuant and rupture through the skin, causing draining sinuses. Treatment is with erythromycin or trimethoprim- sulfamethoxazole.

Herpes Proctitis

Herpes proctitis is caused primarily by type II herpes simplex virus, although the type I virus can cause the same symptoms. The virus is transmitted by direct mucosal contact. Patients present with tenesmus, anal pain, rectal bleeding, discharge, and perianal ulcerations. The pain may be so intense that the patient is reluctant to have a bowel movement. Fever and malaise are frequently present.

The anorectal lesions appear 3 to 7 days after sexual contact. The primary lesions are clusters of vesicles that rupture, coalesce, and form painful ulcers. The ulcers become infected secondarily. These lesions tend to recur, and the recurrent form is usually less painful than the original. The disease is contagious while the lesions are present. Diagnosis is made by viral cultures of vesicular fluid or biopsies.

There is no cure; treatment is symptomatic. Oral acyclovir reduces the frequency and duration of recurrent episodes and reduces virus shedding, but acyclovir does not prevent recurrences and does not alter the long-term natural history of the disease.

Condylomata Acuminata

Condylomata acuminata are warts that occur in the anorectal and urogenital regions, caused by infection with the human papillomavirus. In developed countries, genital warts are now the most common viral sexually transmitted disease, estimated to be three times more common than genital herpes. Anal intercourse is the most common means of transmission of anorectal warts, and there is a high association with other sexually transmitted diseases. Although condylomata are found more commonly in homosexual men, heterosexual men and women can be infected. This virus is autoinoculable and has an incubation period that can be as long as 1 year; both factors account for frequent treatment failures.

Diagnosis

Most patients present after noticing the visible perianal growths. Pruritus, anal discharge, bleeding, and pain are occasionally present. The diagnosis is usually obvious because of the characteristic appearance of the warts. Anoscopy and proctosigmoidoscopy should be performed on all patients because condylomata may be found within the anal canal. Tests for other venereal diseases, e.g., HIV and hepatitis B are indicated. Condylomata lata associated with secondary syphilis are usually smoother, flatter, and lighter in color and can occur simultaneously with condylomata acuminata.

Treatment

There are numerous treatments for condylomata acuminata. Evaluation of treatment efficacy is complicated by occasional spontaneous regression of lesions, reinfection, and lack of prospective, randomized, controlled trials. Bichloroacetic acid and 25% podophyllin application are the two most common treatments performed in the office setting. These treatments are satisfactory only if the warts are small and few in number. Weekly evaluation and treatment are necessary until all the warts are gone.

Excision and electrocoagulation under local anesthesia are effective treatment for the patient with a large number of warts. The warts are destroyed using the cautery; care is taken to preserve the adjacent skin and anoderm. The smoke generated from the procedure contains viable organisms and should be thoroughly evacuated. Carbon dioxide lasers have been used to eradicate condylomata but have been shown to be associated with a slightly higher recurrence rate. Small lesions can be treated using local anesthesia; larger lesions require regional or general anesthesia. Immunotherapy with an autogenous vaccine and intralesional injection of interferon have had variable results. All treatments for condylomata have been associated with recurrence rates up to 70 percent.

Malignancy

There appears to be an association between the human papillomaviruses 16, 18, and 31 and carcinomas of the anal and genital tracts. Malignant degeneration to squamous carcinoma has been reported with increasing frequency in anal condylomata. Immunosuppression, most commonly encountered today with HIV disease, appears to confer additional risk. Resected condylomata specimens should be examined microscopically, and recurrent or persistent condylomata should be submitted for histologic examination. The incidence and rate of malignant transformation are unknown. Radical surgical removal of the rectum has been the usual treatment for these cancers but is associated with a high recurrence rate. Combined chemoradiation has been reported to shrink large lesions, making them surgically curable. The choices of treatment for anal cancer will be discussed later.

Giant condylomata acuminata (Buschke-Lowenstein tumors) involving the perianal region may appear to be histologically benign but exhibit malignant behavior. They are thought to represent a low-grade, well-differentiated variant of conventional squamous cell carcinoma. These tumors do not respond to conservative therapy, and radical surgical excision offers the only hope for cure or adequate palliation.

Acquired Immune Deficiency Syndrome (AIDS)

Acquired immune deficiency syndrome (AIDS) has been associated with numerous gastrointestinal complications. Tumors such as Kaposi's sarcoma and non-Hodgkin's lymphoma, as well as infections with fungi, viruses, atypical bacteria, and protozoa, can involve the entire gastrointestinal tract in immunosuppressed patients. Heterosexuals with AIDS get fewer anorectal infections and malignancies than homosexual men with AIDS.

Kaposi's sarcoma is the most common malignant tumor in AIDS patients. The lesions may appear as small telangiectasias or larger purple nodules; their color is due to extravasation of blood. The skin is the most frequently affected site, but the gastrointestinal tract may be involved as well. These lesions are often multiple and may occur anywhere along the gastrointestinal tract. Usually patients are asymptomatic, but the lesions can cause hemorrhage or obstruction. Diagnosis is made by the endoscopic appearance of the lesions, and biopsies for histologic confirmation should be taken. These lesions are submucosal, and superficial biopsies are often nondiagnostic; deeper biopsies are necessary, and although the lesions have a vascular appearance, they rarely bleed after biopsy. Therapy is palliative and may require chemotherapy with an agent such as vincristine or vinblastine. Surgery is seldom indicated. If surgery is required for complications such as persistent hemorrhage, obstruction, or intussusception, only the involved section of bowel should be resected.

Lymphoma is found with increased frequency in patients with immune deficiencies, particularly in patients with AIDS. Most are non-Hodgkin's B- cell lymphomas, which are highly aggressive, and multiple organ involvement is common. Rectal involvement is rare but has been reported in homosexual men and should be considered in the differential diagnosis of anorectal masses in this population. Patients present with fever and perirectal masses. The lesions should be biopsied for diagnosis. Chemoradiation is the treatment of choice, but the response rate in patients with AIDS is poor. Surgical resection or bypass may be necessary for obstructing or perforating gastrointestinal lymphomas.

CMV is ubiquitous in the homosexual AIDS population. CMV ileocolitis is the most common intestinal infection in patients with AIDS. Patients frequently present with diarrhea, melena or hematochezia, fever, and weight loss. Examination reveals diffuse ulceration that can occur anywhere along the gastrointestinal tract. Biopsies of the ulcers show CMV inclusion bodies. The diagnosis is confirmed by viral culture of biopsy specimens or antigen assay of washings taken from ulcers. Resection may be required for the complications of bleeding or perforation. The mortality is high.

Infections with *Campylobacter*, *Shigella*, *Mycobacterium avium- intracellulare*, *Cryptosporidium*, *Isospora belli*, *Entamoeba histolytica*, and *Giardia lamblia* may cause enterocolitis or intractable diarrhea in patients with AIDS. Many patients present with persistent diarrhea, lower abdominal cramping, and, occasionally, bloody stools. Anoscopic and sigmoidoscopic findings may range from normal-appearing mucosa to friable ulcerations. Diagnosis is based on special stool cultures, examination of fresh stool specimen for ova and parasites, and biopsies of ulcers sent for histologic examination. Treatment is directed at a causative agent, and surgery is rarely necessary.

Sexually transmitted anorectal diseases are common in AIDS patients, including gonorrhea, syphilis, chlamydia, herpes simplex, and papillomavirus infection. Anorectal disease in AIDS patients has been approached with nihilism in the past because of reports of high morbidity and mortality postoperatively and because of short overall survival from AIDS. However, now that new drug treatments are increasing the life expectancy in AIDS patients, it becomes more important to diagnose and aggressively treat anorectal disease to avoid disabling complications.

INFLAMMATORY BOWEL DISEASE

General Considerations

The term *inflammatory bowel disease* encompasses two major entities: *ulcerative colitis* and *Crohn's disease*. There are several synonyms for each of these diseases. Ulcerative colitis is also referred to as *mucosal ulcerative colitis* and *idiopathic ulcerative colitis*. Crohn's disease is also called *segmental colitis*, *regional enteritis*, *regional ileitis*, *terminal ileitis*, *granulomatous colitis*, or *transmural colitis*.

Ulcerative colitis is an inflammatory process involving the colonic mucosa, characterized by alterations in bowel function and symptoms of intestinal inflammation. The most frequent sign of ulcerative colitis is hematochezia, the passage of red blood from the rectum. The presence of abdominal pain, fever, and weight loss depends on the severity of the inflammation (Table [26-2](#)). Ulcerative colitis has been recognized since the nineteenth century, when it was reported in several London hospitals.

Crohn's disease was first described as "chronic interstitial enteritis" by the Scottish surgeon Dalziel in 1913, but the description of the clinical entity "regional ileitis" in 1932 by Crohn, Ginsberg, and Oppenheimer from Mt. Sinai Hospital in New York led to widespread recognition of the disease involving the ileum. Subsequently, Lockhart-Mummery and Morson reported the colonic involvement by transmural inflammation, distinguishing the entity from ulcerative colitis. It is now recognized that Crohn's disease can occur anywhere in the gastrointestinal tract, from mouth to anus, and that the extraintestinal manifestations of the disease may precede those of the intestine.

The annual incidence of both diseases in western Europe and North America increased up to 1970 and has since stabilized or decreased. While men more frequently have ulcerative colitis and women more frequently have Crohn's disease, genetic and environmental factors seem to be important etiologic considerations. Other factors under investigation include smoking, oral contraceptives, alcohol, refined sugar, infectious diseases, and Jewish heritage. A defect in immune regulation in the gastrointestinal tract, in either an initiating or a perpetuating role, is also being investigated. Some observations implicate gut-associated lymphoid tissue in the pathobiology of both ulcerative colitis and Crohn's disease, for example, the granuloma in Crohn's disease (indicative of T-cell-mediated immunity), the lymphoid infiltrate resembling an Arthus reaction in ulcerative colitis, the presence of extraintestinal manifestations of *inflammatory bowel disease (IBD)* in other immunologically mediated diseases, and IBD patients displaying hypergammaglobulinemia and autoantibody production as seen in an immunologically activated state.

Recent studies focus on a fundamental defect of mucosal immune regulation leading to immunologic hyperactivation rather than on a direct autoimmune assault on a specific target cell, the focus of earlier studies. This fundamental defect, leading to uncontrolled immune reaction to environmental agents and antigens, can cause an unregulated immune response, including lymphocyte proliferation, cytokine release, secondary recruitment of auxiliary effector cells, excessive neutrophil products (especially leukotriene B₄ and reactive oxygen metabolites), and ultimately, tissue injury (Fig. [26-45](#)). The actual tissue damage probably reflects a nonspecific "innocent bystander" injury.

Crohn's disease and ulcerative colitis appear closely related; when the disease exists in the colon, 15 percent of cases cannot be clearly differentiated (Table [26-3](#)). Distinguishing Crohn's colitis from ulcerative colitis carries therapeutic significance: There is a significant recurrence of disease involving the small intestine in patients with Crohn's disease treated by colectomy, whereas such recurrence is rare in patients with ulcerative colitis. The two entities are similar because they are both characterized by exacerbations and remissions of intestinal inflammation. Each also has a chronic phase. Ulcerative colitis is a disease of the mucosa that is limited to the colon and rectum. Crohn's disease, on the other hand, can involve any part of the gastrointestinal tract; this chapter will deal mainly with its involvement of the large intestine.

The symptoms also overlap and generally consist of those which would be caused by inflammation of the intestine, the specifics varying with the depth of the inflammation and the location along the intestinal tract (see Table [26-2](#)). Many diagnostic modalities may be used to differentiate and define the extent of the disease as well as the degree of inflammation. These include contrast studies of the intestine, endoscopic evaluation, CT, magnetic resonance imaging (MRI), ultrasonography, and special nuclear scans (Table [26-4](#)).

The tissue changes of ulcerative colitis are depicted in Fig. [26-46](#), which shows the progression from superficial, homogeneous ulceration and purulent discharge, to the intense inflammatory reaction resulting in edema and pseudopolyp formation, to the chronic changes of a flattened, potentially dysplastic lining of the large intestine. The disease generally involves only the mucosal layer of the large intestine. Crohn's disease, as depicted in Fig. [26-47](#), shows the early phase of the disease to involve only isolated areas of the mucosa in the form of aphthoid ulcers. As the activity of the disease progresses, deep ulceration and inflammation extend through the full thickness of the intestine, with thickening of the intestinal wall. It is this full-thickness destruction of tissue that results in the eventual perforation of the intestine, leading to many of the complications of Crohn's disease. In the chronic phase of Crohn's disease, the intestinal wall is thickened, fibrotic, and nondistensible, causing symptoms of intestinal obstruction. In all phases of the disease there may be areas of normal mucosa that are spared the inflammatory process; in contrast, ulcerative colitis is a more homogeneous inflammatory process.

Both ulcerative colitis and Crohn's disease have systemic manifestations contributing to the hypothesis that there is some type of autoimmune phenomenon involved in the causation of IBD (Table [26-5](#)).

The gross as well as the radiologic appearance of the intestine in the two diseases is depicted in Fig. [26-48](#). Ulcerative colitis is characterized by an intestinal wall of normal caliber with severe inflammatory changes of the mucosa and a normal-appearing mesentery. In Crohn's disease, the intestine is markedly thickened, as is the adjacent mesentery, with enlargement of the mesenteric lymph nodes. The serosal surface of the intestine is inflamed, and the fat takes on a strange configuration of enveloping the intestine ("fat wrapping"). Ulcerative colitis appears in contrast radiography as homogeneous ulceration with mucosal edema, on the other hand, chronic Crohn's disease is characterized by segmental narrowing with thickening of the loops of intestine involved.

A better understanding of the differentiation of the two diseases can be accomplished by looking at the effect of the two diseases as they involve the colon (Table [26-6](#)). Ulcerative colitis always involves the rectum and may extend, in continuity, to the more proximal colon; Crohn's disease has a segmental distribution with areas of normal bowel located between diseased segments. Rectal bleeding occurs in both diseases but is usually more of a problem in ulcerative colitis. The distinction between rectal and anal involvement is an important differentiating feature. In patients with ulcerative colitis, the rectum is always involved; only 50 percent of patients with Crohn's colitis will have rectal involvement. Anal disease, on the other hand, is highly suggestive of Crohn's disease. Anal fistulas are rare in patients with ulcerative colitis but are found frequently in patients with Crohn's disease.

Mucosal ulceration exists in both diseases, but the ulcers are more irregular and in a continuous distribution with ulcerative colitis, as opposed to being linear with transverse fissures (cobblestone appearance) in Crohn's disease. Strictures occur rarely in ulcerative colitis; when they do, they are often indicative of cancer. On the other hand, benign stricture formation is a characteristic of Crohn's disease. Ulcerative colitis is considered a premalignant condition. While there is an increased risk of large bowel cancer in patients with Crohn's disease, the risk is less than that of ulcerative colitis. Toxic dilatation, or more appropriately, fulminant colitis, occurs in both diseases. In patients with fulminant ulcerative colitis, the inflamed colon can dilate, presenting the clinical situation termed *toxic megacolon*. Severe inflammation can cause colonic perforation in patients with Crohn's disease, but because of fibrosis and thickening, dilatation is less frequently a component of the severe colonic involvement.

Each of the diseases can present with variable intensity, and the clinical management depends on the activity of the disease. In some cases, there can be rapid progression to the fulminant phase. Management of the patient with IBD requires knowledge of the *acuity* of the disease as well as the geographic *distribution* within the intestinal tract. *Mildly active* Crohn's disease consists of mucosal aphthoid ulcers; mildly active ulcerative colitis consists of mucosal edema and friability. These subtle changes are sometimes difficult to recognize by endoscopy. As the activity progresses to the *moderately severe* form, Crohn's disease is characterized by thickening of the intestinal wall, deep linear ulceration of the mucosa, edema of the bowel wall, wrapping of fat about the serosa, mesenteric thickening, and enlarged mesenteric lymph nodes. In moderately severe ulcerative colitis, there is progression of the mucosal disease with more purulent discharge, diffuse ulceration, and bleeding. As the diseases enter their *severe acute* inflammatory phase, Crohn's disease is characterized by deep ulceration of the bowel wall, increased serosal fat wrapping, and extension of the inflammatory process beyond the wall of the intestine, resulting in a phlegmon or abscess. Ulcerative colitis, on the other hand, is associated with the formation of pseudopolyps with severe fluid, electrolyte, and sometimes blood loss from the intense inflammatory process involving the mucosal surface of the colon and rectum.

The *chronic phase* of both diseases is depicted in Fig. [26-49](#). In ulcerative colitis, the mucosa takes on a dry, granular appearance, and the colon is markedly contracted, as seen in the radiograph. The colon loses its distensibility, and in this phase, where most of the lining of the intestine looks abnormal by endoscopy, the identification of malignant change becomes important. Crohn's disease, in its chronic phase, is characterized by intense fibrosis of the intestinal wall without acute mucosal inflammatory changes. If the rectum is involved, the loss of the reservoir function results in intolerably frequent, and often difficult to control, bowel movements, to the point where patients can be incapacitated with the chronic form of the disease and yet not have any acute inflammatory changes. Steroids and immunosuppressive medications will have little effect on this chronic, fibrotic state.

The two diseases are also similar in the use of antibiotics, anti-inflammatory agents, and immunosuppressive drugs in their management. Medical therapy is summarized in Table [26-7](#).

Ulcerative Colitis

Indications for Surgery

The indications for surgery in the treatment of ulcerative colitis include *active disease unresponsive to medical therapy*, *risk of cancer*, and *severe bleeding*. Because only the large intestine is involved, a proctocolectomy should cure the patient of intestinal disease. Patients requiring operation because of active disease usually have extensive edema and ulceration of the intestine; fluid, electrolyte, and blood loss; and sometimes dilatation of the colon with possible perforation (Table [26-8](#)). These patients with *toxic colitis* or *toxic megacolon* must be treated aggressively with bowel rest, antibiotics, and corticosteroids. Should their clinical situation deteriorate, they should have emergency abdominal colectomy or, if walled-off perforation is encountered, a diverting loop ileostomy combined with a decompressing colostomy, as described for fulminant Crohn's colitis. Barium enema, antidiarrheal agents, and morphine should be avoided because they might intensify the colonic dilatation. Careful observation of the patient is more important than serial radiographs of the abdomen looking for an arbitrary limit to cecal dilatation as an indication for surgery.

The patient at risk for cancer usually has had total colonic involvement for a period of at least 10 years. Studies have shown a 10 percent incidence of cancer in patients with such chronic disease. The risk of cancer in ulcerative colitis is related to the extent of colonic mucosal involvement and to the duration of the disease but apparently not to the intensity of the inflammation. Unfortunately, some patients who had childhood ulcerative colitis that became quiescent develop colon cancer in early adult life. The cancer risk was not recognized because the disease was in long-term remission. Such a colon at risk for developing malignant changes is illustrated in Fig. [26-49](#). Before the advent of colonoscopy, it was observed that almost all patients who developed cancer of the colon manifested changes of mucosal dysplasia that could be detected by sigmoidoscopy and biopsy of the rectum. It was this finding that led to a cancer surveillance plan for patients with chronic ulcerative colitis. Now colonoscopic evaluation of the entire large intestine is possible, and a plan for organized surveillance of patients with chronic ulcerative colitis has been developed, as illustrated in Fig. [26-50](#).

Colonoscopic surveillance has been recommended by the American Society of Gastrointestinal Endoscopy after 7 years of disease in patients with pancolitis and after 10 years of disease in patients with left-sided colitis. Colonoscopy and biopsy for dysplasia should be performed every 1 or 2 years in these patients. If severe dysplasia is identified, surgical

removal of the colon and rectum is indicated. The surveillance regimen includes random segmental biopsies and biopsies of any suspicious lesions. Random biopsies are necessary because malignant growths that occur in ulcerative colitis are frequently of the endophytic, rather than exophytic, type of cancer and are difficult to detect with the colonoscope (Fig. 26-51). Colon cancer in patients with ulcerative colitis is a major exception to the concept of polyp–cancer sequence, i.e., the cancer may arise in a flat mucosal surface. The pathologic determination of *dysplasia* is often difficult because the early changes of dysplasia are subtle, and dysplasia cannot be diagnosed in the presence of active inflammation.

Surgical Management

The characteristic inflammation of ulcerative colitis is confined to the mucosa of the large bowel. Complete excision of the large intestine is curative in this disease (unlike in Crohn's colitis, which carries a significant risk of recurrent disease following excision of involved intestine). These characteristics provide the rationale for sphincter-saving reconstructive procedures as treatment for ulcerative colitis. Since the disease is confined to the mucosa, the rectal sphincters can be preserved; since the disease does not involve the small intestine, a reservoir can be fashioned from the ileum that can serve as a substitute for the excised rectum. If the anal sphincter cannot be preserved, a “continent ileal reservoir” can be constructed (Table 26-9). The ileorectal anastomosis or any other procedure that leaves the rectum in situ carries the risk of recurrence of inflammation as well as the risk of subsequent cancer. The surgical options are illustrated in Fig. 26-52.

The current preference is to give a patient the choice for a sphincter- preserving operation as long as the individual can tolerate the increased magnitude of the surgery and has a demonstrated adequate anal sphincter function. It is most important that the patient not have Crohn's disease. In a few patients, this distinction is difficult to make, and a subset of patients has been recognized as having “indeterminate colitis.” The patients treated by a sphincter-preserving operation have an increased risk of complications at the ileoanal anastomosis and have an increased risk of requiring resection of the pouch because of subsequent complications. Total colectomy with ileal pouch–anal anastomosis also requires, in most cases, a temporary ileostomy, making this a two-stage procedure. Patients who have an impaired anal sphincter or those who do not wish to accept the increased risk of the reconstructive procedure should be treated by total proctocolectomy and ileostomy. If the surgeon treating a patient with fulminant colitis is unfamiliar with the sphincter-saving procedures, an abdominal colectomy with closure of the rectum allows the patient to recover from the life-threatening colitis. Subsequently, this patient can be referred to an institution where the more complex reconstructive procedure can be accomplished.

The use of the continent ileostomy or Kock pouch (see Table 26-9) has decreased since the advent of the new ileal pouch–anal anastomotic procedures and probably should be offered only to patients with ulcerative colitis who have permanent ileostomies that cannot be maintained properly because of severe skin allergies or to patients who have been treated by total proctocolectomy but desire a form of continence. The only advantage of the continent ileostomy is avoidance of the need to wear a permanent appliance. It requires intubation six to eight times a day to empty the pouch. There is also the risk of delayed complications related to the loss of the nipple valve created by intussusception of the ileum.

The preferred sphincter-saving operation for a patient with ulcerative colitis is total proctocolectomy with preservation of the anal sphincters, construction of an ileal reservoir, and anastomosis of the reservoir to the anus (Fig. 26-53 A,B). This removes the distal disease (some current forms of the operation leave a small amount of distal rectum at the anastomosis), maintains transanal defecation with reasonable continence, and provides a satisfactory quality of life without a permanent ileostomy. The main disadvantages of the procedure are frequent bowel movements (approximately five to seven per day), nocturnal fecal soilage (occasional in 55 percent of patients), and “pouchitis” (usually a transient inflammation of the pouch that responds to metronidazole).

The details of this operation include excision of the entire colon and proximal rectum, but only the diseased mucosa of the distal rectum and proximal anal canal is removed. Three centimeters of rectal muscularis, the pelvic floor, and the entire anal sphincter mechanism are preserved. Then 30 cm of terminal ileum is fashioned into a neorectum using either a J or S configuration (J is simpler; S has larger capacity and reaches the anus with less difficulty). Intestinal continuity is restored by connecting the pouch to the anal canal at the dentate line. A temporary ileostomy allows healing of the pouch and anastomosis and protects the patient from sepsis should an anastomotic leak occur. After 2 or 3 months, integrity of the pouch, anastomosis, and sphincter mechanism is evaluated; if all is well, the ileostomy is closed, restoring intestinal continuity. The first 3 months after ileostomy closure can be difficult because of the frequent need to pass stool. The pouch capacity increases with time, and the need to empty the pouch can be reduced to an average of four or five times per day.

None of the surgical procedures for ulcerative colitis should prevent completion of normal pregnancy in women who have been cured of the disease. Even normal vaginal delivery is a possibility after any of the resective or restorative procedures.

Crohn's Disease

General Considerations

The diagnosis of Crohn's disease usually takes longer to establish than that for ulcerative colitis, possibly because of the nonspecific nature of the symptoms: diarrhea, abdominal pain, weight loss, and anal disease. The mean time from onset of symptoms to diagnosis is approximately 35 months.

Surgery for Crohn's disease is indicated only for the management of complications, not for cure of the disease, since recurrence is common. Surgery for Crohn's disease is preferably done as an elective procedure rather than waiting until severe complications make urgent surgical intervention necessary, increasing the risk of postoperative complications. The choice of surgical management for Crohn's disease must take into account the geographic distribution of the disease within the intestinal tract and the nature and severity of the complication requiring surgery.

The intensity of activity of the Crohn's disease may determine the type of complication that occurs and may affect the prognosis, including risk and rate of recurrence. Crohn's disease may be considered to have two phases of activity. The *acute* inflammatory process consists of intense inflammation of the involved intestine, deep ulceration into the bowel wall with possible perforation, phlegmon, or abscess, and adherent loops of bowel not involved with the primary disease. The *chronic* fibrotic phase of the disease exists for a longer period and results in narrowing and stricture formation. Any adjacent organs may be involved by the inflammatory process. Hydronephrosis of the right kidney can result from ileocolonic Crohn's disease causing partial occlusion of the ureter. The condition is relieved when the Crohn's disease is resected.

The surgeon should prepare the patient adequately so that a single operation will suffice to correct the complication requiring treatment. This often involves the use of anti-inflammatory medications, antibiotics, complete bowel rest (including parenteral nutritional support), and when indicated, percutaneous drainage of abscesses. The nutritional fitness of the patient undergoing surgical treatment probably contributes more to a favorable outcome than most other variables. By careful preoperative management, the surgeon can avoid operating on a phlegmon with resulting injury to normal, uninvolved intestine with the risk of postoperative disruption of the anastomosis and subsequent fistula formation leading to the eventual creation of a short bowel syndrome.

Surgical Management

Surgical management of Crohn's disease involves resection of the diseased segment of intestine responsible for the complications requiring operation. The extent of resection usually encompasses intestine that is grossly involved with the disease. Recurrence of disease is not reduced by obtaining wide margins of uninvolved intestine or by verifying normal margins by frozen-section histology. The uninvolved margin of resection usually can be detected by demonstrating a normal margin at the mesenteric-intestinal border. It is not necessary to include a large segment of mesentery in the resected tissue. If normal-appearing bowel remains after resection and there is not significant intraabdominal infection, intestinal continuity can be restored by primary anastomosis. Should there be significant intraabdominal infection or intestine that is so severely inflamed that it cannot be removed safely, an intestinal stoma fashioned from bowel proximal to the inflamed intestine will allow the patient to resume eating and taking medication until the inflammatory process resolves and definitive surgical resection can be accomplished.

The symptoms requiring surgical resection depend on the geographic distribution of the disease.

Ileocolonic Crohn's Disease

As shown in Table 26-10, ileocolonic Crohn's disease presents with internal fistula and abscess formation as often as it does with intestinal obstruction. Here the surgical principle of draining an abscess and allowing a phlegmon to resolve becomes critically important. The timing of operation should be such that sepsis is controlled by total bowel rest and percutaneous drainage of abscesses before definitive resection is carried out. Usually intraabdominal abscesses associated with ileocolonic Crohn's disease can be drained percutaneously with the aid of guidance by CT. This allows definitive surgery after the inflammation has resolved, avoiding injury to noninvolved small intestine and other intraabdominal structures that may be involved secondarily by the inflammatory process. Drainage of such abscesses can lead to fistula formation because of the factors summarized in Table 26-11. For this reason, abscesses should be drained from locations on the abdominal wall that would be amenable to application of an appliance, as used for an intestinal stoma. This allows containment of the output even if it should be of high volume and potentially damaging to the abdominal skin.

Colonic Crohn's Disease

Patients with colonic Crohn's disease often require operation after a shorter duration of symptoms than is usual for patients with small intestinal or ileocolonic disease (see Table 26-10 B). Colonic perforation can occur in patients with Crohn's disease and toxic colitis without the dilatation of the colon that is seen in patients with toxic ulcerative colitis. This is probably due to the thickening of the colonic wall, which prevents dilatation; thus the term *toxic megacolon* is not usually appropriately applied in Crohn's colitis. The prognosis and risk of recurrence for Crohn's colitis depend significantly on the presence of simultaneous involvement of the small intestine. The surgical management depends somewhat on the presence and severity of rectal involvement. The risk of recurrence in Crohn's disease prohibits the use of the more sophisticated sphincter- preserving procedures described for ulcerative colitis and sometimes for familial polyposis.

The choices of surgical procedure for Crohn's colitis include abdominal- perineal proctocolectomy with a permanent end ileostomy, total abdominal colectomy with an end ileostomy (with retention of the rectal segment as a Hartmann's pouch), and total abdominal colectomy with ileorectal anastomosis (sometimes protected with a proximal loop ileostomy). The specific choice of surgical procedure is governed by the condition of the rectum and anal sphincter, as well as by the patient's metabolic and emotional status. The latter becomes an important factor because this disease, which frequently involves young adults, should not result in construction of a permanent stoma unless the individual can participate in the decision. A permanent ileostomy presents a change in body image; and although it can be life-preserving, the choice of a permanent stoma should be made by the patient, not by the parents or the physician. Since an ileostomy is not truly permanent until the rectum is removed, significant effort should be made to retain the rectum and preserve the hope of restoration until the patient realizes that the ileostomy is tolerable; the diseased rectum can interfere with long-term health and normal life activity. Recent reports indicate that the retained rectum, even for Crohn's disease, is at some increased risk of developing cancer. Therefore, surveillance of the rectal stump by regular endoscopy is necessary.

The patient presenting with *acute, catastrophic* Crohn's disease is so ill that urgent operation is often necessary. These patients should be managed as previously described for toxic ulcerative colitis. Intense medical treatment, including intravenous hyperalimentation and antibiotics, should be instituted. Some patients revert to a more stable condition, but others require urgent surgical treatment. If peritoneal signs and the general status of the patient do not improve rapidly, operation is required. A site should be marked

preoperatively for a possible ileostomy and, if the colon is massively dilated, for a possible decompressing transverse colostomy as well. Sigmoidoscopy should be done in the operating room, after induction of anesthesia, to determine the status of rectal disease.

At the time of operation, if a severely diseased intact colon is found, it should be removed along with any involved terminal ileum. If the rectum is uninvolved and the patient is stable, consideration can be given to constructing an ileorectal anastomosis. If the status of the rectum is questionable, an ileorectal anastomosis can be performed but should be protected with a proximal loop ileostomy. If the rectum is significantly diseased, it should be left in place, the colon removed, and an end ileostomy established. Once the patient achieves an adequate level of postoperative health and nutrition, the rectum can either be excised or incorporated in an ileorectal anastomosis. If the rectum is severely diseased, it is safer to make a formal mucous fistula than to close the end of the rectum and leave it in place. This mucous fistula decreases the risk of rectal perforation. If a severely diseased colon with free perforation is found at the time of exploration, colectomy is necessary, but no anastomosis should be made. The abdominal cavity should be irrigated, and an end ileostomy should be constructed with the rectum left in place.

In rare situations, exploration will reveal a sealed-off perforation of the colon, usually in the region of the splenic flexure, with a tense, thin-walled colon. Resection in this situation is unsafe; the surgeon should treat this with a loop ileostomy and a "blowhole" decompressing colostomy, as described by the late Rupert Turnbull and his colleagues. This operation requires both diversion and decompression; neither component should be used by itself.

In a patient with *long-standing colonic Crohn's disease*, especially with severe anal or rectal involvement, a single-stage proctocolectomy and ileostomy may be done. The proctectomy should be done differently from that performed for cancer in order to preserve normal sexual function (Figs. [26-54](#) and [26-55](#)).

Rarely, a colonic stricture can form in an isolated segment of Crohn's disease, causing obstructive symptoms. Resection of such a segment should be considered if the obstructive symptoms are significant. Colonoscopic dilation of strictures has been described in situations where surveillance of the proximal colon was not possible. Since the colon has no critical physiologic function, stricturoplasty to retain a colonic segment is seldom indicated; involved segments should be resected and intestinal continuity restored. Complete colectomy is the better procedure for extensive colonic disease.

Rectal Crohn's Disease

Crohn's disease can involve the rectum or the anus, either separately or simultaneously. It is critical to differentiate these anatomic distributions of Crohn's disease. If a patient with rectal Crohn's disease has severe bleeding and tenesmus that cannot be relieved by medical management (including bowel rest with total parenteral nutrition), consideration should be given to removal of the rectum or at least temporary diversion with a colostomy or an ileostomy. Once the rectum has become so fibrotic that it has lost its reservoir function (see Fig. [26-49](#)), proctectomy should be considered because of intolerably frequent, and sometimes poorly controlled, bowel movements. In the rare situation where only the rectum is involved with Crohn's disease, a completely diverting colostomy may allow the rectum to regain its functional capacity. This is especially important in the patient who has had previous small-bowel resections, when it becomes more important to preserve the water-absorbing capacity of the right colon. An end colostomy also may be considered for patients with colonic sparing but severe destructive anal or perineal Crohn's disease. In such cases, diversion may be needed to control sepsis or anal incontinence. If a colostomy is done in a patient with Crohn's disease, it should be constructed as a protruding spigot similar to that of an ileostomy.

The proctectomy in a patient with Crohn's disease should be performed by confining the rectal dissection to the immediate proximity of the rectum (see Figs. [26-54](#) and [26-55](#)), but any fistulous tracts extending to the perineum should be radically debrided.

Certain precautions must be taken during proctectomy for IBD. The nerves to the genitalia and the urinary bladder lie in close approximation to the rectum (see Fig. [26-8](#)). There is a significant incidence of injury to these nerves when a proctectomy is done for cancer, because some of the surrounding tissue must be included in the resection. For IBD, however, the dissection of the rectum need not involve adjacent tissue, and the dissection should be precisely on the rectal wall.

Another complication of removal of the rectum for IBD is nonhealing of the perineal wound, usually more of a problem in Crohn's disease than in ulcerative colitis. This can be avoided by preserving the external sphincter and levator muscles. The operation involves removal of the rectum from the perineal field and secure closure of the musculature, accompanied by drainage of the pelvis from above, as depicted in Fig. [26-55](#).

Another complication of proctectomy occurs in women when the ovaries, which are normally intraperitoneal structures, fall into the space formed by removal of the rectum. The peritoneum may reconstitute in a fashion that excludes the ovaries from the peritoneal cavity, in effect making them extraperitoneal organs (Fig. [26-56 A](#)). As ovulation occurs, large cystic structures can form in the pelvis, and the woman obviously has reduced fertility. This situation can be avoided by simply suturing the ovaries out of the pelvis after the rectum is removed (see Fig. [26-56 B](#)).

Anal and Perineal Crohn's Disease

Involvement of the anus occurs in 35 percent of all patients with Crohn's disease at some time during the course of their illness. Four percent of patients present with only anal disease as the first manifestation of Crohn's, but all go on to have other intestinal involvement. It is important to recognize the possibility of anal disease being secondary to the presence of Crohn's, because the surgical treatment should be much less radical than for non-Crohn's-related anal disease. Procedures such as excisional hemorrhoidectomy and extensive fistulotomy should be avoided because of the necessity of preserving anal sphincter function in a patient with inflammatory bowel disease who is prone to have diarrhea and loss of rectal capacity. Of particular importance is preservation of the anterior aspect of the sphincter mechanism in a woman, in whom continuity of the sphincter muscle is maintained by only one band of external striated muscle. Through the use of conservative and often prolonged and tedious management of anal and perineal disease, very few patients with Crohn's disease require proctectomy because of the anal-perineal disease. This is especially important as more effective medical management becomes available. Conservative surgical drainage of septic processes and the use of intensive medical treatment allow preservation of the rectum and anal sphincter function and in many instances allow the Crohn's disease to go into remission so that the source of the sepsis can be resolved to one small internal opening, which can be closed with the endoanal sliding flap advancement technique (see Fig. [26-44](#)). The medications most advantageous for treating anorectal Crohn's disease include (see Table [26-7](#)) the antibiotic metronidazole, the anti-inflammatory agents 5-aminosalicylic acid and cortisone (by enema or suppository), and such immunosuppressive agents as azathioprine (Imuran), 6-mercaptopurine (6-MP), and cyclosporine. The long-term effectiveness of the agents is difficult to evaluate because of the intermittent nature of the disease. This conservative management is not possible when severe destruction of the rectum exists. These patients often require eventual proctectomy because the loss of the reservoir capacity of the rectum is intolerable.

Anal Crohn's disease should be suspected when a patient presents with inflamed edematous tags (mistaken for external hemorrhoids), anal or perineal fistulas, or abscesses (Fig. [26-57](#)). Often there are multiple abnormalities and poor healing after minor anal surgical procedures. Management of such a patient should begin with examination under anesthesia, including sigmoidoscopy, to determine the presence of disease within the rectum. The edematous skin tags can be removed if they are causing symptoms. This tissue has been shown to serve as a rich source for *granulomas*, which can help confirm the diagnosis of Crohn's disease. The objective of treatment then becomes the management and control of septic processes, in anticipation of medical treatment to put the Crohn's disease into remission. This can be accomplished with mushroom-tipped catheters or unroofing of abscesses and with the use of setons to provide drainage of fistulous tracts. A superficial fistulotomy can be performed if the external sphincter mechanism is not involved. Special care must be observed for preservation of the anterior component of the sphincter mechanism in women. These conservative and tedious drainage processes may go on for years in an attempt to preserve the rectum. As part of this preservation, evaluation of the sphincter mechanism should be carried out, including manometry and electromyography. Intestinal continuity should never be restored to a poorly functioning anorectum or to one that is extensively destroyed. Such patients would do better with resection and a good intestinal stoma.

Outcome of Surgical Treatment of Crohn's Disease

The incidence of the need for operation and the development of recurrence in the postoperative period for a large series of patients with Crohn's disease, followed over a long period of time at the Cleveland Clinic Foundation, can be seen in Table [26-12](#). After the immediate perioperative period, the major complication of Crohn's disease is the high rate of recurrence. Its true incidence can only be discovered by long-term observation of a large, carefully defined population. This series, originally reported by Farmer, attributed the risk of recurrence to the *pattern of initial presentation* of Crohn's disease within the intestinal tract, suggesting that ileocolonic Crohn's disease had a higher recurrence rate. After 15 years, the rates of recurrence, based on patterns of presentation, converged. Thus the reliance on disease distribution to predict recurrence was no longer useful. Their series showed, in addition, that the rate of recurrence seemed to be biphasic, with the slope of the recurrence curve improving 8 years after surgery, suggesting that the longer the patient lives without recurrence, the less likelihood there is of the disease presenting itself again. Both Farmer and Sachar, from another institution, presented statistics to indicate that the *severity* of the presenting symptoms was perhaps a better predictor of risk for severe complications and early, frequent recurrence of disease. Perforation and intense inflammatory changes as presenting symptoms, including severe anal or perineal disease, carried a much higher likelihood of postoperative recurrence than more indolent symptoms such as obstruction. We also have seen a more rapid as well as increased incidence of recurrence and a more severe intensity of disease in the African American population. Although Crohn's disease was initially said to exist primarily in the Jewish population and to spare blacks, we found that not only did African-Americans acquire Crohn's disease, but also a higher percentage required operation. There was also an increased requirement for second operations, and all of them had extraintestinal manifestations of Crohn's disease. Recent studies have suggested a relationship between the rate of recurrence and the immunologic status of the patient, showing a lower and slower recurrence rate in patients with ileocolonic resections who had the immunosuppressive effect of preoperative blood transfusions. The interpretation of this clinical finding is still not clear.

An important principle to which one must adhere is that the need for surgical management of a complication of Crohn's disease should not be ignored because of the risk of recurrence. In addition, the fact that one operation for resection of Crohn's disease is necessary does not increase the subsequent need for further surgery, nor does it mandate the eventual creation of a short bowel syndrome.

Ileostomy Construction and Management

An ileostomy can be constructed with different configurations, depending on the goal to be accomplished by its construction. A permanent ileostomy is usually constructed with the end of the ileum, and enough of the mesentery is preserved to allow adequate vascularization (Fig. [26-58](#)). The stoma is everted on itself to prevent the serious problem of "ileostomy dysfunction" that historically led to severe fluid and electrolyte imbalance due to partial obstruction of the small intestine. This technique of eversion was described by Brooke and by Crile and Turnbull in 1954. A *loop* of ileum also may be used for construction of a stoma (Fig. [26-59](#)). This leaves the mesentery intact and is usually constructed on a temporary basis to protect distal, precarious anastomoses or the new restorative procedures for maintaining anal continence, although these latter procedures are not indicated in patients with Crohn's disease because of the risk of recurrence. A loop ileostomy can be constructed with the bowel in continuity or separated (Fig. [26-60](#)).

The techniques of ileostomy construction are based on the fact that the output from an ileostomy is relatively high in volume, liquid in consistency, and contains active proteolytic enzymes. Thus a properly constructed ileostomy must be situated precisely on the abdominal wall at a site chosen carefully preoperatively with the patient in various positions (Fig. [26-61](#)). The abdominal incision performed on patients for IBD should always preserve the right lower quadrant skin, even if the possibility of an ileostomy seems remote at the time of the operation. The ileostomy stoma must be constructed with a protruding spigot configuration to allow an appliance to seal perfectly to the skin (Fig. [26-62](#)). An ileostomy stoma must have adequate blood supply, a goal not easy to accomplish, especially in the obese patient.

An individual with a well-constructed and properly located ileostomy should be able to empty the appliance four to six times a day and should not need to have complete change of the appliance more often than every 4 or 5 days. Neither belts nor supporting straps should be necessary, and the ostomate should be able to perform all routine activities (Table 26-13). The only true disability caused by a properly constructed ileostomy is a change in body image.

Long-term management of an ileostomy includes provision of adequate fluid replacement in hot weather, because the individual is at risk for rapid dehydration during periods of intense physical activity. Oral electrolyte- containing solutions are beneficial for this purpose. The ileostomy patient also should be advised to have available antidiarrheal agents for control of episodes of high output from the stoma. Large quantities of fibrous foods should be avoided, because they can cause blockage of the intestinal stoma (Fig. 26-63). If this occurs, the patient must be seen in the emergency room, where the ileostomy can be irrigated through a #24 Foley catheter inserted just below the fascia with 3 mL of saline in the balloon. Then 50 mL of warm saline is used to irrigate the stoma. The diagnosis of food blockage can be confirmed by the passage of particles of food after each irrigation. These patients often require intravenous fluids and nasogastric decompression to alleviate the severe cramps and dehydration that result from these episodes of small-intestinal obstruction. If the obstruction is not diagnosed as due to food blockage, other causes should be sought, and a water-soluble contrast study should be performed through the intestinal stoma. This can serve as a therapeutic as well as a diagnostic modality because of the cathartic action of the contrast solution. Digital inspection of an ileostomy is inappropriate, because the stoma is smaller than that of a colostomy, and insertion of a finger may be injurious.

A patient with a properly constructed ileostomy should have a normal life expectancy, assuming no malignant growth existed at the time of initial operation, and should anticipate no restrictions of normal life activity, with the exception of the extra time needed to provide meticulous care of the intestinal stoma.

NEOPLASTIC DISEASE

Etiology

Although the exact cause of colon and rectal cancer is not known precisely, recent laboratory work has provided a veritable explosion in the understanding of the molecular basis of colorectal carcinogenesis. These advances have significantly altered many concepts about the development of cancer of the large bowel, and studies at the molecular level promise to radically alter colorectal cancer screening, diagnosis, treatment, and prognostication in the coming years. It is now recognized that colorectal cancer is a genetic disease, meaning that the cause of the uncontrolled proliferation of cells that we recognize as carcinoma resides in abnormalities or alterations in the genetic code. These genetic mutations may be in the germ line, in which case the disease is inherited, or somatic mutations in the genes may occur, which would result in the type of cancer that we usually have referred to as *sporadic*.

Genetic Predisposition

It has been estimated that approximately 10 to 15 percent of colorectal cancer is familial and that 1 person in 200 may carry high-risk alleles of the genes causing inherited colorectal cancer. It also is estimated that the same genes may be involved in as many as 15 percent of sporadic cancers.

Familial Adenomatous Polyposis

Pathophysiology and Diagnosis

Familial adenomatous polyposis (FAP) is the prototypical hereditary polyposis syndrome. It is an autosomal dominant disorder diagnosed when a patient has more than 100 adenomatous polyps in the large bowel or when a member of an FAP family has any number of colonic adenomas detected. FAP includes a spectrum of syndromes formerly defined by various extraintestinal manifestations. FAP also includes Gardner's syndrome (epidermal inclusion cysts, osteomas of bone, and colonic polyps) and Turcot's syndrome (colonic polyps and brain tumors). The genetic defect responsible for adenomatous polyposis has been detected on chromosome 5, near the q21 locus. The gene has been called the APC (adenomatous polyposis coli) gene. FAP occurs in anywhere from 1 in 8000 to 1 in 29,000 individuals. The common expression of the syndrome is the presence of multiple polyps in the colon and the associated extraintestinal manifestations, including epidermoid cysts, desmoid tumors in the abdomen, osteomas of the bones, and brain tumors (usually gliomas or medulloblastomas). The gene expression occurs in 100 percent of patients with the defect. Autosomal dominance results in expression in 50 percent of offspring. Between 10 and 20 percent of all patients with FAP appear to harbor the genetic defect as a result of spontaneous mutation. All patients with the defective gene will develop cancer of the colon if left untreated. The average age of discovery of a new patient with FAP is 29 years. The average age of a patient who is newly discovered to have colorectal cancer related to FAP is 39 years.

Two rare variants of FAP include *attenuated adenomatous polyposis coli* (AAPC) and *hereditary flat adenoma syndrome* (HFAS). AAPC patients have relatively few polyps but retain a high risk of colorectal cancer. Patients with HFAS develop small adenomas (usually less than 100) that are frequently dysplastic and prone to malignant transformation. One interesting marker for FAP is congenital hypertrophy of the retinal pigmented epithelium (CHRPE), which is seen on indirect ophthalmoscopy in approximately 70 to 80 percent of FAP patients.

Our understanding of the genetic basis for colorectal cancer has resulted in clinical applications for screening of patients in FAP kindreds by DNA analysis for the APC gene or its products in peripheral blood leukocytes. This test, which requires only venipuncture, has obvious advantages over the standard screening, which consists of an annual endoscopy. This is particularly useful for young patients for whom screening is indicated. A single negative blood test, showing the noninheritance of a mutated APC gene, suggests that the individual will not develop polyposis and may not require intensive screening. This depends on the genetic defect's being clearly identified by testing the blood of known involved members of the family. It is believed that occasional surveillance colonoscopy is still indicated.

Upper endoscopy should be used to screen for gastric and duodenal adenomas beginning at age 30, even though such polyps have been found in patients under 20 years of age. Prior to the development of genetic screening for the APC gene, young children were screened by ophthalmoscopic examination. If the patients were found to have an area of retinal pigmentation, the chances of developing colonic polyps approached 100 percent. DNA analysis probably will replace the need for such screening procedures.

Surgical Management

Appropriate treatment for patients with FAP is removal of all colonic and rectal mucosa. Total proctocolectomy with permanent ileostomy accomplishes this goal, but the development of sphincter-saving procedures has virtually eliminated this operation as an acceptable form of therapy, unless the patient should have already developed a cancer of the distal rectum before operative treatment.

Total proctocolectomy with ileal reservoir and ileoanal anastomosis is the most commonly recommended operation for patients with FAP. The procedure must include a mucosectomy to the level of the dentate line to remove all mucosa at risk. Patients who undergo this procedure for FAP have a better functional result than patients similarly treated for ulcerative colitis, in that the incidence of inflammation in the ileal pouch (pouchitis) is much less in patients with familial polyposis. An alternative approach, total abdominal colectomy with ileorectal anastomosis, has been used successfully by several institutions. This latter approach was used extensively before the development of the technique of ileal pouch–anal anastomosis. The disadvantage of subtotal colectomy is that the precancerous rectum remains in situ, and repeated endoscopic procedures are needed every 6 months to detect and eradicate (by fulguration or snare excision) any adenomatous polyps that appear in the rectum. The early fears of unacceptable incontinence, intractable diarrhea, and impotence in men that might accompany proctocolectomy with ileal pouch–anal anastomosis, thus making subtotal colectomy with ileorectal anastomosis the preferred procedure, have not been confirmed.

FAP patients treated by proctocolectomy of any type remain at risk of death from upper gastrointestinal cancer. In one series this risk was greater than the risk of death from cancer in the residual rectum after total abdominal colectomy and ileorectal anastomosis. These patients require continued periodic surveillance by gastroduodenoscopy.

Extracolonic Manifestations

Some patients with FAP develop epidermoid cysts, osteomas, desmoids, and upper gastrointestinal neoplasms (Gardner's syndrome). The epidermoid cysts require no treatment unless they become symptomatic or cause significant cosmetic deformities. It is extremely rare for osteosarcomas to arise from osteomas in patients with FAP. The intraabdominal *desmoid* is probably the only incapacitating, lethal extraintestinal manifestation. After surgical procedures, dense fibrous tissue forms in the mesentery of the small intestine and encroaches on the vascular supply, tethers the small intestine, and causes obstruction or ischemia. Treatment has been attempted with chemotherapy, radiation, tamoxifen, and sulindac. Operative therapy is completely inadequate and should be reserved only for decompression of obstruction or to relieve incapacitating symptoms. Sulindac has been reported to cause tumor regression in some patients with desmoid tumors.

Upper gastrointestinal neoplasms in patients with FAP (Gardner's syndrome) include duodenal or ampullary adenomas, which are premalignant, and hyperplastic fundic polyps in the stomach, which do not become malignant. The current recommendation is for upper gastrointestinal surveillance after the age of 30 and endoscopic polypectomy, if possible, to remove all large adenomas within the duodenum. If an ampullary cancer is discovered at an early stage, pancreatoduodenectomy (Whipple procedure) is indicated.

Turcot's syndrome (colonic polyps and intracranial gliomas or medulloblastomas) is very rare, with only 50 patients reported in the literature. Patients with Turcot's syndrome usually die at an early age, before developing colonic polyposis and before having children.

Hereditary Nonpolyposis Colorectal Cancer

Aldred S. Warthin first recognized an increased incidence of cancer in certain families in 1913. One family characterized by Warthin became the prototype of cancer families. This family was afflicted by an excess of uterine and gastric cancers. The family was evaluated four times in the past 80 years, and a predominance of colorectal cancers has been detected in family members. A half century after Warthin's observations, Henry Lynch collected data that accurately characterized these cancer-prone families. Colorectal cancer is the most predominant cancer in this syndrome, but it is not associated with multiple polyps, which characterize familial polyposis. For this reason, the syndrome was named *hereditary nonpolyposis colorectal cancer (HNPCC)*. In 1984 the terms *Lynch syndrome I and II* were proposed to indicate two apparently distinct clinical presentations. In Lynch syndrome I, the cancer usually occurs in the proximal colon, is site- specific within an affected family, and is the only type of tumor these patients develop. Lynch syndrome II is characterized by development of colorectal, endometrial, gastric, upper urinary tract, ovarian, and other types of cancer.

There are no phenotypic markers for HNPCC, so a standard clinical definition of the syndrome is necessary. The most widely accepted definition uses the *Amsterdam criteria*, which require (1) at least three relatives with histologically verified colorectal cancer, one of which is a first- degree relative of another, (2) involvement of a least two generations, and (3) at least one colorectal cancer diagnosed before the age of 50 years. HNPCC is characterized by an autosomal dominant inheritance pattern, an early age of colorectal cancer development, a predominance of right-sided cancers, and a tendency toward the development of synchronous and metachronous cancers.

Molecular scientists recognized widespread genetic instability in most cancers studied in patients with HNPCC, and for this reason, a DNA “mutator” gene was suspected as playing

a carcinogenic role. The particular genetic instability in tumors from patients with HNPCC is characterized by variations in length of “microsatellite” DNA, which are short repetitive DNA sequences located throughout the genome. While microsatellites vary in length among individuals (a fact used in forensic DNA “fingerprinting”), they should be the same in all cells from a single individual. HNPCC tumors have microsatellites that differ in length from the normal cells of the same individual, indicating a loss of fidelity in DNA repair. This defect in the DNA repair process has been referred to as a *replication error* (RER). To date, four mismatch repair genes have been identified, and these are responsible for the majority of, but not all, HNPCC cancers. These genes are *hMSH2*, located on chromosome 2p; *hMLH1*, located on chromosome 3p; *hPMS1*, on chromosome 2q; and *hPMS2* on chromosome 7p.

The cancers that arise in patients with HNPCC are more often poorly differentiated and mucin-producing than sporadic colorectal cancer. “Signet ring” cancers are also more common in HNPCC tumors. Despite these findings, which are usually associated with a poor prognosis, the prognosis for patients with HNPCC is more favorable than that of patients with sporadic colorectal cancer of the same pathologic stage. Approximately 20 percent of HNPCC patients with colon cancer will have a synchronous cancer, and about 25 percent will develop a metachronous cancer of the remaining colon. It is recommended that patients with this syndrome be treated with subtotal colectomy.

Colorectal cancers arising in HNPCC patients develop through a typical adenoma-carcinoma progression. The hypermutable cancer may accelerate the time frame in which malignancy occurs. The optimal intervals for surveillance in this disease have not yet been ascertained. Because most of the tumors will occur in the proximal colon, flexible sigmoidoscopy is not an effective screening approach. A 3-year interval of screening significantly reduces the incidence of colorectal cancer, but surveillance intervals of 1 or 2 years may be more appropriate for this syndrome. There has been no significant study on the impact of any diagnostic screening to prevent the development of upper gastrointestinal tract cancers or gynecologic cancers.

Assays undoubtedly will become available that identify mismatch repair gene mutations in suspected HNPCC kindreds. This advance will be of practical and theoretical importance: practical, to identify gene carriers in a given HNPCC kindred, and theoretical, because HNPCC kindreds are currently defined by family history alone, which may be incomplete or misleading. Individuals may carry the disease trait but not fulfill the current clinical criteria. Future definitions of HNPCC will be based on genetic analysis rather than on family history alone.

Acquired Somatic Defects

The chromosome defect in FAP is a germ cell line defect and is present from birth. The majority of patients with colorectal cancer have no inherited component, and the initiating genetic mutation that causes neoplastic growth occurs in a single cell or in a group of mucosal cells. These tumors are not inherited, but there may be a familial predisposition to their development. Lynch has shown that the risk for developing colorectal cancer is increased threefold to ninefold if one or more first-degree relatives have had colorectal cancer.

Available evidence suggests that adenomas of the colon develop after such a gene mutation. The adenomatous tissue contains crypt cells with atypical genetic expression. Tumor formation may be the result of more than one mutation. A *somatic* mutation, associated with an *inherited* mutation, may be expressed as the adenoma or tumor progresses. The inherited mutation is felt to be tumorigenic but may not be expressed or detectable in the tumor. Fearon and Vogelstein have proposed that, once the adenoma has developed, a second mutation may be required to change the adenoma to a cancer. A progression of mutations actually can occur in the course of the development of a malignancy. Oncogenes function by initiating events that result in abnormal cellular growth and the development of tumors. For example, the *ras* gene family has been found in 50 percent of colorectal cancers and in adenomas larger than 1 cm, but it has been found in less than 10 percent of adenomas smaller than 1 cm.

As a tumor develops, subsequent mutation can result in the deletion of suppressor genes. This loss usually occurs on chromosomes 17, 18, and 5. For example, the p53 gene is absent from chromosome 17 in 85 percent of colorectal cancers. The chromosome 5 MCC gene (mutated colorectal cancer) is found in some tumors in patients with nonpolyposis cancers. The chromosome 18 DCC gene (deleted in colorectal cancer) is found in more than 70 percent of colorectal cancers. These mutations are postulated to affect cell-to-cell relationships in all tumors and thereby also affect the development of metastases.

Fearon and Vogelstein have proposed a model for genetic changes leading to colorectal cancer (Fig. 26-64). First, a mutational *activation* is initiated by oncogenes. This mutational activation is accompanied by a mutational *inactivation* of multiple suppressor genes. The mutations allow uncontrolled growth in varying degrees. More mutations are required for the development of cancer than for the development of benign polyps. The progression of cellular changes from normal mucosa to adenoma to cancer could be related to a progression of mutations over time.

Environmental Factors Diet

Diet has been proposed as a significant etiologic factor in the development of colorectal cancer. Fats have been suggested to be toxic to the colonic mucosa. Diets high in oleic acid (found in olive oil, coconut oil, and fish oil) cause no increase in cancer in animals. The monounsaturated fatty acids (omega-3 and omega-6 fatty acids) appear to be less carcinogenic than polyunsaturated or saturated fats. Epidemiologic studies of populations that consume less than 5 percent of their diet as fat have shown a lower incidence of colorectal cancer, whereas those having diets with 20 percent of their fat as either corn oil or safflower oil have an increase in cancer. Therefore, it appears that unsaturated animal fats and highly saturated vegetable oils may cause some event to occur in the colonic mucosa that stimulates the development of colorectal cancer.

Some studies suggest that certain elements of the diet protect against the development of neoplasia. Selenium, dithiothiones, thioethers, terpenes, and carotenoids might act as “anticarcinogens” by reducing free oxygen radicals in the colon at the mucosal surface. An increase in dietary fiber may lower the incidence of cancer in patients who have a high-fat diet. An increase in fat, however, can negate the beneficial effect of the fiber. A high-fiber, low-fat diet has been described as better protection against neoplasia than a fat-free diet. An increase in bulk also tends to dilute carcinogens, shorten colonic transit time, and as a result, decrease the growth of harmful bacteria. So far, controlled trials have shown little relationship between dietary fiber and colon cancer, but the studies used a relatively low dose of fiber.

The National Research Council established interim guidelines for diet recommendations in 1982 until definitive studies could be performed. These recommendations included

- (1) Decrease fat in the diet from 40 to 30 percent of total calories.
- (2) Increase consumption of fiber-containing foods.
- (3) Limit salt-cured, pickled, and smoked foods.
- (4) Limit food additives shown to be potential carcinogens.
- (5) Establish research protocols for detection of mutagens in foods.
- (6) Limit alcohol consumption.

Epidemiologic studies indicate that diet has a role in the development of colon cancer. People in less-industrialized nations are noted to have a low incidence of colorectal cancers. These people have fewer processed foods and more natural fiber in their diets. People from these countries who immigrate to the industrialized United States or United Kingdom acquire the high risk of colon cancer found in these countries.

Exposure to Carcinogens

No clear relationship has been established between specific carcinogens and colorectal cancer, but potential agents currently under investigation include bile acids (such as chenodeoxycholic acid), food additives, alcohol, and ionizing radiation. Each of these may function as a promoter of mutational changes in the colonic mucosa, but none has been clearly shown to have a carcinogenic effect. Oxygen free radicals, which are unstable by-products of oxygen metabolism, may serve as promoters or chemical stimulants to the development of altered gene expressions. This is not a true carcinogenic effect but the creation of a “milieu” that predisposes to the development of mutations.

Premalignant Conditions Ulcerative Colitis

The overall incidence of neoplasia in patients with pancolitis is 1 percent per year after 10 years; so the cumulative risk of a cancer is 10 percent by 20 years' duration of disease. Dysplasia identified in the colonic mucosa by repeated colonoscopic biopsies has been shown to be a precursor of cancer. The cancers tend to be more advanced because they are difficult to detect at an early stage. Approximately 35 percent are Dukes' C or D lesions. There is a controversy over the implication of adenomatous polyps found in patients with chronic ulcerative colitis. The question arises as to whether this represents dysplasia and is an indication for total colectomy or whether this is a benign polyp arising from inflamed mucosa.

The most effective method for preventing colon cancer in patients with ulcerative colitis is to remove the colon once dysplasia has been identified. The risk of cancer in the presence of dysplasia is approximately 30 percent.

Crohn's Disease

The overall incidence of cancer occurring in patients with Crohn's disease is approximately 7 percent over 20 years. Most of the intestinal cancers were found in the excluded segments of patients treated by segmental bypass. This procedure is no longer recommended because of a 20 percent incidence of adenocarcinoma and persistent disease in these bypassed segments. Patients with colonic strictures have a slightly higher incidence of adenocarcinoma at the site of the fibrotic narrowing. Reports of adenocarcinoma arising at the site of stricturoplasty in the small intestine have made it apparent that there is a risk of adenocarcinoma in these lesions. For this reason, a biopsy of the intestinal wall should be performed at the time of stricturoplasty. There also have been reports of squamous cell cancer and adenocarcinoma arising in chronic fistulas (especially of the anus and perineum) in patients with Crohn's disease. Overall, the risk for neoplasia in patients with Crohn's disease is only slightly higher than that of the general population and is certainly lower than in patients with ulcerative colitis or familial adenomatous polyposis.

Detection

Tests for Occult Blood

A colorless phenol in guaiac gum is converted to a blue quinone by oxidation. The reaction relies on the presence of a peroxidase catalyst. Oxidation is accomplished by the addition of hydrogen peroxide in the presence of a catalyst, such as hemoglobin. Unfortunately, there are other catalysts in the diet. Careful elimination of some of these products may be necessary to improve the accuracy of the test. Red meat, some vegetables, and other intrinsic peroxidases may cause the reaction in the absence of hemoglobin. The

guaiac occult blood test will detect 20 mg of hemoglobin per gram of stool or 20 mL/day.

An immunofluorescent test for occult blood relies on the conversion of hemoglobin to fluorescent porphyrins and detects between 5 and 10 mg of hemoglobin per gram of stool. The false-positive rate is prohibitively high.

There are inherent problems in using the detection of occult blood as a screening test for colorectal cancer. Other sources of bleeding may produce positive tests, or the test may be too sensitive for blood. Cancers might bleed only intermittently or not at all, and the occult blood test may be falsely negative. Test processing, dietary manipulation, ingestion of gastrointestinal irritants (aspirin), the number of tests, and the interval of testing all affect the accuracy of the occult blood screening process.

There have been numerous uncontrolled studies of occult blood testing for screening populations for colorectal cancer. These reports usually show 2 to 6 percent positive tests. The positive predictive value for cancer in these studies has been 2 to 5 percent, and the positive predictive values for a polyp in these studies has been close to 20 percent. Cancer has been detected in 0.03 to 0.2 percent of all tested subjects, and polyps have been found in 0.6 percent.

The results of screening 46,000 individuals for occult blood using the guaiac test revealed a sensitivity of 89.3 percent, a specificity of 92.7 percent, and a positive predictive value for cancer of 2.5 percent. Long- term follow-up results from a University of Minnesota study showed an increase in more advanced lesions B and C in the control group, which translates to a decrease in mortality for the screened group. The cost- effectiveness of the test for occult blood as a screening tool is questionable. False-positive tests result in expensive evaluations to rule out real disease. False-negative tests result in patients presenting with a more advanced lesion that ultimately may cause more expensive, radical treatment.

Diagnosis Rectal Examination

The digital rectal examination can reach approximately 8 cm above the dentate line. It was long believed that 50 percent of colorectal cancers were within the reach of the finger. It has been shown that almost 50 percent of all colorectal cancers and polyps will occur proximal to the splenic flexure. The digital rectal examination remains an important tool in the detection of colorectal cancer and should not be abandoned. Twenty percent of colorectal cancers can be palpated and their degree of fixation to surrounding tissue evaluated.

Proctosigmoidoscopy

Rigid proctosigmoidoscopy uses a lighted tube 2 cm in diameter and 20 to 25 cm long. The examination usually reaches 20 to 25 cm from the dentate line, but the acute angulation of the rectosigmoid junction can prevent complete insertion of the instrument. This examination should detect 20 to 25 percent of colorectal tumors. Rigid proctosigmoidoscopy is safe and effective for screening low-risk adults under 40 years of age when combined with evaluation of the stool for occult blood. The endoscopist must remember to follow the contour of the rectum, advancing the scope only when the lumen can be seen. An enema is sometimes used to prep the patient before the examination.

Flexible Sigmoidoscopy

The flexible sigmoidoscope is a fiberoptic or video scope that measures 60 cm in length and should reach the proximal left colon or even the splenic flexure in most patients (and will identify 50 percent of colorectal cancers). The patient does not need a complete bowel prep because the left colon can be cleansed by one or two small enemas. The flexible sigmoidoscope should not be used for therapeutic polypectomy, cautery, and the like, except in special circumstances, such as after an ileorectal anastomosis. Polypectomy or biopsy using electrocautery in unprepped colon can be disastrous if an explosion of colonic methane gas occurs or perforation allows leakage of feces into the peritoneal cavity.

Flexible sigmoidoscopy every 5 years beginning at age 50 is the current endoscopic screening method recommended for asymptomatic persons at average risk for colorectal carcinoma. An adenomatous polyp found on flexible sigmoidoscopy is an indication for colonoscopy, because even small (<10 mm) adenomas in the distal colon are associated with aggressive neoplasms in the proximal colon in 6 to 10 percent of patients.

Contrast Studies

The most commonly used contrast study to detect colorectal cancer is the air-contrast barium enema. An air-contrast (double-contrast) barium enema has been found to be 90 percent sensitive in detecting polyps larger than 1 cm. The air-contrast barium enema, in conjunction with the flexible sigmoidoscope, has been suggested as a cost-effective alternative to colonoscopy for patients who do not tolerate colonoscopy or for use on an alternating basis with colonoscopy for long-term follow-up in patients who have had a previous polyp or cancer excised. The risk of perforation of the colon by barium enema is low (less than 0.02 percent). If perforation is a possibility, water-soluble contrast should be used rather than barium. Barium peritonitis is a disastrous complication that causes severe infection and subsequent intraperitoneal fibrosis. The patient usually requires an emergency operation to clear the barium from the abdomen and construction of a colostomy to protect the repair of the perforation. Water-soluble contrast material unfortunately does not provide the necessary detail for detecting small colonic mucosal lesions.

Colonoscopy

Colonoscopy allows visualization of the mucosa of the entire colon and rectum and usually the terminal ileum. Colonoscopy originally depended on flexible fiberoptics as the source of the imaging. New technology has allowed a video camera to be placed at the tip of the flexible colonoscope, allowing greater flexibility and better resolution of image. The standard colonoscope is 160 cm in length. Colonoscopy is the most accurate method of detecting polyps less than 1 cm in diameter. It also allows biopsy, polypectomy, control of hemorrhage, and dilation of strictures. Adequate colonoscopy includes good patient compliance, good bowel preparation, patient sedation in most cases, and monitoring of vital signs and blood oxygenation. Colonoscopy is a safe procedure, and major complications (including bleeding, anesthetic complications, and perforation) should occur in less than 0.2 percent of patients. Colonoscopy is useful in the diagnosis and management of inflammatory bowel disease, nonacute diverticulitis, sigmoid volvulus, gastrointestinal bleeding, nontoxic megacolon, colonic foreign body, colonic strictures, neoplastic disease, and unexplained diarrhea.

Complications after colonoscopy are more frequent after therapeutic colonoscopy (polypectomy, stricture dilation, control of hemorrhage) than after diagnostic colonoscopy. The most common complications of diagnostic or therapeutic colonoscopy are related to the use of conscious sedation. The most common major complication after therapeutic colonoscopy is hemorrhage after polypectomy (up to 3 percent). Postpolypectomy hemorrhage may occur immediately, in which case local measures are appropriate for control (epinephrine injection at bleeding site, electrocautery, resnaring polyp stalk). Management of delayed hemorrhage requires colonoscopy or angiography if the patient is bleeding massively. The source is usually arterial when the eschar separates from the polypectomy site. The majority of patients stop bleeding spontaneously, but colonoscopic measures or vasopressin via arteriogram catheter may be required if bleeding persists. Perforation is the most common major complication after diagnostic colonoscopy and is associated with free intraperitoneal air, abdominal pain, and variable degrees of peritoneal signs depending on the contamination of the abdominal cavity. A patient who develops free air without peritonitis and minimal contamination of the abdomen may be observed closely and treated with bowel rest, antibiotics, and intravenous fluids. The presence of (or progression to) diffuse peritonitis indicates the need for exploration. Depending on the size of the perforation, degree of contamination, and status of the patient, the patient may be treated with colectomy with primary anastomosis (plus or minus proximal diverting stoma), colectomy with colostomy and mucous fistula or Hartmann stump, or debridement and closure of the perforation.

Imaging Techniques

As technology progresses, more sophisticated imaging techniques are becoming available. CT, MRI, positron-emission tomographic (PET) scan, and transrectal ultrasonography are specific imaging techniques and not screening tests. They are important in the evaluation, staging, and follow- up of patients with colorectal cancer. They are used to evaluate primary cancers and their potential metastases to adjacent or distant organs.

Computed Tomography

Computed tomography (CT) allows preoperative evaluation of the abdominal cavity in patients with colorectal cancer. The CT scan can identify metastases to the liver, adrenal gland, ovary, lymph nodes, and other organs in the pelvis, and it can verify the integrity of the urinary tract because intravenous contrast material is excreted by the kidney. The CT scan is useful in searching for recurrent or residual cancer in patients with an elevated *carcinoembryonic antigen (CEA)* level after surgery for colorectal cancer. A combined angiogram and CT scan with dynamic imaging (scan during arterial injection of contrast material) is useful to evaluate the vascular anatomy of the liver and to accurately identify all possible metastases in the liver. The sensitivity of the angio-CT is approximately 95 percent.

The CT scan plays a special role in patients with rectal cancer because of the difficulty in staging the lesion preoperatively. Treatment options other than total rectal excision are available for selected patients with favorable lesions, as will be discussed in the section on rectal cancer. Sphincter- saving operations and local therapy may be appropriate if the tumor has not invaded deeply or metastasized to regional lymph nodes. Pelvic CT scanning documents rectal wall invasion by the tumor with a 60 to 90 percent accuracy and detects lymph nodes larger than 1 cm in 75 percent of patients.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a relatively new technique for evaluating colorectal cancer. Axial and sagittal views can be used to detail anatomy. T₁- and T₂-weighted images facilitate the differentiation of cancer from normal tissue and fibrotic scar. A coil placed in the rectum allows enlarged, detailed images of the rectum that may facilitate staging of rectal cancer. MRI is a lengthy study that requires the patient to lie quietly in a small tunnel, causing patients with claustrophobia to dislike the technique. The test does not require the use of contrast material. Early experience suggests that MRI offers little or no advantages over CT in the preoperative evaluation of patients with colorectal cancer. MRI is more specific for tumor in the liver than CT scanning and is frequently used to clarify a questionable lesion seen on CT scan. Because it is more sensitive than the CT scan, it is also used to identify other liver metastases when a liver resection is contemplated.

Positron-Emission Tomography

Positron-emission tomography (PET) is still investigational but eventually may be most helpful in evaluating recurrent tumor in the pelvis where scar formation is very dense. The PET scan detects differences in tissue metabolism using an injected substrate, fluorodeoxyglucose. Scar and recurrent tumor appear essentially the same on CT. The PET scan, however, will show an increase in metabolism in an area of cancer. Positron emission is greatest in hypermetabolic tissue such as tumors.

The major advantage of the PET scan may be to identify extrahepatic or intraperitoneal disease before performing a liver resection for metastasis or wide radical resection of local recurrence. This reduces unnecessary surgery and improves the selection of patients who will benefit from resection of recurrent or metastatic disease (Fig. [26-65](#)).

Transrectal Ultrasound

Transrectal ultrasonography or endosonography of the rectum is useful for staging rectal cancer. There is no radiation risk, and the procedure takes little time and can be directed to the upper rectum using a modified proctoscope. The ultrasound image allows clear delineation of the layers of the rectal wall and, as a result, a very accurate definition of the depth of invasion of the tumor into the bowel wall: Stage T1=limited to mucosa and submucosa; Stage T2=limited to muscularis propria; Stage T3=through the entire bowel wall (Fig.

26-66). The most important aspect of staging is the identification of those lesions which invade through the bowel wall into surrounding fat. Ultrasonography easily detects small lymph nodes, but the positive predictive value for cancer is only 50 percent for those under 1 cm. Larger lymph nodes (>1 cm) seen on ultrasonography have a 70 percent positive predictive value for cancer. It is difficult to perform endosonography in a patient with an obstructing lesion because the rectal probe cannot pass beyond the lesion. Endosonography of a rectal cancer also may reveal invasion of the tumor into adjacent prostate, sacrum, or vagina (Stage T4).

Endoluminal Ultrasound

Colonoscopic ultrasound evaluation of a colonic lesion is available. The small side-scanning transducer is placed on the colonoscope tip. The planar view allows determination of depth of invasion, attachment to adjacent structures, and spread to close mesenteric lymph nodes by tumors in the colon. The usefulness of such information is unclear at present because treatment is determined by the portion of the colon involved rather than depth of invasion.

Ultrasound-guided biopsy of the lymph nodes or extraluminal tumor in the pelvis is possible with newer ultrasound equipment. This has the benefit of documenting local recurrence of tumor in the pelvis in patients after previous sphincter-sparing resections of a rectal cancer. Patients who have tumor present in lymph nodes at the time of diagnosis of a rectal cancer are not candidates for local treatment.

Monoclonal Antibodies

Hybridoma techniques have allowed the development of a library of monoclonal antibodies to colorectal cancer. There are two types of monoclonal antibodies: one that recognizes CEA and the other that recognizes cell membrane features of colon cancer. Monoclonal antibodies tagged with a radioactive isotope allow tumor imaging. Therapeutic destruction of rectal or colonic cancer using this technology may be possible in the future.

Surveillance Screening

Screening must be differentiated from evaluating patients who are at high risk for developing colorectal cancer. Screening programs are aimed at the general population. Cost-effectiveness, reliability, ability to follow up on findings, and a reduced mortality in the screened population are factors to consider when evaluating a screening program. *Sensitivity* of the screening method is based on the *true positives* in the population and is often difficult to prove. *Specificity* is determined by the *true negatives*, which are defined by a negative test. This also is difficult to evaluate because lengthy follow-up is necessary.

Even though screening is an excellent idea, there are limitations. The ideal situation might indeed be to perform colonoscopy on the entire population and remove all polyps to prevent the occurrence of colorectal cancer. This obviously is impractical because of the inordinately high expense, tremendous amount of time involved, and risk of complications of colonoscopy. The medical community has defined *high-risk* groups and is focusing its attention on these groups in order to reduce the incidence of cancer and to improve the cost-benefit and risk-benefit ratios for its patients. Traits of high-risk individuals are listed in Table 26-14.

Recommendations

The summary of recommendations of the US Preventive Services Task Force (USPSTF) is as follows: Screening for colorectal cancer is recommended for all persons aged 50 and older with annual fecal occult blood testing (FOBT), or sigmoidoscopy (periodically unspecified), or both.

There is sufficient evidence to determine which of these screening methods is preferable or whether the combination of FOBT and sigmoidoscopy produces greater benefits than does either test alone.

There is also insufficient evidence to recommend for or against routine screening with digital rectal examination, barium enema, or colonoscopy, although recommendations against such screening in average-risk persons may be made on other grounds. Persons with a family history of hereditary syndromes associated with a high risk of colon cancer should be referred for diagnosis and management.

Colonoscopy is recommended for blood in the stool, a past history of adenomatous polyps, a positive family history of colorectal cancer, a history of ulcerative colitis or FAP, or an adenomatous polyp found on flexible or rigid sigmoidoscopy. The last recommendation is based on the fact that about 30 percent of patients with a rectosigmoid adenoma will have synchronous neoplasms elsewhere in the colon.

High-Risk Individuals

Previous Neoplasia

Metachronous neoplasms, polyps or cancer, have been reported in 40 to 50 percent of patients with a primary colorectal cancer. Cancer has developed in 2 to 5 percent of these patients. The risk of subsequent cancer in patients who have had an adenomatous polyp removed varies from 2.7 to 7.7 times that of the general population. The risk of cancer is increased by polyp number, polyp size, and the presence of villous architecture in the polyp. The National Polyp Study reported that 32 percent of patients who had adenomatous polyps removed via colonoscopic polypectomy were found to have metachronous neoplasms at colonoscopy 3 years later. In addition, colonoscopic polypectomy resulted in a lower-than-expected incidence of colorectal cancer in these patients, suggesting that routine surveillance may reduce the incidence of metachronous cancer. The influence of surveillance on survival is unknown. Patients who have had resection of a cancer or a polyp should have routine surveillance.

The following are guidelines for surveillance after resection of a colorectal cancer. These recommendations may vary depending on the number of polyps, the ease of the examination, and the age of the patient (Fig. 26-67). The plan can be summarized as follows:

- (1) Colonoscopy in the perioperative period to remove all synchronous polyps and detect synchronous cancers.
- (2) Colonoscopy 1 year after surgery to check for missed synchronous lesions and to detect any new lesions. Colonoscopy can be repeated yearly until no further lesions are identified.
- (3) Colonoscopy 3 years after a negative 1-year examination.
- (4) Colonoscopy every 5 years after a negative 3-year examination.

A similar surveillance strategy can be used after colonoscopic removal of adenomatous polyps, with the exception that the first follow-up colonoscopy can be performed 3 years after polypectomy.

Family History

There is a significantly increased risk of cancer in individuals with a family history of colorectal cancer. This risk depends on the number of first-degree relatives who have had cancer. This information should be used to begin earlier screening with colonoscopy of the group at risk. Patients who are members of families with FAP and Lynch syndromes also should have routine surveillance. The National Polyp Study also has demonstrated an increased risk of colorectal cancer in individuals whose first-degree relatives have adenomatous polyps.

It is very common for young patients (under 40 years) with colorectal cancer to have first-degree relatives with colon cancer (89 percent) and to be part of an HNPCC family (18 percent). Therefore, it is advisable for family members of young patients with colon cancer to be screened with colonoscopy at an early age (25 years old).

Hereditary Nonpolyposis Colon Cancer

HNPCC is an autosomal dominant disease that carries a 50 percent risk of cancer in family members. Metachronous colon cancer is also possible in affected individuals. The appropriate screening or surveillance protocol for these individuals is not known. Genetic testing for microsatellite instability as an indicator of errors in mismatch repair is not adequate because a large proportion of tumors in patients without HNPCC have microsatellite instability. The use of white blood cell mutational analysis in family members of patients with HNPCC is under investigation. Recommendations for individuals with HNPCC include total abdominal colectomy and ileorectal anastomosis with yearly screening of the residual rectum. Family members in HNPCC families should have colonoscopy every 2 years beginning at age 18 or at least 5 years before the age at diagnosis of the youngest family member with cancer. Mutational analysis eventually may be used to detect one of the at least four defects (MSH2, MLH1, PMS1, PMS2) in the mismatch repair genes on chromosomes 2 and 3 in individuals at risk for cancer. The need for prophylactic colectomy rather than continuous surveillance colonoscopy has not been established.

Ulcerative Colitis

Patients with ulcerative colitis for longer than 10 years should be examined by colonoscopy and biopsies for dysplasia, as discussed previously, with treatment based on the fact that the cancer risk in the setting of severe dysplasia is 30 percent (see Fig. 26-50).

Polyps

Hamartoma Peutz-Jeghers Syndrome

The combination of hamartomatous polyps of smooth muscles and mucocutaneous pigmentation was first described in 1896 by Hutchinson. The existence of *familial* hamartomatous polyps originally was described by Peutz and then again in 1949 in a follow-up article by Jeghers. The syndrome consists of pigmentation, produced by melanin in the mucocutaneous areas, and of hamartomas of intestinal smooth muscle throughout the gastrointestinal tract. This is an autosomal dominant syndrome and carries with it a well-documented risk of cancer in the breast, cervix, ovary, fallopian tubes, thyroid, lung, skin (basal cell), gallbladder, pancreas, testicle, and bile ducts. An overall risk of 2 to 13 percent for developing intestinal cancer arising in the stomach, small intestine, and colon has been documented in these patients.

Symptoms of the hamartomas include bleeding or intestinal obstruction secondary to intussusception. Treatment includes removing any polyp that is larger than 1.5 cm, even if asymptomatic. If a surgeon is forced to operate for symptoms, every effort should be made to completely clear the polyps with intraoperative endoscopy and polypectomy. Cancer, if present, is usually found in the mucosa overlying or adjacent to the hamartoma. After an operation to remove the polyps, colonoscopy is recommended every other year to survey for recurrence of colonic polyps. Patients also should undergo periodic screening for breast, cervix, testicle, ovary, upper gastrointestinal, and pancreatic cancers.

Juvenile Polyposis

Juvenile polyposis was first described by Verse in 1908. The familial inheritance of these polyps was reported by Veale at St. Mark's Hospital in 1966. Juvenile polyps occur as

cystic dilatations of glandular structures within the fibroblastic stroma of the lamina propria. Juvenile polyps usually cause symptoms of gastrointestinal bleeding or obstruction due to intussusception, with the polyp as the lead point. These complications require surgical or endoscopic removal of the polyp. There are varying patterns of occurrence of juvenile polyps. Approximately 1 percent of all infants have a single juvenile polyp discovered in infancy. A second peak incidence is seen at 25 years of age. The most common cause of gastrointestinal bleeding in a child is a juvenile polyp. There has been no malignant potential documented for these isolated juvenile polyps.

Isolated polyps are best treated with polypectomy, primarily for establishing the correct diagnosis. No other treatment is indicated. Autoamputation of the polyp often causes the initial bleeding. Once the bleeding has stopped, no further treatment is necessary.

Multiple polyposis coli (diffuse juvenile polyps) is an autosomal dominant syndrome with high penetrance that carries an increased risk of cancer in the gastrointestinal tract and in other nongastrointestinal tissues. The syndrome usually causes bleeding, obstruction due to intussusception, or malnutrition due to excessive protein loss. Diffuse juvenile polyposis occurs in less than 1 percent of patients with juvenile polyps and may carry an even higher risk of cancer when mixed or heterogeneous types of polyps are present (polyps of both adenomatous and juvenile types). Adenomas have been documented on juvenile polyps as well as in adjacent mucosa. The malignant potential has been estimated at approximately 10 percent in patients with the multiple polyposis coli type of juvenile polyposis and is even higher in patients with the diffuse variety. As in the other polyposis syndromes, the risk of cancer appears to increase with the duration of the disease and the age of the patient.

The multiple juvenile polyposis syndrome requires colonoscopic polypectomy in patients with a few colonic polyps because of the possibility of bleeding, intussusception, and a low but real incidence of adenomatous change. In patients with this condition, it is sometimes best to perform an abdominal colectomy with ileorectal anastomosis and to continue to screen the rectum. The entire colonic and rectal mucosa should be removed in patients with the diffuse form of juvenile polyposis and an ileal reservoir constructed with ileal pouch–anal anastomosis.

Hyperplastic Polyps

Hyperplastic polyps are common in the colon. They have been estimated to be 10 times more common than adenomas. Their typical histologic findings consist of epithelial dysmaturation and hyperplasia. They are usually less than 5 mm in diameter and show a thickened mucosa without atypia. There is usually no evidence of adenomatous change. They are associated with an increase in myofibrils and T cells in the lamina propria. The clinical significance of hyperplastic polyps continues to be the subject of some debate, but most studies indicate that they are not premalignant lesions and are not associated with adenomatous change elsewhere in the colon. *Serrated or mixed polyps* have a combination of hyperplasia and adenoma. These polyps have been associated with the development of cancer.

Hyperplastic polyps tend to increase in incidence with age. There is also a rare inherited syndrome of hyperplastic polyposis in which larger hyperplastic polyps occur in young adults. Hyperplastic polyps can be biopsied, destroyed, or removed during colonoscopy.

Other Lesions

There are several other less well-known and rare hamartomatous syndromes. *Cowden's syndrome* is an autosomal dominant defect that includes hamartomas of all three embryonal cell layers. Tricholemmomas, breast cancer, thyroid disease, and gastrointestinal polyps with occasional gastrointestinal cancers are typical of the syndrome. Treatment is based on symptoms. Polyps should be removed, and the patient should be screened for other cancers.

Cronkhite-Canada syndrome is typified by nonfamilial juvenile polyps with other epidermal changes but no evidence of malignancies. The polyps should be removed only if they cause symptoms.

The *Ruvalcaba-Myhre-Smith syndrome* includes developmental abnormalities, microcephaly, and juvenile polyps. It is a very rare syndrome that occurs in males, and to date, no cancers have been documented. The polyps should be removed when symptomatic, and other members of the family should be screened.

Adenoma Pathology

The *adenoma*, or *adenomatous polyp*, of the colon or rectum is a benign neoplasm. It represents proliferation and unrestricted cell division in a well- circumscribed area of glandular epithelium within the colonic mucosa. The surface is usually rounded and lumpy, like a raspberry, or flat and velvety with a shaggy appearance. Polyps can exist in a pedunculated (with a stalk), sessile (flat), or semisessile (raised) form. Each of these macroscopic forms may have similar histologic adenomatous appearances of the epithelium and the same cytology. The histologic architecture of the polyps may vary from branched tubular glands, to fingerlike, elongated villi, to villous configuration.

Polyps are classified as *tubular adenoma*, *tubulovillous adenoma*, or *villous adenoma* depending on the predominant pattern. In general, 65 to 80 percent of all adenomatous polyps removed are tubular adenomas, 10 to 25 percent are tubulovillous, and only 5 to 10 percent are pure villous adenomas. Tubular adenomas usually are pedunculated, and villous adenomas usually are sessile. However, all types of histologic characteristics can be found in each type of polyp. Incompletely differentiated epithelial cells are found along the fingerlike villi. The degree of differentiation decreases as the polyp becomes more like a cancer. The term *severe atypia* is now accepted for the finding of a malignancy in the epithelium of a polyp that has not invaded the muscularis mucosae of the bowel. Such lesions previously were referred to as *carcinoma in situ*.

Polyp-Cancer Sequence

It is generally accepted that a benign adenoma has been the precursor to a colorectal cancer in the majority of patients. However, Shimoda has shown that cancers also may arise de novo in nonadenomatous mucosa. These flat cancers usually are advanced and seem to have arisen as intramucosal cancers with no evidence of preceding polyp formation. This finding is consistent with a rapid progression of the genetic changes postulated by Fearon and Vogelstein as a polyp changes to a cancer (Fig. [26-68](#)).

The evidence for the existence of an adenoma-carcinoma sequence includes the following:

(1) Polypectomy has been shown to decrease the incidence of cancer. Patients with small adenomas have a 2.3 times increased risk of cancer after polypectomies as compared with an 8-fold increase in the risk of cancer in patients who do not undergo polypectomy.

(2) Colonic adenomas are observed more frequently in patients with cancer. Nearly 30 percent of all patients with a colorectal cancer also will have a synchronous polyp.

(3) Larger adenomas are found to contain cancer and severe dysplasia more often than are smaller polyps. Sixty percent of adenomas larger than 2 cm are villous adenomas. Villous adenomas have a 40 percent risk of containing a cancer, as compared to a 22 percent risk of cancer in tubulovillous adenomas and a 5 percent risk of cancer in tubular adenomas; however, the size of the polyp seems to be more important than the histologic features. The risk of a cancer in a villous adenoma, tubulovillous adenoma, or tubular adenoma larger than 2 cm is 53, 46, and 35 percent, respectively.

(4) Severe dysplasia has been shown to progress to cancer in polyps. The differentiation between carcinoma in situ and invasive cancer relies on the depth of invasion of the dysplastic area. Invasion beneath the muscularis mucosae defines invasive adenocarcinoma in a polyp because the cancer cells at this depth have access to the vascular and lymphatic systems.

(5) Residual adenomatous tissue is found in the majority of invasive cancers. This is presumptive evidence that the cancer has arisen within the polyp and has progressed to replace the majority of the polyp.

(6) Patients with familial adenomatous polyposis (>100 polyps) develop cancer 100 percent of the time if the colon is not removed. The adenomas of FAP are histologically the same as sporadic adenomas.

(7) There is a high prevalence of adenomas in populations with a high rate of cancer. This seems to indicate that the polyp is a precursor or a necessary factor in the development of cancer.

(8) It has been shown that the presence of an adenoma places a patient at a lifetime risk for the development of cancer.

(9) The peak incidence for the discovery of colonic polyps is at 50 years of age. The peak incidence for the development of cancer is at 60 years of age. This would indicate that there is a 10-year time span for the conversion of the adenomatous polyps to cancer. Investigators at the Mayo Clinic reported that a polyp larger than 1 cm has a cancer risk of 2.5 percent in 5 years, 8 percent in 10 years, and 24 percent in 20 years.

The adenoma-carcinoma sequence suggests that colonic mucosa progresses through stages to the final development of an invasive cancer. Normal epithelium is stimulated by some event to allow undifferentiated dividing cells to leave the crypts and move to the surface of the villi. Continued proliferation of these cells on the surface of the mucosa results in a polyp or adenoma. As proliferation continues, the glands begin to resemble normal tissue less and less. Eventually this disorganized growth crosses the muscularis mucosae barrier and becomes invasive cancer.

Treatment Pedunculated Polyps

Pedunculated polyps have a stalk that is usually less than 1.5 cm in diameter. Colonoscopic polypectomy is the best treatment for most pedunculated polyps. The cautery snare is placed at a point on the stalk to adequately remove the polyp with a clear margin from the head but distant enough to avoid thermal injury to the colonic wall at the base of the stalk. It is also important to avoid transmission of electric current via the head of the polyp to the opposite wall of the colon. Complete removal and retrieval of the polyp are essential for histologic diagnosis (Fig. [26-69](#)).

Semisessile Polyps

Semisessile polyps have a broad pedicle, larger than 1.5 cm. These polyps usually can be removed in piecemeal fashion if they do not have a malignant appearance. Bites of 0.5 to 1.5 cm are taken with the cautery snare until the stalk is seen. It is important to mark the area with 0.1 mL of India ink as a tattoo in the mucosa to facilitate repeat colonoscopic examination or surgical removal of the same site.

Sessile Polyps

Sessile polyps larger than 2 cm usually can be removed in piecemeal fashion also (Fig. 26-70). Small, 0.5- to 1.5-cm bites are taken to avoid burning the full thickness of bowel. A lower current also helps to avoid full-thickness burning. A “second look” colonoscopy and polypectomy is necessary if residual tissue is left behind as in the semisessile lesion.

Colectomy

Cancer in the head of a polyp may be treated by colonoscopic polypectomy (Fig. 26-71). Colectomy must be performed when the cancer within the head of the polyp has unfavorable features. Because the incidence of nodal metastases in these patients varies widely (1 to 25 percent in different series), various characteristics of excised polyps have been examined to improve the estimation of this risk, including level of invasion of the malignant process into the polyp; local invasion of lymphatic, vascular, and neural tissues; degree of differentiation of the malignant cells; and DNA ploidy. If the neoplasm is limited to the mucosa or invades only the head of a pedunculated polyp, the risk of lymph node metastasis is small (0 to 3 percent), and patients may be considered for close follow-up rather than resection. If the carcinoma reaches the base of the polyp, or if the lesion is sessile, then the risk of lymphatic spread may be as high as 10 to 27 percent. Intermediate lesions that invade only the neck or the stalk of the polyp are rarely associated with lymph node metastases unless the lesion is poorly differentiated or there is lymphovascular invasion. According to Nivatvongs, the finding of lymphatic or vascular invasion, poorly differentiated adenocarcinoma, or cancer close to the resection line of the stalk indicates the need for colonic resection. The risk of local recurrence is at least 10 percent, and the risk of spread of cancer to lymph nodes is approximately 10 percent in these patients. It should be noted that if a patient does not undergo resection, colonoscopic follow-up may not detect persistent or recurrent tumor because the lesion may reside outside the lumen of the bowel. Each case must be individualized, taking into consideration the life expectancy, operative risk, and personal philosophy of the patient.

A sessile polyp, by definition, has no stalk, and the submucosa is immediately adjacent to the muscularis propria. The invasion of the cancer through the muscularis mucosae into the submucosa puts the patient at high risk for local recurrence and spread of cancer to regional lymph nodes. A fold of adjacent mucosa is occasionally confused as the pedicle of a sessile polyp. Therefore, even if completely excised, the sessile polyp with an invasive carcinoma requires colectomy for complete cure. Laparoscopic colectomy may be a less invasive approach to managing polyps that are benign in appearance and have no obvious cancer present on biopsy analysis but are too large to be removed colonoscopically.

Villous Adenoma of the Rectum

Villous adenomas of the rectum are typically flat, velvety, and soft sessile polyps within the rectum. They occasionally present with watery diarrhea and hypokalemia. The finding of a large (>4 cm) villous adenoma in the rectum, with areas of induration, indicates a very high risk for cancer (90 percent). Transrectal ultrasonography of the villous lesion is helpful to determine the thickness of the lesion. Ultrasonography, however, is unable to distinguish between carcinoma in situ and invasive cancer. Because of the risk of sampling error in these large, exuberant lesions, the only adequate biopsy is complete excision, preferably transanally if possible. If cancer is present, the patient should be treated with appropriate resection. The transanal excision should include adequate peripheral margins for complete cure if cancer is present. It is helpful to inject the submucosal layer with epinephrine both to raise the lesion from the underlying muscle and to reduce blood loss. The defect should be closed with suture to provide primary healing and to mark the site. There is a high risk of recurrence if inadequate excision is performed.

Occasionally, a villous tumor will cover the entire mucosal surface of the distal rectum. If the polyp appears to be benign, a coloanal anastomosis after distal mucosal proctectomy and full-thickness proximal proctectomy are the preferred treatment. The coloanal anastomosis allows preservation of the anal sphincter and removes all the mucosa at risk in the rectum. It is important to document by frozen section the absence of cancer in this situation unless the tumor is well above the anal canal and there is very little risk of invasion into the levator or external sphincter muscles.

The use of a colonic J-pouch in selected individuals may improve their function after a coloanal anastomosis. The terminal 10 to 15 cm of the left colon are folded into a J, and the intervening septum is divided and the two limbs stapled together with a linear-cutting gastrointestinal anastomosing stapler introduced through a hole in the apex of the J. The coloanal anastomosis is then performed using an end-to-end intraluminal circular stapler or a hand-sewn anastomosis to the anal canal mucosa. A protecting loop ileostomy is usually placed if there is concern for the anastomotic integrity for any reason.

Thermal ablation of the villous adenoma has been used in some patients in whom local excision is not possible. The disadvantages of thermal ablation include the risk of undiagnosed cancer or cancer developing in the base of a repeatedly cauterized, scarred segment. If the villous adenoma recurs after several laser treatments, the patient should be referred for surgical treatment.

In the past, transsphincteric (York-Mason) and transsacral (Kraske) approaches to the rectum were used to remove villous adenomas and allow sphincter preservation. These methods are currently used infrequently because the coloanal anastomosis and low stapled anastomotic techniques allow preservation of anorectal function and appear to be more effective in treatment of the disease.

Colon Cancer

Incidence

Cancer of the colon and rectum is the most common cancer of the gastrointestinal tract. In women, colorectal cancer is second only to breast cancer as a cause of cancer-related death. In men, it is the third most common lethal cancer, preceded by carcinoma of the lung and prostate. The incidence of this malignant tumor increased in the United States during the first part of this century but has stabilized over the past four decades.

It is estimated that approximately 131,000 new cases of colorectal cancer (94,000 colon and 37,000 rectal) will develop in the United States in 1997, and approximately 58,300 patients will die of the disease. Rectal cancer is slightly more common in men, whereas there is a slight predominance of colon cancer in women. An American has approximately a 5 percent probability of developing colorectal cancer during a 70-year life span. Most cases of colorectal cancer are diagnosed in patients over the age of 50, and the incidence of the disease rises steadily after that age. Despite the clear relationship with aging, colorectal cancer is not strictly a disease of the elderly; between 6 and 8 percent of cases occur in individuals under the age of 40. The onset of familial and hereditary forms of the disease occurs at a much earlier age, typically around the third decade.

Signs and Symptoms

The signs and symptoms of colorectal cancer are varied and nonspecific. The symptoms that most often prompt patients to seek medical attention include rectal bleeding, a change in bowel habits, and abdominal pain. Whether a patient has any noticeable symptoms or what form the symptoms take depends somewhat on the location of the tumor and the extent of disease.

Subacute Presentation

Tumors in the *right colon* typically do not cause changes in bowel habits (although large, mucus-secreting tumors may cause diarrhea). Patients might notice dark or tarry stools, but more often these tumors cause truly occult bleeding, which is not detected by the patient. Such chronic blood loss may cause iron-deficiency anemia, with resulting fatigue, dizziness, or palpitations. When a postmenopausal woman or an adult man develops iron-deficiency anemia, colorectal cancer should be suspected and appropriate diagnostic studies performed. Because the bleeding associated with colon tumors tends to be intermittent, negative tests for occult blood in the feces do not rule out the presence of a large-bowel cancer.

Lower abdominal pain is more often associated with tumors located in the narrower left colon. The pain is of a cramping nature and may be relieved by bowel movements. These patients are more likely to notice a change in bowel habits and the passage of bright red blood.

Less common nonacute symptoms of large-bowel cancer include weight loss and fever. About 50 percent of patients who have other symptoms also report a loss of body weight, but weight loss is almost never the sole manifestation of a colorectal tumor. Fever is an unusual presenting symptom. Septicemia is rare but can occur with any stage of large-bowel tumor; *Streptococcus bovis* bacteremia is highly suggestive of colorectal carcinoma.

Rarely, colon cancer will present as the lead point of colonic intussusception in an adult. In all adults who are found to have obstruction or partial obstruction because of intussusception, a colonoscopy or air-contrast barium enema is warranted to rule out a colon cancer.

Acute Presentation

A significant proportion of patients are first seen with acute symptoms reflecting obstruction or perforation of the large bowel. Colonic obstruction is highly suggestive of cancer, particularly in older patients. Complete obstruction occurs in less than 10 percent of patients with colorectal cancer, but it is an emergency that requires immediate diagnosis and surgical treatment. Ideally, this surgical emergency could be avoided by early recognition of changes in bowel habits. Patients with complete obstruction complain of inability to pass flatus or feces, cramping abdominal pain, and abdominal distention. Examination reveals a distended, tympanitic abdomen; occasionally the obstructing tumor can be palpated as an abdominal mass.

If the obstruction is not relieved and the colon continues to distend, the pressure in the intestinal wall can exceed the capillary pressure, and oxygenated blood will not reach the bowel wall, resulting in ischemia and necrosis. In such situations the patient will complain of severe abdominal pain, and abdominal examination will reveal rebound tenderness and decreased or absent bowel sounds. If not treated immediately, the necrosis will progress to perforation with fecal peritonitis and sepsis.

The large bowel also can perforate at the tumor site, probably because a transmural tumor loses its blood supply and becomes necrotic. Such cases are easily mistaken for acute diverticulitis, and the inflammatory process may be confined to the site of the perforation; however, in some cases a perforation may not be contained, resulting in generalized peritonitis. In rare cases, perforation into an adjacent organ (usually the bladder or vagina) occurs and is manifested by pneumaturia, fecaluria, or feculent vaginal drainage.

Unfortunately, the first signs of colon cancer may be caused by metastatic disease. Massive liver metastases may cause pruritus and jaundice. Ascites, enlarged ovaries, and scattered deposits in the lungs detected by a chest radiograph can be caused by an otherwise asymptomatic colon cancer. Treatment is rarely beneficial in such advanced disease.

Diagnosis and Evaluation

In patients with symptoms suggestive of colon cancer, the definitive diagnosis is usually established by endoscopy (flexible sigmoidoscopy or colonoscopy) or barium enema. Other tests are necessary to evaluate the extent of disease and search for metastases.

Barium studies of the colon may demonstrate the primary lesion (Fig. 26-72) and reveal a synchronous cancer elsewhere in the colon (which occurs in 3 to 5 percent of patients). Dietary restrictions and cathartics usually are necessary to prepare the patient for barium enema. However, if acute colonic obstruction is suspected and plain films of the abdomen

reveal dilated colon, water-soluble contrast study may be obtained with no preparation, to reveal the location and nature of the obstructing lesion.

Colonoscopy is currently the most accurate and complete examination of the large bowel. Colonoscopy and barium enema studies should be regarded as complementary to each other. The purpose of a *complete* colon and rectal evaluation for patients with large-bowel cancer is to rule out synchronous carcinomas and polyps.

A chest x-ray should be taken routinely to rule out pulmonary metastasis. CT of the abdomen is being used increasingly to assess the extent of invasion of the primary tumor and to search for intraabdominal metastatic disease.

Elevated liver function test results, including alkaline phosphatase, lactate dehydrogenase, bilirubin, and transaminase enzyme determinations, can suggest liver metastases. These tests are useful in the postoperative follow-up and, if elevated, can suggest the need for CT scan to search for hepatic metastases.

The serum level of CEA is important in the evaluation of patients with colorectal cancer. This antigen, a glycoprotein, is present in embryonic and fetal tissue and in colorectal cancers but is absent in normal adult colonic mucosa. In patients with cancer that has not penetrated the bowel wall, the serum CEA level is usually not elevated. The test is somewhat nonspecific, since it can be elevated in patients with tumors of the lung, breast, stomach, or pancreas. Levels also may be elevated in smokers and in patients with cirrhosis, pancreatitis, renal failure, and ulcerative colitis. Thus the test is not useful for screening.

An elevated CEA level does have a high correlation with tumor recurrence and with the presence of metastases from colorectal cancer. If the CEA level is elevated before operation, the recurrence rate is higher, regardless of the disease stage. Postoperative CEA levels may indicate the completeness of surgical resection or the presence of occult metastases. A rising CEA titer after treatment may indicate a recurrence, before clinical disease becomes evident. When used alone, the CEA assay is 70 percent accurate in predicting the development of liver metastases within 1 year; in combination with CT scans, accuracy increases to up to 90 percent.

Surgical Treatment Preoperative Bowel Preparation

Wound infection and intraabdominal abscess formerly were common problems following colorectal surgery. The primary source of infection was the endogenous bacteria in the bowel lumen, with *E. coli* being the most common aerobic species and *Bacteroides fragilis* the most common anaerobic organism involved in septic complications. The large bowel cannot be sterilized prior to surgery, and colorectal operations are classified as “clean-contaminated” procedures by the American National Research Council; operations during which the large bowel is opened virtually always expose the operative field to colonic bacteria. Accordingly, steps must be taken before the operation to reduce the bacterial population as much as possible. The preoperative preparation generally includes two components: *mechanical cleansing* and *antibiotic administration*.

There is no absolute consensus regarding appropriate mechanical bowel preparation. A decade ago the most common method was a 3-day regimen consisting of a low-residue or liquid diet combined with laxatives (magnesium citrate or castor oil) and enemas. This approach was time- consuming, was often hampered by incomplete patient compliance, and severely restricted the patient's caloric intake for 3 days before major surgery. Other approaches are used more commonly today, including mono- and dibasic sodium phosphate purgatives and whole-gut lavage with polyethylene glycol (Golytely or Colyte).

A commonly used bowel preparation today is an isotonic lavage solution containing polyethylene glycol (PEG) in a balanced salt solution. PEG also acts as an osmotic purgative, but it does not serve as a culture medium for bacteria and is not associated with the production of explosive colonic gas. With this method of cleansing, the patient may have a light meal at lunch and clear liquids the evening before surgery. To achieve adequate cleansing of the colon, an average of 4 L of PEG solution must be ingested within 4 h. The solution can be drunk or instilled through a small nasogastric tube. This method has been associated with less fluid retention than saline lavage but is still somewhat uncomfortable for the patient. Metoclopramide may be given one-half hour before starting the lavage to reduce nausea.

Mono- and dibasic sodium phosphate acts as a purgative when given in adequate volume (45 mL) and accompanied by large volumes (24 oz) of clear liquids. Two doses (noon and 6 p.m.) the day prior to surgery are adequate to achieve a complete mechanical bowel preparation. Patients with renal failure or severe hypertension on sodium restriction should be given this preparation cautiously because hypocalcemia, hyperphosphatemia, hypernatremia, and acidosis may occur. Patients with severe congenital megacolon may develop hypernatremic dehydration. Fleet's phospho soda and clear liquids has become a preferred alternative to whole-gut irrigation and is better tolerated than high-volume preparations, with equal results in bowel cleansing.

Mechanical bowel preparation will reduce the absolute number of colonic bacteria, but the bacterial concentration in the lumen seems unaffected, and the postoperative wound infection rate without antimicrobial use remains unacceptably high (between 30 and 60 percent). Reduction of colonic bacterial concentration can be achieved by oral or intravenous antibiotic preparations, and there is no consensus concerning the ideal preparation. Most surgeons use a combination of oral antibiotics (neomycin plus erythromycin, 1 g each at 1 p.m., 2 p.m., and 11 p.m. the day before operation or 0.5 g of neomycin instead of erythromycin) and an intravenous broad-spectrum antibiotic administered immediately before the operation. The timing of the administration of antibiotics is important; the postoperative infection rate can be reduced to well below 10 percent with proper bowel cleansing and preoperative antibiotic administration, but postoperative antibiotics do not appear to be effective.

Operative Technique: Colon Carcinoma

The objective in the treatment of carcinoma of the colon is to remove the cancerous segment of bowel, the mesentery containing its lymphatic drainage, and any organ that has been directly invaded by the tumor. Since lymphatic channels of the colon accompany the main arterial supply, the length of the bowel resected depends on which vessels are supplying the segment containing the cancer (Fig. 26-73). Surgical techniques that minimize the risk of intraoperative spillage of tumor cells are essential. The arterial supply to the uninvolved intestine must be preserved so that intestinal continuity can be restored by anastomosis.

During the operation, the peritoneal cavity is carefully explored, and the liver is examined to identify any unsuspected metastases. The intestine is encircled with ties, proximal and distal to the tumor, to prevent intraluminal spread of cancer cells during manipulation of the bowel. The main segmental artery supplying the cancerous segment of bowel is ligated and divided, allowing resection of the mesentery in continuity with the bowel. If the tumor is adherent to or invading adjacent organs such as the small bowel, ovaries, uterus, or kidney, an en bloc resection should be performed if technically feasible. Adhesions between the tumor and contiguous organs are often inflammatory, but this cannot be determined before resection. If the adhesions prove to be cancerous and they are merely divided instead of removed by an en bloc resection, the chance for cure will be lost. If all tumor cannot be removed, a palliative colon resection is generally indicated to relieve symptoms and prevent future obstruction and bleeding from the primary tumor. In the rare situation of a nonresectable tumor, a bypass operation should be considered to relieve or prevent intestinal obstruction. If multiple colon carcinomas are present, or if a colon carcinoma is associated with multiple neoplastic polyps, a subtotal colectomy (total abdominal colectomy) with ileorectal anastomosis should be considered.

Carcinoma of the right colon is treated by right hemicolectomy, which includes excision of approximately 10 cm of terminal ileum. The ileocolic artery, right colic artery, and right branch of the middle colic artery are ligated and divided, and an anastomosis is fashioned between the ileum and the left transverse colon. The anastomosis can be either hand-sewn or achieved by stapling instruments.

Carcinoma of the hepatic flexure or the right transverse colon is treated by extending the hemicolectomy to include the middle colic artery along with its left branch (see Fig. 26-73).

Carcinoma of the midtransverse colon is treated by extending the hemicolectomy even farther and performing the anastomosis between the ileum and the proximal descending colon. An alternative, in this situation, is to ligate only the middle colic artery and excise the transverse colon, making an anastomosis between the ascending and descending colon.

In a similar fashion, the surgical treatment of left colon cancer incorporates resection of the arteries and accompanying mesentery, as shown in Fig. 26-74.

The resected specimen should be inspected immediately by a pathologist to assess the surgical margins. A 5-cm margin of normal bowel on either side of the tumor is ideal; however, margins as small as 2 cm from the tumor edge may be satisfactory if adequate mesentery is resected with the specimen. Wider margins are required for a poorly differentiated or anaplastic carcinoma. While the anastomosis can be fashioned by either hand-sewn or stapling techniques, it is essential that the bowel edges be meticulously approximated to form a lumen of adequate size, that there be no tension on the anastomosis, and that the blood supply to both sides of the anastomosis is adequate.

The functional results after colectomy vary according to the segment of colon resected. The right colon absorbs approximately 1000 mL of fluid delivered from the terminal ileum. After a right colectomy, the stool generally is softer, and 750 mL/day is passed rather than 250 mL. A left colectomy or sigmoid colectomy generally results in several small stools per day but the same volume as before surgery. Patients who require a total abdominal colectomy with ileorectal anastomosis will experience 4 to 10 bowel movements per day immediately after their operation from 1000 mL of ileal contents entering the rectum during a 24-h period. Over time this will decrease as the ileum compensates for loss of the right colon and begins absorbing bile salts and more water. Younger patients tolerate removal of the colon better than the elderly, but this option should not be withheld from older patients.

Laparoscopic colectomy has been described for all types of colorectal disease. The first cases were reported in 1991, and since that time, numerous reports have entered the literature. Several large series have documented the safety and potential efficacy of this technique in the management of colorectal disease, including cancer. Randomized control trials have not confirmed these findings, and the use of laparoscopic colectomy in the treatment of cancer is controversial. Laparoscopic techniques such as laparoscopic segmental colectomy, abdominoperineal resection, rectopexy, ostomy construction and takedown, and small-bowel resection can provide earlier recovery (shorter postoperative ileus and hospital stay) and less pain for most patients regardless of the reason for operation. Laparoscopic colectomy requires advanced skill, thorough knowledge of intraabdominal anatomy, and an ability to recognize structures from unusual angles and perspectives. The same principles of surgical technique that guarantee a good outcome for open operations apply to laparoscopic procedures.

Emergency Operations

Obstruction

When a colon or rectal cancer causes complete obstruction, immediate surgical treatment is necessary. Obstructing cancer of the right or transverse colon usually can be treated by resection and primary anastomosis. The entire colon proximal to the obstruction should be resected, and the terminal ileum then should be anastomosed to the remaining normal colon. In such cases, diversion by proximal ileostomy is rarely needed.

Obstruction by a left-sided cancer presents a more difficult problem. If the obstruction is only partial, with feces and gas present in the rectum, it may be possible to proceed with preoperative cleansing of the colon as described earlier. However, when radiography reveals a distended colon with no air in the rectum, the obstruction is complete, and emergency surgical treatment is mandatory. Water-soluble contrast should be performed to confirm the presence of an obstruction and to determine its exact location.

The appropriate surgical procedure depends on the location of the obstruction, the initial surgical findings, and the surgeon's experience and judgment. The current trend is toward

immediate resection of the lesion. However, if the colon is extensively dilated and the patient's condition unstable, it may be appropriate to relieve the obstruction by a colostomy placed proximal to the lesion (described in the section on rectal cancer). After the patient's condition has stabilized, the bowel can be properly prepared and the obstructing lesion resected at a later time. If the surgeon feels that it is possible to resect the lesion, several options are available, including the following:

(1) Primary resection without anastomosis, bringing the proximal end of the colon to the abdominal wall as a colostomy and the distal end to a separate location on the abdominal wall as a mucous fistula. If the tumor is located so far distally that the distal end of colon cannot be exteriorized, the Hartmann procedure is used.

(2) Primary resection with anastomosis. Anastomosis between two segments of unprepared bowel is associated with an anastomotic dehiscence rate above 20 percent. There has been interest in cleansing the proximal bowel at the time of emergency celiotomy by the technique of intraoperative colonic lavage. A catheter is inserted into the cecum through an appendicostomy, and several liters of saline solution are instilled. The solution washes out the bowel contents through a large-bore catheter (or sterile anesthesia tubing) that has been placed in the colon proximal to the cancer. The cancerous segment of bowel, including the site of insertion of the evacuating tubing, is then excised, and an anastomosis is fashioned using the prepared, cleansed colon.

(3) Primary resection with anastomosis and proximal protective colostomy or ileostomy.

(4) Subtotal colectomy with ileosigmoidostomy. This approach is particularly suited for treating obstructing lesions of the sigmoid colon. The procedure requires more dissection and takes longer than segmental resection, but it eliminates the problem of synchronous polyps or cancers and removes the entire obstructed distended segment. In addition, the excellent blood supply of the ileum helps to ensure that the anastomosis is secure and reduces the risk of anastomotic leakage.

Perforation

Cancer causing a perforation of the colonic wall represents a life- threatening surgical emergency. The diagnosis may not be obvious before celiotomy because the clinical picture can mimic a perforated peptic ulcer or diverticulitis with generalized peritonitis. Thorough exploration of the peritoneal cavity is mandatory. Often, it can be difficult to distinguish an inflammatory pelvic mass caused by diverticulitis from that caused by a perforated sigmoid colon cancer.

There are fewer surgical options for treating a perforated colon cancer than for an obstructing cancer. The goal of operation is to remove the diseased, perforated segment of bowel. It may be possible to fashion an anastomosis; however, an anastomosis of unprepared bowel fashioned in a contaminated field should always be protected by proximal colostomy or ileostomy. The temporary diverting stoma can be closed about 10 weeks after the emergency operation.

An alternative is to resect the perforated segment and exteriorize the proximal and distal limbs as described above (or to use Hartmann's operation for more distal lesions). After the patient has recovered from the initial surgery, intestinal continuity can be restored.

After the perforated segment has been resected, the peritoneal cavity should be thoroughly irrigated with saline solution to remove all visible contamination, and intravenous antibiotics should be continued postoperatively.

Every effort should be made to perform a curative operation for obstructing or perforated cancers. The prognosis is somewhat poorer for these patients, but the 5-year survival rate approaches 30 percent in patients with no obvious metastases who are treated by immediate resection of the lesion.

Staging and Prognosis

In the absence of obvious metastatic disease, the precise stage of colorectal cancer can be determined only after surgical resection and histopathologic analysis. Unlike other solid tumors, the size of the primary lesion has little influence on prognosis of colon cancer. The factors that are most closely related to outcome are (1) the depth of tumor penetration into the bowel wall, (2) the involvement of regional lymph nodes, and (3) the presence of distant metastases. Numerous staging systems have been developed over the past several decades, but the system proposed by Dukes in 1932 for description of rectal cancer has continued to be used widely because of its simplicity (Fig. [26-75](#)). The classification scheme proposed by Dukes concerned only rectal cancer and recognized three stages; however, the most often used variant of this system recognizes a fourth stage (distant metastases) and has been extended to include colon cancers. This system fails to include important prognostic information such as vascular invasion, perineural invasion, histologic differentiation, or DNA content of tumor cells. Nevertheless, the simplicity of the Dukes classification system and its consistent correlation with prognosis suggest that it will continue to be in use for some time.

The American College of Surgeons' Commission on Cancer has urged adoption of the TNM (tumor-node-metastasis) staging system (Fig. [26- 76](#)). This system separately identifies the depth of invasion of the tumor (T), the regional lymph node status (N), and the presence of distant metastases (M):

Primary Tumor (T)

TX—Primary tumor cannot be assessed.

T0—No evidence of primary tumor.

T1—Tumor invades submucosa.

T2—Tumor invades muscularis propria.

T3—Tumor invades through the muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissues.

T4—Tumor perforates the visceral peritoneum or directly invades other organs or structures.

Regional Lymph Nodes (N)

NX—Regional lymph nodes cannot be assessed.

N0—No regional lymph node metastasis.

N1—Metastasis in 1 to 3 pericolic or perirectal lymph nodes.

N2—Metastasis in 4 or more pericolic or perirectal lymph nodes.

N3—Metastasis in any lymph node along the course of a named vascular trunk.

Distant Metastasis (M)

MX—Presence of distant metastasis cannot be assessed.

M0—No distant metastasis.

M1—Distant metastasis.

The stage of the TNM system is as follows:

The TNM system provides more detailed pathologic information and can be converted easily to the simpler Dukes system. Stage I is equivalent to Dukes' Stage A, Stage II to Dukes' Stage B, Stage III to Dukes' Stage C, and Stage IV to Dukes' Stage D.

The 5-year survival rates clearly demonstrate the prognostic importance of disease staging. The best outcome is associated with Stage I disease, with more than 90 percent of patients surviving at 5 years. For Stage II disease, this figure drops to between 60 and 80 percent, and for patients with lymph node metastasis (Stage III), 5-year survival rates range from 20 to 50 percent. When distant metastases are present, fewer than 5 percent of patients survive for 5 years.

For all but Stage IV disease, survival rates have improved since the 1940s and 1950s. Whether this improvement is attributable to diagnostic or treatment advances is not clear. More thorough and precise staging procedures may now be responsible for eliminating or reducing the misclassification of patients, which can artificially and adversely affect the observed response to treatment.

Other disease factors that have a negative prognostic influence include poor histologic differentiation of the tumor (mucin-producing tumors and “signet ring” cell tumors have a poorer prognosis) (Fig. [26-77](#)), venous or perineural invasion by the cancer, bowel perforation, elevated CEA level, and aneuploid nuclei.

Adjuvant Chemotherapy

Colorectal carcinoma has been resistant to most chemotherapeutic agents. However, chemotherapy following extirpation of all detectable disease is theoretically appealing because effective agents should have an advantage if the tumor burden is minimal. Chemotherapy is most effective when the burden of carcinoma is smallest and the fraction of malignant cells in growth phase is highest. Recently, there have been indications that the combination of 5-fluorouracil (5-FU) and levamisole or 5-FU and leucovorin is associated with increased survival when administered postoperatively to selected patients with no apparent residual disease (*adjuvant chemotherapy*).

A large intergroup clinical trial examined the effect of levamisole alone, levamisole with 5-FU, and observation only in patients with resected colon carcinoma. Levamisole alone produced no significant effect, but the combination of 5-FU and levamisole improved disease-free survival rate and overall survival rates compared with surgery alone in patients with Stage III colon cancer. Therapy with 5-FU and levamisole reduced the risk of cancer recurrence by 39 percent, cancer-related deaths by 32 percent, and the overall death rate by 31 percent in these patients. There was no survival benefit in patients with Stage II disease who received chemotherapy. A combination of 5-FU and leucovorin has improved

survival rates in patients with Stage III colon cancer.

The role of adjuvant chemotherapy for rectal cancer is less well defined. Variation in surgical technique, particularly with regard to the extent of mesorectal excision and the use of pre- or postoperative radiation, makes comparison of available data difficult. The few prospective, randomized trials evaluating postoperative adjuvant chemotherapy suggest that there may be a modest survival advantage in treating Stage II and Stage III rectal cancer.

Long-Term Follow-Up

There is some controversy about the frequency of follow-up examinations for tumor recurrence in patients treated for colorectal cancer. Some physicians have adopted a nihilistic approach (because of poor prognosis once recurrent cancer is detected) and recommend that once a patient is discharged following surgery, further treatment should be given only if symptoms of recurrent disease develop.

A small group of patients, however, definitely benefit from detection and aggressive treatment of recurrent cancer. About 70 percent of recurrent cancers become detectable within 2 years of initial treatment and 90 percent within 4 years. Patients who have been treated successfully for colon or rectal cancer have a higher incidence of metachronous colorectal cancer, and early detection and treatment of these cancers can improve the prognosis for these patients. This fact alone should provide sufficient rationale for long-term follow-up of all patients treated for colorectal cancer.

Follow-up evaluation may include physical examination, sigmoidoscopy, colonoscopy, liver function tests, CEA assay, chest radiography, barium enema, liver scan, CT, and MRI.

Physical examinations following surgical treatment for colorectal cancer may assuage both patient and physician, but they are of little value in the early detection of recurrent disease. By the time a recurrent cancer has become palpable by abdominal examination, it is invariably unresectable.

Sigmoidoscopy is of some value when following patients treated with low anterior resection and anastomosis for rectal or sigmoid cancer because it allows direct inspection of the anastomosis. *Colonoscopy* is most useful for the detection of metachronous polyps or cancers in patients with previously treated colorectal cancer.

Both *liver function tests* and *CEA assay* can indicate the presence of liver metastases from colorectal cancer. A significant elevation of any of the liver function tests or a rising CEA level calls for a CT scan of the abdomen and a chest radiograph.

The principles of managing metastatic disease are similar for cancer of the colon and the rectum and are discussed in the following section on rectal cancer.

Rectal Cancer

Pathophysiology

As with colon cancer, the vast majority of malignant neoplasms of the rectum are adenocarcinomas. The significant premalignant conditions such as adenomatous and villous polyps, familial adenomatous polyposis, and ulcerative colitis are also the same. Adenocarcinomas of the rectum must be differentiated from squamous cell cancer of the anal canal because the management is entirely different. Malignant melanoma rarely can be found in the rectum, and its management again differs from that of adenocarcinoma. The prognosis of rectal malignant melanoma is so poor that wide resective surgery is not always indicated.

Rectal cancer is considered separately from colon cancer because of its anatomic location and configuration. Because the rectum resides within the confines of the pelvis, wide excision of the cancer and surrounding structures (as is possible with colon cancer) is usually impossible. The proximity of the rectum to the anal sphincter mechanism also creates unique problems of management. In order to achieve a curative distal margin beyond the cancer, a surgeon must consider the risk of injury to the sphincter mechanism. If the sphincter cannot be preserved to function perfectly, it should be removed. It is this need to remove the sphincter mechanism that results in the need for a colostomy, and it is wrong to jeopardize cure of a cancer to avoid a colostomy. The details of colostomy construction and care will be described later, but it is critically important for the patient to understand that a colostomy is usually constructed because of the anatomic location of the cancer, not its severity. Most patients assume that the need for a colostomy indicates a hopelessly incurable cancer.

Rectal cancer also requires special consideration because the innervation of the urogenital system lies in close proximity, as in fact do the organs of the urogenital tract (see Fig. 26-8). There is a high rate of impotence in men from radical treatment of rectal cancer, and we are reminded that accurate definitions of sexual dysfunction in women are lacking. The relationship of the rectum to the genitourinary system can be of supreme importance in determining the surgical procedure itself; the posterior wall of the vagina can be resected in continuity with an invasive rectal cancer, but a cancer invading the prostate or bladder base in a man requires a much more extensive and complicated procedure. The rectum also requires special consideration because it has a dual arterial blood supply (see Fig. 26-6), and the lymphatic channels of cancer metastasis follow the routes of the arterial system (see Fig. 26-7). The primary physiologic function of the rectum is to serve as a reservoir for fecal material, which can be stored until the individual chooses to empty it. Any disturbance of the reservoir or continence mechanism can result in significant handicap to the individual. This consideration is of prime importance in determining the treatment of rectal cancer. It is because of the distensible nature of the rectal reservoir that cancers can grow to considerable size before causing any symptoms. This fact makes screening for rectal, as well as colon, cancers mandatory. The organ is accessible, and asymptomatic (more curable) cancers should be sought by routine screening or surveillance, especially in individuals known to be at significant risk.

Perhaps the most unique aspect of the anatomy of the rectum is its easy accessibility. The anus allows access to the rectum with several therapeutic and diagnostic modalities, including the physician's finger. This easy access has resulted in consideration of tumor treatment less than the radical resective procedures that often require removal of the rectum and anus, necessitating construction of a colostomy.

These unique features of the rectum must be considered for the screening, diagnosis, and treatment of patients known to have or suspected of having rectal cancer. One must consider the *local* factors related to the rectum itself. The next level of consideration involves the relationship of the cancer to the structures *adjacent* to the rectum such as lymph nodes, sphincter mechanism, and surrounding organs. Perhaps the most important prognostic consideration lies in the status of the cancer with respect to *distant* metastasis. Rectal cancer can spread through the lymphatics of the mesenteric or iliac system. It can metastasize to the liver via the portal venous system or to the lungs, or rarely to the brain or bones, via other hematogenous routes.

Diagnosis and Classification

The important aspects of complete evaluation of rectal cancer are related to the *local*, *regional*, and *systemic* manifestation of the cancer (Fig. 26-78).

Local Aspects

Local evaluation of a rectal cancer helps determine the proper modality of management and gives some insight into the prognosis of the cancer. Careful digital rectal examination must be performed to evaluate size, fixation, and ulceration of the cancer, as well as any suggestion of extension of the cancer to pararectal lymph nodes or adjacent organs. The rectal cancer needs to be visualized by the surgeon using a rigid sigmoidoscope, adequate biopsy taken, degree of fixation to surrounding tissue evaluated, risk of obstruction predicted, size and ulceration of lesion determined, and distance from the distal edge of the tumor to the dentate line measured carefully. Flexible fiberoptic instruments are not totally reliable because only tiny biopsies can be taken, and the flexibility of the instrument can give a false sense of security relative to the distance between the cancer and the mucocutaneous junction (dentate line). It is this distance that ultimately determines if a surgeon can preserve the anal sphincter mechanism.

Cancers that have an adequate "clinical" classification system allow the treating physicians to securely plan a course of treatment before operation. So far this cannot be fully accomplished with rectal cancer because the important variables either have not been defined completely or cannot be determined before initiating treatment. The previously noted classification systems (see Figs. 26-75 and 26-76) describe the depth of cancer invasion and the status of cancer spread to surrounding lymph nodes. This is a "histologic" classification that requires removal of the rectum and pararectal tissue before its application.

The biologic behavior of rectal cancer cannot be predicted by its location or size. Poorly differentiated cancers have a worse long-term prognosis than those which are well differentiated. Some very aggressive histologic patterns such as "signet ring" cell and mucinous cancers carry an especially poor prognosis. Attempts are being made to further predict the biologic aggressiveness of rectal cancers by analysis of the DNA from biopsies of the cancers (see Fig. 26-77). These biologic predictors become important when local, nonresective techniques are described for small, favorable-appearing cancers. If the cancers that look favorable but have aggressive biologic behavior can be identified, they should be treated by nothing less than radical resection.

The *depth of invasion* of a rectal cancer is known to be an important variable. In order for a rectal cancer to be classified as "invasive," it must extend at least into the muscularis mucosae, for at this level it has access to the vascular and lymphatic systems, and metastasis becomes a possibility. Morson showed long ago that even a small, mobile cancer, confined to the rectal wall but extending into the muscularis mucosae, will have a 10 percent incidence of metastasis to pararectal lymph nodes. A major, unfulfilled challenge in evaluating rectal cancer is the pretreatment determination of lymph node involvement by cancer.

The depth of cancer invasion can be determined accurately by use of *transanal ultrasonography* (see Fig. 26-65). Each layer of the rectal wall can be identified and its penetration by cancer described. Although lymph nodes can be visualized by ultrasonography, the presence of cancer within these nodes cannot be accurately predicted. CT scanning of the rectum has been extremely helpful in evaluation of the cancer itself, but nuclear magnetic resonance imaging, especially with the use of newly available transrectally positioned coils, should be very helpful in predicting depth of invasion and involvement of lymph nodes and other pararectal structures by the primary cancer. Sometimes transanal excisional biopsy of an entire small lesion is helpful for determining depth of invasion, but this will not define lymph node involvement.

The advantages of these accurate descriptions of the cancer become evident when the treatment is chosen and decisions must be made regarding extent of operation and use of adjuvant modalities such as chemotherapy or radiation therapy.

Regional Aspects

Regional evaluation of pararectal structures involves transanal ultrasound and CT scanning or MRI, as just described, plus some special considerations. A major factor early in the evaluation of a patient with rectal cancer involves determination of the possibility and extent of resectability. After a cancer grows through the wall of the rectum, it can invade any of the surrounding structures. This is usually determined by evaluation of the *fixation* or tethering of the tumor to these structures. This makes complete examination of these structures necessary. A woman should have a complete pelvic examination with care to determine if the tumor is suspected of invading the vagina or has spread to the ovaries. In a man, evaluation of extension into the prostate or bladder is important. This could require transanal ultrasonography, CT scanning, MRI, or even cystoscopy and biopsy.

It is suspected that the extent of fixation of the tumor is an important predictor of prognosis. It is also a major factor in determining the need for adjuvant radiation therapy, sometimes coupled with chemotherapy. Even if the cancer shrinks with preoperative adjuvant therapy, consideration must be given to resection of the involved structures originally suspected of invasion by the cancer. The performance of very extensive resective procedures must be tempered by the patient's age and general health. The determination of extent of fixation of the cancer is complicated by the fact that many invasive cancers are surrounded by an intense inflammatory reaction that creates the sensation of fixation rather than actual invasion by the cancer.

The surgeon also should know the status of the upper urinary tract. If, for example, one of the ureters is involved with the invasive cancer, a determination should be made before operation that the contralateral kidney is functioning. Specific plans may need to be made for a urologist to deal with the bladder and ureter at the time of surgery. Our own preference is to use intravenous contrast material at the time of CT scanning for liver metastases to evaluate kidney size and function, as well as position and possible involvement of the ureters.

One of the most frustrating aspects of regional evaluation of rectal cancer is the inability to determine cancer involvement of the adjacent, or regional, lymph nodes. This one fact would be most helpful in determining need for adjuvant treatment preoperatively. CT and transanal ultrasound, as well as distal palpation, have allowed determination of the presence of enlarged nodes but have not been helpful in determining presence of cancer within these nodes. There is hope that improved MRI techniques, use of monoclonal antibodies, and perhaps PET scanning will be helpful in this important aspect of staging. Most studies have shown the involvement of lymph nodes in the resected specimen to be the most influential predictor of prognosis. Recently, more credence is being placed on the involvement of the "tangential" margin of resection (Fig. 26-79). This is the peripheral margin, including the extent of clearance of the cancer from surrounding tissue. Interestingly, this margin is not reported by the pathologist unless special effort is made to "ink" the tissue immediately after the resection. A great deal of discussion exists in the surgical literature over what represents an adequate distal margin, the range being 2 to 5 cm. This is based on studies to evaluate the extent of microscopic spread of cancer distal to the palpable edge of the tumor. What difference does it make if the distal margin is 2 or 5 cm when the tangential margin is minimal or nonexistent? Many surgeons believe that this nonreported regional margin is the major cause of local recurrence of rectal cancer. Although the cure of rectal cancer can be very high, the cure of locally recurrent rectal cancer is exceedingly small and often requires devastatingly radical surgery. Thus the complicated evaluation of regional spread is critical.

Distant Spread

Determination of distant spread of rectal cancer is important because these patients generally are considered to be incurable. The knowledge of metastasis to the liver or lungs may significantly modify the surgical management of the primary cancer. Routine evaluation for distant metastatic disease consists of a chest radiograph, determination of CEA level, and a contrast-enhanced CT scan of the upper and lower abdomen. The latter also allows evaluation of the urinary tract, as described previously. Suspicious lesions in the liver may need further evaluation by MRI or angio-CT. CT also will help in determining metastasis to the ovaries or dissemination within the peritoneal cavity. Rectal cancer rarely metastasizes to the bones or to the brain, and in the absence of symptoms, these two areas are not included in routine surveillance. The liver must be involved extensively with cancer before liver function tests become abnormal, and most authors find limited use in these tests. PET scanning is extremely sensitive in its ability to detect metastatic or recurrent tumor and is often helpful in planning treatment.

Surgical Treatment General Principles

The surgical treatment of rectal cancer should accomplish complete removal of the cancer and involved regional tissue. The resection should encompass an adequate margin around all facets of the cancer, not just the usually reported distal margin. The extent and timing of the surgery must be planned carefully, including partial or complete resection of surrounding structures. Because most of the rectum resides within the confines of the bones of the pelvis, the technical accomplishment of an anastomosis can be difficult. This difficulty has resulted in a history of significant complications with the colorectal anastomosis and many suggestions for avoiding serious complications, including the use of temporary, protecting intestinal stomas. The ability to construct low anastomoses, deep within the pelvis, has improved in recent years with the advent of the intraluminal surgical stapling instruments. This has markedly reduced the need for abdominal perineal resection without reducing the level of local control of the rectal cancer (Fig. 26-80 and Table 26-15).

Basic principles of cancer surgery should be used, in that dissection of the rectum and surrounding tissue must be accomplished first, and then consideration should be given to restoration of intestinal continuity (Fig. 26-81). Intestinal continuity should be restored ("low anterior resection") only if the anastomosis can be performed with an excellent blood supply and no tension. In addition, the sphincter muscle must function adequately. It is a disservice to accomplish a heroically low anastomosis in an elderly person, only to leave her or him with impaired continence. After all, an opening of the colon without sphincter control is a "colostomy," and a person is much better served to have a well-positioned, well-constructed colostomy on the abdominal wall rather than in the perineal area, which is inaccessible and incapable of having secure coverage by an appliance.

If anal sphincter function cannot be preserved, or if the cancer is so low that the sphincter or anus must be encompassed in the resection, the entire rectum must be removed and egress of feces accomplished by construction of a permanent colostomy (Fig. 26-82). The operation is performed by mobilization of the left colon and rectum through a laparotomy or celiotomy, with dissection of the distal rectum from the perineum, and is referred to as an *abdominal-perineal*, or *AP*, *resection*. The precise terminology is an *abdominal-perineal proctosigmoidectomy*.

Preparation of a patient for resection of a rectal cancer should include antibiotics and mechanical bowel preparation, as described for colonic cancer, plus a few special considerations. The patient should always have potential colostomy sites identified and marked on the abdominal wall before surgery (Fig. 26-83). This should be done even if an anastomosis is anticipated, because unexpected problems can be encountered at the time of surgery, and a colostomy might be required. An unpredicted colostomy is made worse by having it in a poor location. End colostomies are usually constructed of the distal descending (not sigmoid) colon and are located in the left lower quadrant of the abdomen or in the midline, sometimes at the umbilicus. The site is chosen as illustrated in Fig. 26-83. The patient is marked in the supine position and then asked to sit and move about. The site of the stoma should be accessible to the patient for care and on the summit of a fold of fat, not in a crease or on a scar or bony prominence. Any position off the midline should bring the stoma through the body of the rectus muscle. A low anastomosis is sometimes protected with a temporary loop ileostomy, and for this reason, it is advantageous to mark the right lower quadrant before surgery (see Fig. 26-61). The best sites are marked with ink, and the next day, in the operating room, the sites are identified by scratching the skin with a needle.

The operation is performed with general anesthesia, sometimes supplemented with epidural anesthesia; the latter provides perfect relaxation and may facilitate a lower dissection of the rectum and anastomosis. It is not unusual for blood transfusion to be required during or immediately after the procedure, and preparation should be made well in advance, especially if "directed donors" are involved. If the cancer is suspected of involving the bladder or ureter, or if there has been previous pelvic surgery, cystoscopy and placement of ureteral catheters after induction of anesthesia can be extremely helpful. This does not preclude injury to the ureter but usually makes its intraoperative identification and preservation easier.

A patient who is to have surgical resection of the rectum should be positioned on the operating table so that a sterile field can be prepared for access to the perineum, as well as to the abdomen (Fig. 26-84). This allows mobilization of the left colon and rectum from above and passage of anastomotic stapling instruments or removal of the rectum from below. Before the operation is started, a Foley catheter is placed in the bladder, a nasogastric tube in the stomach, and a #34 mushroom-tipped catheter in the rectum. Irrigation of the rectum with saline solution is accomplished through the rectal catheter; and when the effluent is clear, approximately 100 mL of povidone-iodine solution is instilled in the rectum.

The abdomen is opened through a midline incision, and exploration is carried out, looking for other intraabdominal problems, especially the presence of metastatic disease to the peritoneum, the ovaries, or the liver. Small liver metastases, especially on the surface of the liver, may have been missed by CT scan. Any suspicious lesions should be biopsied and undergo frozen-section examination while the operation proceeds. The liver is most accurately evaluated for metastatic disease by use of intraoperative ultrasonography.

The entire left colon is then mobilized on its mesentery, using the embryonic fusion plane (white line of Toldt) between the mesentery and the fat of the lateral pelvic wall (Fig. 26-85 A,B). When this is done properly, the ureter and genital vessels can be identified and reflected posteriorly. Especially if low anastomosis is a possibility, full mobilization of the splenic flexure of the colon may be helpful.

The inferior mesenteric artery is ligated at the aorta (see Fig. 26-85C). This is done not so much to enhance the cure of the cancer as to allow better mobilization of the descending colon and to clearly define the parameters of the distal dissection. This is the first of five potential injury points to the innervation necessary for normal sexual function (Fig. 26-86 C). The mesentery is then incised to the junction of the descending and sigmoid colon. The ascending left colic artery and the inferior mesenteric vein will be transected as this is done (see Fig. 26-85 C). If the need for further mobility is anticipated, the inferior mesenteric vein should be transected a second time at the peripheral margin of the duodenum (see Fig. 26-85 D). This will allow the descending colon, with its blood supply through collaterals from the superior mesenteric artery, to be placed deep within the pelvis without tension.

The bowel is then transected at the junction of the descending and sigmoid colon. The proximal component is protected for construction of an anastomosis or a colostomy. If an anastomosis is anticipated, preparation can be made for using the stapling instrument by inserting a purse-string suture (see Fig. 26-84).

The distal dissection of the rectum is then completed (see Fig. 26-86), first posteriorly between the presacral fascia and the enveloping fascia of the rectum (the second and third nerve injury points), then laterally with transection of the "lateral ligaments" (the fourth nerve injury point), and finally anteriorly with care taken to avoid the seminal vesicles or vagina (the fifth nerve injury point). During this dissection, the rectum rises out of the pelvis. Before beginning the anterior dissection, the surgeon may irrigate the rectum from above with 40% ethanol in an attempt to lessen the chance of implanting viable tumor cells should the rectum be entered during the difficult anterior dissection. The extent of the distal dissection is then determined by the location of the cancer, aiming for a margin 3 to 5 cm beyond the palpable edge of the tumor. If the cancer cannot be palpated, sigmoidoscopy should be performed to precisely locate the cancer and an adequate transection site marked from the abdominal aspect. The dissection can be extended to within the levator muscles. The rectum can be transected with a linear stapling instrument in anticipation of a double- stapled anastomosis (Fig. 26-87). If anastomosis is not possible, the rectum can be removed from below by a second operating team (Fig. 26-88), or the abdominal part of the procedure can be completed, including colostomy construction, the patient turned to the prone-flexed position, and the rectum removed by perineal dissection.

If the rectum and sphincter mechanism are completely removed, a permanent colostomy must be constructed using the prepared distal descending colon. If an anastomosis is constructed but is of questionable security (suspect blood supply, tension, or surrounding sepsis), a protecting loop colostomy or ileostomy, of a temporary nature, can be constructed. This should occur only rarely, because any problems should be corrected before completing the operation. A leaked colorectal anastomosis, even with a temporary colostomy, is a serious problem and is better avoided by correcting the cause for concern.

A special situation is created when a *coloanal anastomosis* is considered (see Fig. 26-81). This involves stripping the distal rectal mucosa and constructing an anastomosis between descending colon and anus, similar to the technique of ileal pouch–anal anastomosis used after colectomy and mucosal proctectomy for mucosal ulcerative colitis or familial

polyposis. In fact, some centers are describing construction of a colonic J-pouch as part of the “coloanal” procedure. If a coloanal anastomosis is constructed, it should be protected with a temporary proximal diverting colostomy or, preferably, a protecting loop ileostomy. Some surgeons find limited use for the coloanal anastomosis because removing only the mucosa is not adequate treatment for an invasive cancer. The coloanal procedure is an excellent, albeit complex, procedure for benign neoplasms, such as “carpet-type” villous adenomas, and for management of radiation-induced rectal injury, where normal well-vascularized tissue can be pulled through the radiation-damaged rectum.

The *Hartmann resection* is a compromise type of resection used occasionally for rectal cancer (see Fig. 26-81). It involves resection of the rectum and/or sigmoid colon and construction of an end colostomy, but it avoids anastomosis and perineal dissection of the distal rectum and perineum. This procedure is used most often for treating sigmoid diverticulitis, but it can be used for management of rectal cancer if there has been too much obstruction or sepsis to allow a safe anastomosis. It is also useful for the elderly or severely unstable patient in whom an adequate distal margin can be accomplished but anastomosis is inappropriate because the procedure should not be prolonged or because the sphincter may not function adequately for a very low anastomosis. If there is no reason to anticipate distal obstruction of the rectal segment, the proximal end can be closed and allowed to reside within the peritoneal cavity. If there is an anal stricture or any other possible distal obstruction, a mucous fistula should be constructed of the distal rectum.

When the Hartmann procedure is done, it is usually anticipated to be a temporary situation with ultimate construction of a colorectal anastomosis to restore intestinal continuity. This eventual anastomosis is sometimes not safe or possible, so the Hartmann procedure becomes the definitive procedure. For this reason, the stoma site should be chosen carefully, because these “temporary” colostomies can become “permanent.”

Metastatic Disease

The management of metastatic disease from rectal cancer is the same as that for colon cancer. Suspicious lesions on or within the liver should have biopsies taken early during the operative procedure and frozen-section evaluation completed. If a small number of easily resectable lesions exist, they can be removed with some margin, once the rectal cancer has been definitely managed. If many lesions exist, biopsy should be taken to help plan subsequent treatment. If massive replacement of the liver exists, management of the primary cancer may need to be modified. Such patients have an extremely limited life expectancy, and the now “palliative” procedure should do just that: provide relief of symptoms with as little morbidity as possible. This may mean only a colostomy without attempted resection of a “fixed” cancer, or it may mean resection with a “short” distal margin to eliminate the need for a colostomy during the few remaining months of life.

If the patient can have adequate resection of local and regional aspects of the rectal cancer, significant cures are being reported with liver resection when there are fewer than four lesions and both lobes of the liver are not involved. This is determined by repeat evaluation of the liver after the patient has recovered from treatment of the primary lesion. Most oncologists will treat diffuse hepatic involvement with systemic chemotherapy, although some prefer to wait until symptoms occur. The delivery of chemotherapeutic agents directly to the liver via the portal vein or the hepatic artery has been described, but no reports have yet shown a favorable ratio of treatment benefits versus morbidity of this modality of treatment.

Metastases to the lung, the second most common site of metastasis from colorectal cancer, are also managed by resection if the primary site can be considered “cured” and the lesions within the lung appear to have the potential for “cure” by resection.

Complications

Complications resulting from the surgical management of rectal cancer overlap with those of any major abdominal procedure, including sepsis, myocardial infarction, bleeding, pulmonary embolus, and wound problems.

There are some specific problems related to rectal cancer. One is risk of injury to sexual function. The sites of these injuries have been described. It is not known precisely how to avoid these injuries and still do an adequate cancer operation. There is at least a 50 percent incidence of significant impotence in men following resection of the rectum for cancer. For this reason, it is critical to discuss the situation with the patient before surgery and to record the pretreatment status of sexual function. It is prudent to include this risk of sexual impairment as part of a preoperative informed-consent note. This and mention of the possible need for a colostomy are the two most important elements of such a note for the patient with rectal cancer.

If a man is rendered impotent by treatment of a rectal cancer, it is advisable to wait a year before seeking consultation for implantation of some type of penile prosthetic device. The wait is important to be sure that the malignant growth has been cleared from the pelvis and to give the patient a chance to overcome functional and psychological impediments to normal sexual function that can result from pelvic surgery and the change in body image caused by the colostomy.

Leakage from colorectal anastomosis has been reported in up to 20 percent of cases using current techniques. This complication can be decreased by constructing the anastomosis with well-vascularized bowel under no tension and by draining the pelvis from above. It is suspected that most “leaks” are due to sepsis in the pelvis that dissects into the anastomosis rather than to primary defects in the anastomosis. Young, muscular men have a higher incidence of anastomotic leaks. This may be due to the technical difficulty of operating within a muscular pelvis, or it may be due to the power of their sphincter mechanism, which acts as a postoperative obstruction and stresses the anastomosis. Such patients should have dilation of the anal sphincter in the operating room, at the conclusion of the procedure, and every few days in the postoperative period, until normal intestinal function returns.

A leaked colorectal anastomosis usually presents between 4 and 7 days postoperatively. The symptoms range from mild temperature elevation, to fecal fistula in the wound, to diffuse peritonitis. When such a problem is suspected, feeding is discontinued and radiologic studies are performed, at first supine and upright films of the abdomen and chest looking for extraluminal gas. CT scan can be helpful to show abscess formation, inflammation, or extraluminal gas, and a water-soluble contrast study can demonstrate the actual leak. Barium should be avoided because leakage of barium (especially mixed with stool) creates a severely destructive form of peritonitis.

The management of a leaking colorectal anastomosis depends on the severity of the problem. The majority cause minimal symptoms of sepsis and are demonstrated only with water-soluble contrast studies of the rectum. Antibiotics and bowel rest usually suffice for treatment. If the leakage has caused an abscess that drains into the rectum or a fistula that drains to the wound, the patient should be placed on antibiotics, complete bowel rest, and total parenteral nutrition for at least 2 weeks. If a large leak is demonstrated, or if the patient has symptoms of diffuse peritonitis, laparotomy should be performed with the intention of constructing a completely diverting colostomy with mucous fistula, or a loop ileostomy. Rarely the anastomosis is taken down and the proximal component used for the colostomy, but the anastomosis should never be reconstructed in the face of significant sepsis. It is important to drain the area of sepsis with the drain placed external to the rectum. Drains placed through the rectal wall perpetuate the fistula.

A special problem can occur intraoperatively during the performance of the rectal dissection: massive venous bleeding from the presacral space. This type of bleeding has been notoriously difficult to control because it actually comes from venous structures within the bone. The older control maneuvers of ligating the iliac vessels are ineffective and may be hazardous. The specimen should be removed and the pelvis packed for 24 to 48 h, or, preferably, a surgical metal “tack” should be driven into the sacrum to compress the venous space.

Malfunction of the urinary system, mainly urinary retention, is also common after resection of the rectum. This is especially true in men, in whom prostatic hypertrophy may coexist. The perineal dissection of the rectum comes very close to the membranous urethra. Foley catheters should be left in place at least 1 week after proctectomy. If urinary symptoms exist preoperatively, urologic consultation should be obtained. Sometimes a patient must be discharged from the hospital with an indwelling urinary catheter or have prostatic resection performed before discharge. Women also may have problems with bladder function postoperatively. The other problem is distortion of the vagina, which impairs sexual function in the postoperative period.

Obstructing Rectal Cancer

Obstructing rectal cancer causes a special problem because it forces the surgeon to operate on intestine that cannot be prepared, and it precludes the use of such adjuvant measures as preoperative radiation therapy. The cancers frequently are at an advanced stage and are fixed to adjacent structures; the patient may be medically compromised by the obstructed intestine as well as by the cancer. The general principles are the same as those discussed previously for obstructing cancer of the left colon.

The simplest and safest way of handling an obstructing rectal cancer is to do a limited laparotomy and construct a *decompressing* transverse colostomy (Fig. 26-89). Ileostomy may not be sufficient for decompression because a competent ileocecal valve may prevent reflux of colonic contents to the ileum. This can be done through a small upper midline incision directly over the dilated colon. The choice of location for the incision and the stoma can be aided by a preoperative x-ray of the abdomen with a coin placed at the umbilicus. Either a loop colostomy (over a small supporting rod) or “blowhole” colostomy (using only one wall of a massively dilated colon) can be constructed (Fig. 26-90). Construction of a decompressing colostomy allows subsequent complete evaluation of the patient and elective resection of the rectal cancer. If adjuvant preoperative treatment is not elected, the definitive resection can be done during the same hospitalization. If adjuvant therapy is chosen, the patient can be discharged from the hospital and the definitive, elective resection performed weeks or months after the decompressing procedure. The major disadvantage of the staged procedure with initial colonic decompression is the inability to explore the entire abdominal cavity at the time of decompression. This may carry some risk in the patient with a “competent” ileal-cecal valve, preventing decompression of the obstruction into the small intestine. Such patients may have massive cecal dilatation and be at some risk of necrosis of the cecal wall.

Some surgeons who operate for obstructing rectal cancer prefer to resect the cancer, using a Hartmann resection, as described previously. Others prefer to resect the cancer and all the dilated abdominal colon, allowing construction of an ileal-rectal anastomosis (see Fig. 26-81), which can be done safely when the cancer and dilated colon are removed. This type of anastomosis causes some, but usually not significant, increase in the number of daily bowel movements.

One also can resect an obstructing rectal cancer, construct an anastomosis, allow the bowel to decompress through the connection, and then protect the anastomosis with a temporary transverse colostomy or loop ileostomy, as described previously.

Colostomy Construction and Management

The construction of a colostomy is sometimes needed in the management of rectal cancer. The indications for its use have already been described, but it is important to emphasize several points. A colostomy is an opening of the colon to the abdominal wall, without the benefit of a sphincter to control the timing of its emptying. The need for a colostomy is determined more by the location of the cancer than by its severity. This is important for patients to understand, since they usually assume, as does all of our society, that the need for a colostomy indicates incurability of the cancer. In years past, this was in fact the case. Until Miles popularized the safe surgical removal of the rectum by the abdominal-perineal approach, most cancers continued to grow until they obstructed as late-stage lesions, and a colostomy was required to prolong a life complicated by the misery of uncontrolled growth of a rectal cancer within the pelvis. As explained previously, colostomies are also used to protect distal complicated anastomoses or perforations or to decompress a colon that is dilated because of distal obstruction. A loop ileostomy has been used increasingly to accomplish the same goal. Its construction does not require colonic dissection or any manipulation of the blood supply to the colorectal anastomosis. Its closure can be performed easily without involving the colon or its vessels.

The function and care of a colostomy are determined by the physiologic differences between the proximal and distal colon. The proximal colon functions to absorb water from the material that passes to it from the ileum. Its contents are liquid, and its peristaltic motion is frequent and irregular. The distal colon acts as a reservoir to allow fecal material to accumulate until it can be expelled. Its content is solid or semisolid, and its peristaltic motion is powerful and infrequent.

Although the functional aspects are important, colostomy construction is better defined by the surgeon according to the required *objective of the stoma* rather than its location. A surgeon must decide if a *decompressing* or a *diverting* stoma is required.

A *decompressing* colostomy is constructed to relieve the colonic distention caused by distal obstruction. A transverse loop colostomy is the most frequently employed stoma of this type (see Fig. 26-89). It is made by bringing a loop of colon to the abdominal wall and suspending it over a small supporting rod. If the colon is too massively dilated to bring through the abdominal wall, only one wall of the colon is used to form a so-called blowhole colostomy (see Fig. 26-90). The technique can be used for a dilated cecum as well, but this results in a stoma that is difficult to manage. Studies have shown that a well-constructed loop transverse colostomy also will provide *diversion* for as long as 6 weeks. After that time, the posterior wall of the colon falls below the abdominal wall, and fecal material can pass into the distal segment.

If complete diversion is required because of distal perforation of the intestine, a loop colostomy is inadequate. Complete diversion can be guaranteed only if the colon is divided, with construction of an end colostomy and mucous fistula.

All colostomies are opened primarily in the operating room, and full thickness of the intestine is sutured to full thickness of skin. This “maturation” of the colostomy allows immediate application of an appliance and avoids subsequent stricture of the stoma, a condition that causes significant difficulty for the patient, requiring ineffective dilation of the stoma and eventual revision. The construction of a colostomy by suspending a dilated loop of colon over a large glass supporting rod and opening it 24 to 48 h later should be relegated to history.

Any patient with abdominal trauma, diverticulitis, or a cancer anywhere in the left colon or rectum should have potential colostomy and ileostomy sites marked preoperatively, as described previously, and the possible need for a stoma should be discussed. For the patients who have a high probability of needing a stoma, more definitive preoperative preparation is made. They and their close family are given information about the stoma and its function, if possible by an enterostomal therapy nurse or other nurse who works closely with surgeons and their ostomy patients. If possible, a visit is arranged with another person who has had successful construction of a similar stoma. This visit can be arranged through the United Ostomy Association, a well-organized volunteer group made up of people who have had ostomy surgery.

The immediate *postoperative care* of the colostomy involves observation for viability and infection and application of an appliance. Supporting rods are removed after 1 week in most patients. Colostomies initially become edematous and then shrink considerably, requiring adjustment in the size of the appliance opening. If a colostomy becomes necrotic because of inadequate blood supply, gentle evaluation must be made into the lumen of the stoma. Necrosis deep in the abdominal wall requires laparotomy and reconstruction of the stoma. More superficial necrosis will be tolerated but usually results in eventual stricture of the stoma.

A patient with an end colostomy and a preoperative regular bowel habit may elect to “control” the colostomy with an *irrigation* regimen. This takes advantage of the infrequent, mass peristaltic motions of the left colon that can be stimulated by distending the distal colon with irrigation solution—the same effect as an enema in the rectum. These patients can begin small-volume irrigation (250 to 500 mL of saline solution or warm water) on the fifth postoperative day and increase to the normal 1000-mL irrigating volume. An individual who irrigates an end colostomy successfully often will not wear an appliance over the stoma but at most a small cover with a pad to absorb mucous and a charcoal filter to control odor.

The long-term care of a colostomy depends on the type of stoma and individual preference. A transverse colostomy requires constant wearing of an appliance that must be emptied multiple times during the day. An end colostomy on the left side can be irrigated or controlled with diet and medication, or it can be left alone to function with an appliance in place. Colostomy problems are usually related to a poor location of the stoma that makes sealing an appliance difficult and the control of gas and odor impossible. Since the colostomy has no sphincter, gas passes without control. Colostomy patients therefore must be observant of gas-forming foods and should have available medications to slow intestinal function during social occasions.

Bleeding and obstructive symptoms should be evaluated for proximal sources, especially synchronous or metachronous cancer. A person with rectal cancer is at increased risk of developing additional cancers. Surveillance endoscopy should be performed through the colostomy just as it would be through the anus. Colostomies can become blocked by impaction just as a rectum does, and the presenting symptoms may be frequent passage of liquid stool around an obstructing bolus. This should be considered before prescribing antidiarrheal agents to a patient having “diarrhea” from the colostomy.

Colostomy stricture usually results from a stoma opened in a delayed fashion in which serositis developed or from a poorly vascularized colostomy. An initially huge stoma can stricture down to a tiny, incapacitating opening. The stenosis is always at skin level, prevents irrigation, and can be the source of enormous difficulty for the patient. These strictures can be corrected easily by excising the scarred skin and resuturing well-vascularized bowel to the skin (Fig. 26-91).

Adjuvant Therapy for Rectal Cancer

The overall 5-year survival rate of rectal cancer has been no better than 50 percent in many series. Death results from distant metastatic disease or, perhaps more significantly, from recurrent disease in the pelvis. Local recurrence in the pelvis is usually reported to be between 20 and 30 percent. This pelvic recurrence is the source of severe misery and suffering. Local recurrence happens because the ability to do wide resection of the rectal cancer and surrounding tissue is limited by the confines of the pelvis. Adjuvant radiation therapy has been advocated to control tumor spread to the periphery of the margins of resection (Fig. 26-92). Some prefer to apply this postoperatively when the adequacy of cancer resection is in doubt. Others prefer to use the radiation therapy preoperatively to destroy the cancer at the periphery before surgical dissection is performed. Our statistics have shown a very low incidence of local recurrence and a high 5-year survival rate with preoperative radiation therapy (Table 26-16). Two treatment regimens were used: The shorter course is used when tumor shrinkage is not required. The biologic dose of radiation is highly dependent on the timing of administration, so 2000 cGy administered in 5 days is not very different from 4500 cGy delivery over a 5-week period. In the longer regimen, there is a 7-week waiting period after completion of radiation therapy to allow resolution of all radiation-induced inflammatory changes and to permit surgery before the fibrotic phase of radiation injury begins.

There is little complication resulting from the use of preoperative radiation therapy, whereas many have seen serious problems with the use of postoperative radiation therapy. This is usually caused by injury to the small intestine, which becomes fixed in the pelvis after surgery (see Fig. 26-92). The major disadvantage of preoperative radiation therapy is that some favorable lesions, not needing adjuvant radiation therapy, will be included. In some series, these favorable but invasive cancers have always been treated with something less than surgical resection, as will be explained shortly.

Some institutions use a compromise referred to as the “sandwich” technique, in which a short course of radiation therapy is given preoperatively, with an additional postoperative dosage used if the pathology of the cancer is unfavorable. Because of the low risk and good results from the preoperative regimens, we have not seen the need for the “sandwich” technique. A modern schema for the utilization of adjuvant radiation therapy in the management of rectal cancer is summarized in Table 26-17.

Currently, systemic adjuvant chemotherapy is used to improve long-term survival by reducing the incidence of distant metastatic disease and to improve local disease control as a radiosensitizer in combination with external-beam radiotherapy. Data from large trials indicate that patients with Stage II and Stage III rectal carcinomas achieve a modest survival benefit from adjuvant chemotherapy. Preliminary evidence suggests that combined-modality treatment with 5-fluorouracil-based chemotherapy in conjunction with radiation therapy provides additional survival benefit. Decreased local recurrence rates with chemoradiation therapy also suggest that 5-fluorouracil acts, in part, as a radiosensitizer. Another local benefit of chemoradiation therapy is its ability to downstage locally advanced rectal cancers (as demonstrated by transrectal ultrasonography) when given preoperatively, which may render a tumor resectable. Trials are underway to further define the role of chemoradiation in the treatment of rectal carcinoma.

Nonresectional Therapy

So far we have described only radical resection for invasive rectal cancer, yet it has long been known that some cancers are detected in their early phase, before onset of regional extension. In these cases, patients could be cured by effective local destruction of the tumor (Table 26-18). Adequate local palliation also becomes an issue in patients with widespread metastatic disease and a severely limited life expectancy.

Identifying the cancer appropriate for something less than resection is made difficult because no adequate clinical staging system exists for rectal cancer in the pretreatment state. Morson warned that even small presumed Dukes' A lesions will have spread to regional lymph nodes 10 percent of the time. New diagnostic modalities described previously, such as transanal ultrasound, CT scanning, MRI, monoclonal antibody, nuclear scan, and PET scanning, and accurate tumor markers of biologic activity should soon allow more accurate selection of favorable yet invasive rectal cancer that is amenable to treatment by something less than radical proctectomy.

These cancers have been treated by local excision, excision and deep electrocoagulation, and most recently, *endocavitary radiation* (Fig. 26-93). This latter technique applies high-dose, superficial, low-voltage radiation directly to the cancer. This accurately directed high dosage avoids injury to normal surrounding tissue, the dose-limiting factor of external radiation treatment.

We have advanced from excision and deep coagulation of these favorable but invasive cancers, to endocavitary radiation, and finally, to external combined with endocavitary radiation treatment. We have had good results with selected cancers but have learned that initially “aggressive” cancers require resection, even in high-risk patients and those with metastatic disease. The future probably will show that external radiation, combined with any adequate form of local destruction, will constitute adequate, definitive treatment for some rectal cancers. Endocavity radiation is not available in all centers.

Incurable Cancer

The management of hepatic and pulmonary metastases has been described previously. The question arises as to what to do with the rectal cancer itself in the patient who presents with incurable, massive metastatic disease. If the life expectancy is longer than 6 months, it is probably appropriate to give 4500 cGy external radiation (perhaps combined with systemic chemotherapy) to shrink the tumor and then to perform a palliative resection. This takes away a significant amount of “out-of-hospital” time from the patient whose time has become precious, but it is clearly the best form of palliation, even if it requires a colostomy. An alternative recently described is to give a course of external radiation, with or without chemotherapy, and maintain a lumen through the cancer by laser destruction, dilation, or stenting of the tumor, thus avoiding resective surgery and the need for a colostomy. This choice must be used in highly selected patients. Since both plans start with external radiation therapy, the ultimate choice of treatment can be delayed until response to the external radiation is observed. It also allows the surgeon to better understand the patient, his or her desires, and his or her general state of health during the process.

Recurrent Cancer

A special and complicated problem exists for local recurrence of rectal cancer. It had been thought previously that the cancers recurred at the distal margin of the anastomosis and grew into the lumen. This surely happens with an inadequate margin, but most surgeons in the field now believe that there is residual cancer on the pelvic wall at the time of initial resection. It takes approximately 18 months for this cancer to grow large enough to present through the anastomosis. These cancers, by their nature, are fixed to the pelvic wall and surrounding viscera. They cause significant symptoms of pain secondary to sacral nerve roots, obstruction of the ureters, or rectal obstruction after low anterior resection are difficult to palliate and almost impossible to cure. This low salvage for locally recurrent rectal cancer has been the major impetus for investigating adjuvant modalities of treatment, such as preoperative radiation therapy.

Locally recurrent disease can be detected by biopsy after a low anterior resection and in women through the vagina after an abdominal-perineal resection. A more difficult problem exists in men after an abdominal- perineal resection, when no orifice exists to allow access to the suspicious area. Any postoperative patient with symptoms in the pelvis or a rising CEA titer should be suspected of recurrent disease. PET scanning is becoming most helpful in the diagnosis of these patients. Once the suspicious area is identified, CT-guided biopsy becomes helpful in confirming the diagnosis.

Once the diagnosis is made, therapy must be planned carefully. External radiation usually combined with chemotherapy is especially important if it has not been used before. The tissue damage from radiation is cumulative, and repeat courses are impossible. Resection should be planned to include all involved organs, such as vagina, bladder, sacrum, or adherent small intestine. Preoperative cystoscopy with biopsy and careful pelvic examination are mandatory. Removal of the rectum and urinary bladder with surrounding lymphatic tissue is called a *pelvic exenteration* (Fig. 26- 94). This requires the patient to have two permanent stomas, one for feces and one for urine. Some but not all of the sacrum can be removed, as described previously in the section on anatomy.

Consideration has been given to intraoperative radiation therapy to the tumor using a linear accelerator; this requires a combined operating room–radiation therapy suite, and the results so far have not been favorable. Techniques are being described for implanting high-dose afterload radiation therapy catheters to the areas suspicious for unclear margins.

Despite such heroic measures, the palliation and salvage rate of recurrent rectal cancer is very low (10 to 20 percent). The mode of death from locally recurrent rectal cancer involves much more intense suffering than that which results from the progressive malnutrition of distant metastatic disease. For these reasons, it is important that a surgeon managing rectal cancer know all the management options and that the first therapy applied be the best “curative” procedure for a given patient.

Other Rectal Tumors Lymphoma

Most gastrointestinal lymphomas represent metastatic disease. Primary, non-Hodgkin's, colonic lymphomas account for approximately 10 percent of all gastrointestinal lymphomas. The gastrointestinal tract is a common site of HIV-associated non-Hodgkin's lymphomas. For the diagnosis of primary lymphoma of the gastrointestinal tract to be made, there should be no palpable peripheral adenopathy, no involvement of the liver or spleen, a normal white blood cell count, and no involvement of other sites. The cecum and rectum are the most common sites of colonic involvement.

Lymphoma of the intestinal tract may appear as annular thickening, bulky exophytic growth, or thickened dilatations of the bowel wall. The cut surface has the appearance of “fish flesh.” Colonic lymphomas are classified by cell type and in order of frequency are histiocytic, lymphocytic, mixed cell, and Hodgkin's diseases.

Diagnosis

Patients are typically 50 to 60 years old, with colonic lymphoma more common in men and rectal involvement more common in women. Abdominal or rectal pain, altered bowel habits, weight loss, and rectal bleeding are the most common presenting symptoms. Approximately 20 percent of patients will present with obstructive symptoms.

An accurate history and physical examination with complete blood work, chest x-ray, barium enema, abdominal CT scan, and bone marrow biopsy are used for preoperative staging. Most rectal lymphomas are palpable by digital examination or visible by biopsy through a sigmoidoscope. Patients with colonic lymphoma may have tender, palpable abdominal masses. Barium enema examination may reveal multiple lesions consisting of filling defects and infiltrating or ulcerating lesions. The appearance of a lymphoma on barium enema examination can be similar to that of a carcinoma. The lesions often are submucosal; consequently, superficial colonoscopic biopsies are not diagnostic. CT scan may help to characterize primary colonic lymphomas and to identify tumor spread or invasion.

Treatment

Complete excision is the treatment of choice for these tumors. Resection of primary gastrointestinal lymphomas permits accurate staging, better local control of the tumor, and decreased complications of bleeding and perforation. Liver and lymph node biopsies, as well as splenectomies, have been recommended for complete operative staging.

Postoperative radiation therapy and chemotherapy are given according to the stage of the tumor. Radiation therapy is indicated for palliation of unresectable disease and in cases when the surgical resection is not complete. Chemotherapy is recommended for treatment of systemic disease.

Prognosis depends on the stage at diagnosis. The 5-year survival rate following curative resection is 50 percent. The best prognosis exists in patients with intraluminal lymphomas less than 5 cm in diameter with no lymph node metastases. Patients with AIDS and those with widespread disease have a poor prognosis.

Retrorectal Tumors

Pathophysiology

The retrorectal space is bound anteriorly by the rectum, posteriorly by the presacral fascia, superiorly by the peritoneal reflection, inferiorly by the rectosacral fascia, and laterally by the lateral ligaments, ureters, and iliac vessels (see Fig. 26-37). More than 50 percent of these lesions are congenital (Table 26-19). The remainder are classified as neurogenic, osseous, or miscellaneous lesions. Inflammatory lesions and metastatic carcinoma also should be considered in the differential diagnosis of lesions in this space. Malignancy is more common in lesions found in the postnatal pediatric population than in adults. In the adult population, 10 percent of cystic lesions are malignant, whereas solid lesions have a 60 percent malignancy rate.

Developmental cysts constitute the majority of congenital lesions and may arise from any of the germ cell layers. Dermoid and epidermoid cysts are benign lesions that have an ectodermal origin. When these cysts communicate with the skin surface, a postanal dimple is found. These cysts can become infected and may be misdiagnosed as a fistula-in-ano. Enterogenous cysts are endodermal in origin and are benign, thin-walled, and lined by columnar epithelium. They are usually asymptomatic, but they have a tendency to become infected. Teratomas are true neoplasms and contain tissue from each germ cell layer. They are more common in women and are considered tumors of infancy and childhood. Teratomas are uncommon in adults, but when they occur, 30 percent become malignant.

Chordomas are the most common malignant tumors found in this region and are believed to arise from remnants of the notochord. These cancers are slow-growing, invasive lesions that destroy adjacent bone. Plain radiographs show the expansion and destruction of bone, trabeculation, and calcification.

Anterior sacral *meningoceles* contain cerebrospinal fluid. Patients present with headaches, often associated with constipation and low back pain. The “scimitar” sign (a sacrum with a rounded, concave border without bony destruction) is the pathognomonic x-ray appearance of anterior sacral meningoceles. Meningitis can occur, and aspiration of these lesions should be avoided to prevent this complication.

Diagnosis

Many patients are symptom-free and the tumor is found on routine pelvic or rectal examination. Symptomatic patients with retrorectal tumors often complain of postural pain in the lower back, perianal, or rectal region, with the pain often referred to the legs or buttocks. Other complaints include recurrent infections, constipation, diarrhea, urinary symptoms, or obstructed labor. More than 90 percent of these lesions are palpable by digital rectal examination.

Plain x-ray or CT scans are used to confirm the diagnosis and to aid in surgical planning. CT scans help to define the limits of the lesion and to determine whether it is cystic or solid. Bony destruction indicates malignancy. Barium enema will show anterior displacement of the rectum. Myelograms may be indicated if central nervous system involvement is suspected. Biopsy is not recommended if the lesion is deemed operable because tumor seeding along biopsy tracts and septic complications after needle biopsies have been reported.

Treatment

Surgical resection is the treatment of choice, even in asymptomatic patients, because of the risk that the lesion may become infected, cause dystocia, be malignant, or have malignant potential. The abdominal approach is recommended for high retrorectal and extraspinal neurogenic lesions. The posterior (transsacral) approach is recommended for low lesions and infected cysts. For large lesions, an abdominal-sacral approach has been most useful. The coccyx needs to be removed to gain better exposure and to decrease the risk of recurrence, since it is frequently the source of the cysts. If needle biopsy was performed, the tract must be included in the resection to prevent tumor implantation in the needle tract. En bloc resections of sacrum, neural structures, and rectum are sometimes needed for curative resection of chordomas. Anterior sacral meningoceles can be treated by posterior laminectomy, anterior transabdominal, or a combination anteroposterior approach.

Benign tumors and cysts have a good prognosis and are treated adequately by surgical excision. Chordomas have a high local recurrence rate. They are slow-growing tumors, and 10-year survival rates vary from 20 to 70 percent. High-dose radiotherapy may provide palliation in inoperable or inadequately resected chordomas. Chemotherapy has no role in the management of tumors in this region.

Colonic Carcinoid

Carcinoid tumors arise from neuroectodermal tissue. In the gastrointestinal tract they originate in the enterochromaffin cells at the base of the crypts of Lieberkühn. These cells contain neurosecretory granules and are part of the amine precursor uptake and decarboxylation (APUD) system. Approximately 2 percent of gastrointestinal carcinoids occur in the colon and 15 percent in the rectum. Colonic carcinoids occur most frequently in the cecum, followed by the transverse and sigmoid colon. The male-to-female ratio is equal, and the peak incidence is in the sixth to seventh decades of life. There is a high incidence of synchronous or metachronous lesions in patients with colonic or rectal carcinoids.

Diagnosis

Colonic carcinoids smaller than 1 cm are usually asymptomatic and almost never malignant. They are submucosal and rarely seen on barium enema examination or colonoscopy.

They are usually found incidentally during operation for other disease.

Because most midgut and hindgut carcinoids are clinically silent, the diagnosis is often made late in the course of the disease. Symptomatic colonic carcinoids are often bulky, advanced lesions. Many patients present with weight loss, anorexia, abdominal discomfort, and occasionally a palpable mass. Barium enema may reveal polypoid or circumferential lesions, simulating findings seen with adenocarcinomas. Carcinoid tumors evoke a desmoplastic reaction that may distort surrounding tissues. Less than 5 percent of colonic carcinoids cause the carcinoid syndrome; if the syndrome is present, it usually indicates liver metastases.

Invasive malignancy correlates with size of the lesions. Lesions smaller than 2 cm rarely metastasize, but symptomatic carcinoids larger than 2 cm are usually aggressive malignancies. Eighty percent of patients with lesions larger than 2 cm have metastases at the time of diagnosis, 45 percent have local spread, and 38 percent have distant metastases, with the liver being the most common site of distant spread.

Lesions greater than 2 cm that have invaded the muscularis propria or show positive nodes have a very poor prognosis. Median survival for these lesions is less than 12 months. The overall 5-year survival rate for colonic carcinoid is less than 50 percent.

Treatment

Small lesions found incidentally during exploration may be removed by wedge or segmental resection. Local excision can be curative for lesions less than 2 cm discovered before invasion of the muscularis propria, if lymph nodes are negative. The surgical treatment for larger lesions with no liver metastasis is similar to that for colonic adenocarcinoma. Single liver metastases should be resected. Resection of the primary tumor can be palliative in patients with otherwise incurable metastatic disease. There is evidence that a-interferon used in the treatment of malignant carcinoids resulted in decreased symptoms and stabilization of disease. Somatostatin has been used for management of symptomatic carcinoid syndrome. The prognosis of patients with colonic carcinoids is worse than that of patients with carcinoids of the rectum or appendix.

Rectal Carcinoid

Diagnosis

Rectal carcinoids are yellow-gray submucosal nodules covered by intact mucosa. They are usually small and asymptomatic and may be seen on proctosigmoidoscopy. Larger lesions can ulcerate, causing rectal bleeding and pain. Malignancy correlates with the size of the lesion and is based on invasion into the muscularis propria, not histologic differentiation. There is a 4 percent chance of malignancy in lesions smaller than 2 cm, but it is unsafe to assume solely on the basis of its size that a lesion is benign. More than 60 percent of rectal carcinoids larger than 2 cm have liver metastases, and 90 percent have local lymph node metastases at the time of diagnosis.

Treatment

Transanal excision is indicated for small, asymptomatic rectal lesions. The depth of invasion should be evaluated, and a more extensive cancer operation should be performed for those lesions with invasion of the muscularis propria. Malignant lesions should be treated by anterior resection or abdominal perineal resection. Radical surgery, however, has not been beneficial for rectal carcinoids with evidence of distant metastatic disease. The 5-year survival rate among persons with no metastases is 92 percent. The 5-year survival rate is 44 percent if there are local lymph node metastases and less than 10 percent if distant metastases are present.

Composite Carcinoid-Carcinomas

Composite carcinoid-carcinomas (adenocarcinoids) are uncommon tumors that have histologic features of both carcinoid and adenocarcinoma. Neoplastic change involving a common precursor cell is more likely than coincidental malignant change of two mature cell types.

These tumors behave more like adenocarcinomas than carcinoids. They have been reported in various locations along the gastrointestinal tract; 80 percent are found in the appendix and 10 percent in the colon and rectum. Metastases to regional lymph nodes are found in 69 percent and to the liver in 23 percent of patients at the time of diagnosis.

Surgical treatment should be planned as if the lesions were adenocarcinomas. Somatostatin may control symptoms by preventing release of pharmacologically active tumor products.

Anal Neoplasms

Tumors of the Anal Margin Squamous Cell Carcinoma

A major consideration in managing anal cancers involves the precise anatomic location of the lesion. Squamous cancer of the skin at the anal *margin* behaves similarly to other cutaneous squamous cell cancers, whereas squamous (or transitional) cancer of the anal *canal* is a high-grade cancer with significant risk of metastasis and death.

Squamous cell carcinomas of the anal margin arise between the dentate line and the outer limit of perianal skin (defined as 5 cm from the anal verge). These tumors are well-differentiated keratinizing lesions similar to squamous carcinoma of the skin.

Diagnosis

These cancers are more common in men. Patients frequently present with complaints of a palpable mass, bleeding, itching, pain, or tenesmus. The lesions have rolled, everted edges and a central ulceration. Associated anal condylomata or chronic fistula-in-ano may be found in up to 15 percent of patients. Any chronic, nonhealing ulceration in the perianal area should be biopsied to rule out squamous carcinoma. These cancers are slow-growing and metastasize late, and most patients present 12 to 24 months after the onset of symptoms.

Treatment

Small lesions are treated by wide local excision with a 2-cm margin. Combined chemotherapy and radiation have been used successfully to induce regression of large lesions. Abdominal-perineal resection should be reserved for patients with fecal incontinence and those who develop local recurrence after conservative treatment. Synchronous metastases to the inguinal nodes occur in 8 to 40 percent of patients and are treated by inguinal node dissection once positive nodes have been identified. Lesions less than 5 cm have a better prognosis, and the overall 5-year survival rate is 60 to 80 percent.

Basal Cell Carcinoma

Basal cell carcinoma is a rare tumor of the anal margin and behaves like basal cell carcinoma elsewhere on the skin. It is more common in men and presents as a lesion with raised edges and central ulceration. Basal cell carcinoma is treated by wide local excision with adequate margins and primary closure or skin grafting. Large lesions may require abdominal- perineal resection. Although these cancers rarely metastasize, there is a 30 percent local recurrence rate. Recurrences are treated by reexcision.

Bowen's Disease

Bowen's disease is an intraepidermal squamous cell carcinoma (carcinoma in situ) that is a rare, slow-growing cancer. It usually presents in the elderly but has been reported in association with anal condyloma in young, sexually active patients.

Diagnosis

Patients often complain of perianal itching, burning, or bleeding. Many lesions go unnoticed but may be found incidentally during histologic examination of tissues removed during minor anal procedures. Discrete, erythematous, scaly plaques are found on examination. Lesions may have the appearance of eczema or chronic irritation due to pruritus ani.

The presence of ulceration may indicate the development of an invasive carcinoma. Less than 10 percent of untreated lesions go on to develop invasive squamous cell carcinoma, and 35 percent of these develop metastases. Associated malignancies have been reported in the past with high percentage of patients with Bowen's disease, but recent studies have proved this to be incorrect.

Treatment

Treatment consists of wide local excision with adequate margins, as determined by frozen section. Multiple biopsies in all four quadrants of the perineal skin are then taken to ensure complete resection. Skin grafts may be necessary for coverage if the excision is extensive. Recurrent lesions, without invasion, can be treated by reexcision.

Paget's Disease

Extramammary, perianal Paget's disease is a rare pathologic entity. It arises from the intraepidermal portion of the apocrine glands. Paget's disease is frequently but not always associated with an underlying carcinoma. If left untreated, adenocarcinoma of the apocrine glands may develop after a long preinvasive phase.

Diagnosis

Patients usually are 60 to 70 years old, and there is a female predominance. Severe, intractable pruritus is characteristic of this disease. Examination reveals an erythematous, eczematous rash. Diagnosis often is delayed because lesions frequently are treated with a variety of topical medications without success before biopsy. A biopsy should be obtained from any nonhealing, pruritic anal lesion in order to exclude this diagnosis. Histologic examination reveals Paget cells, which are large pale cells with eccentric nuclei. A detailed physical examination and complete evaluation of the gastrointestinal tract should be performed; patients with extramammary Paget's disease are at increased risk of developing noncontiguous malignancies.

Treatment

Wide local excision with clear margins, confirmed by frozen section, and with multiple biopsies of the perianal skin is the treatment of choice. Abdominal-perineal resection may be necessary for the very few advanced lesions associated with invasive carcinoma. Lymph node dissection is indicated only for patients with proven positive inguinal nodes.

The most frequent sites of metastatic disease are the inguinal and pelvic lymph nodes, followed by liver, bone, lung, brain, bladder, prostate, and adrenal glands. Patients with metastatic disease do poorly despite aggressive treatment.

Anal Canal Cancer Epidermoid Carcinoma

The cloacogenic or transitional zone of the anal canal is located 6 to 12 mm above the dentate line. Carcinomas of this area may be referred to as *nonkeratinizing squamous, basaloid, cloacogenic, or transitional*. Basaloid carcinomas have the characteristic histologic appearance of palisading nuclei. Squamous carcinomas in this region are generally

nonkeratinizing. Although these cancers have different histologic features, they exhibit similar biologic behavior and are grouped together as epidermoid carcinomas of the anal canal.

Diagnosis

These cancers are more common in women. Many patients have only minor symptoms and are often erroneously diagnosed as having benign anorectal disorders. These lesions can present as an indurated, bleeding mass that may itch or cause discomfort; however, some patients present with a painless mass lesion.

Digital rectal examination reveals the size, location, and degree of fixation of these tumors. Proctosigmoidoscopy verifies the exact location of the tumor relative to the dentate line. Biopsies of the mass are necessary for diagnosis. Evaluation of the remainder of the colon should be done with colonoscopy or barium enema. Examination of both inguinal regions determines if there is any suspicious nodal enlargement, and a chest radiograph and CT scan of the liver are performed to search for distant metastatic disease.

Between 30 and 40 percent of these patients have metastatic disease at the time of diagnosis. The risk of metastasis increases with the depth of invasion, the size of lesion, and the histologic grade of the lesion. When located below the dentate line, these cancers metastasize to the inguinal nodes. Those above the dentate line will spread to the superior rectal, internal pudendal, hypogastric, or obturator lymph nodes. The most common site of distant metastatic disease is the liver.

Treatment

Small, early, node-negative lesions that are confined to the submucosa may be treated by local excision. The treatment for larger, more deeply invasive lesions has changed in the past two decades. In the past, abdominal-perineal resection was the standard treatment for squamous carcinoma of the anal canal. Local recurrence after abdominal-perineal resection was 25 to 50 percent, and the 5-year survival rate ranged from 50 to 70 percent.

Radiation therapy along with surgical treatment for residual disease has been used successfully. A 5-year survival rate of 79 percent has been reported, but there is a high complication rate associated with the high doses of radiation used for treatment.

In 1972, Nigro began using combined chemoradiation in an effort to reduce the radiation dose necessary to adequately treat these tumors. In his initial protocol, 3000 cGy external radiation, combined with 5-fluorouracil and mitomycin C, was followed by abdominal-perineal removal of the rectum. No residual carcinoma was found in 60 to 90 percent of patients, and the protocol was modified to reserve surgery for those patients with residual disease after chemoradiation.

Simultaneous chemoradiation is the preferred method of treatment for squamous carcinoma of the anus (Table 26-20). Local recurrence is 15 percent and is treated by abdominal-perineal resection. Treatment toxicity is increased for those patients with a history of pelvic surgery and those patients requiring abdominal-perineal resection after chemoradiation. Several salvage chemoradiation protocols have been used with variable success. Negative prognostic factors include the presence of involved nodes, lesions greater than 5 cm, and invasion of contiguous organs other than the rectum and skin. The overall 5-year survival rate is 83 percent, and as expected, patients with visceral metastases have a poor prognosis.

The presence of involved inguinal lymph nodes at the time of diagnosis of the primary carcinoma is a bad prognostic sign. Involved inguinal nodes are included in the radiation field, but lymph node dissection is reserved only for patients with positive nodes after chemoradiation. There is no indication for prophylactic lymph node dissection.

Squamous cell carcinoma has been reported in the chronic perineal wounds and sinus tracts seen in Crohn's disease. Malignancy should be considered in any patient with continuous anal pain or a nonhealing perineal wound. Biopsy of such sinus tracts is mandatory and may be diagnostic.

Adenocarcinoma

Adenocarcinoma of the anal canal is usually the distal extension of a primary rectal cancer. It may rarely arise from the columnar epithelium of the anal glands or within a long-standing anorectal fistula. Patients complain of perianal pain, swelling, and frequently have an abscess or fistula-in-ano. Abdominal-perineal resection is indicated in these carcinomas, sometimes after preoperative radiation therapy. Many of these patients have distant metastases at the time of diagnosis, and the long- term outlook is poor.

Melanoma

Melanoma represents 1 to 3 percent of anal canal cancers. It is the third most common site for melanoma, following the skin and the eye. The majority arise from the epidermoid lining of the anal canal adjacent to the dentate line. They spread submucosally, and by the time they cause symptoms, the extent of invasion is usually beyond surgical cure.

Diagnosis

The average age at presentation is between the fifth and sixth decades of life, the male-to-female ratio is equal, and the majority of patients reported in the literature are Caucasian.

Patients commonly present with bleeding, pain, or an anal mass. They may complain of alteration in bowel habits and are often misdiagnosed as having a thrombosed hemorrhoid. Most melanomas in this region are nonpigmented or lightly pigmented polypoid lesions.

Metastases occur via lymphatic and hematogenous routes, with lymphatic spread to the mesenteric nodes being more common than to inguinal nodes. Thirty-eight percent of patients have metastatic disease at the time of diagnosis, with lung, liver, and bone the most frequent sites of hematogenous spread.

Treatment

There has been no difference in survival in patients treated by wide local excision or abdominal-perineal resection; however, the radical resection is more effective for control of local disease and is the only procedure that removes clinically undetected lymph nodes.

Prophylactic lymph node dissection is of no value, and therapeutic lymph node dissection is advised only for those patients with positive inguinal nodes. Current chemotherapy has been ineffective. Overall 5-year survival rate is less than 20 percent, with few reported long-term survivors. Five- year survival rates in patients with lesions larger than 1.6 mm have not been reported.

PSYCHIATRIC DISORDERS

Many psychiatric disorders include symptoms of anorectal pathology as manifestations of the psychiatric disease. Surgeons must be aware of this and limit surgical therapy to specifically diagnosed surgically remediable problems. It is a serious error to operate for severe anorectal symptoms without definite findings of a primary disease process. For example, there has been extensive work seeking a psychiatric basis for the irritable bowel syndrome.

Patients who present with severe constipation or pelvic floor malfunction (such as nonrelaxation of the anal sphincter mechanism) have been shown to have a high incidence of psychological abnormalities, but no specific psychiatric diagnosis has been consistent.

The problem of unexplained anal pain is a difficult diagnostic dilemma. One must consider psychological overlay in most patients who continue to complain of anal pain despite no abnormal findings on examination. The full evaluation of these patients must include physical examination, CT scan, defecography, anal manometry, and electromyography. Cancer, inflammation, abscess, and nerve root compression are all considered possibilities. If the pain persists despite a negative evaluation, one must consider a psychological causation and refer the patient for behavioral evaluation. It is possible that spasm of the levator floor and the proctalgia fugax syndrome are related to stress, much as are migraine headaches. For these patients, treatment of the underlying problem is appropriate after cancer and other surgical problems are eliminated as possibilities.

CHAPTER 27 - The Appendix

Rosemary A. Kozar
Joel J. Roslyn

ANATOMY AND FUNCTION

The appendix first becomes visible during embryologic development in the eighth week of life as a protuberance off the terminal portion of the cecum. During both antenatal and postnatal development, the growth rate of the cecum exceeds that of the appendix, displacing the appendix medially toward the ileocecal valve. The relationship of the base of the appendix to the cecum remains constant, whereas the tip can be found in a retrocecal, pelvic, subcecal, preileal, or right pericolic position. These anatomic considerations have significant clinical importance in the context of acute appendicitis. The three taenia coli converge at the junction of the cecum with the appendix and can be a useful landmark to identify the appendix. The appendix can vary in length from less than 1 to greater than 30 cm; most appendices are 6 to 9 cm in length. Appendiceal absence, duplication, and diverticula have all been described.

For many years, the appendix was erroneously viewed as a vestigial organ with no known function. It is now well recognized that the appendix is an immunologic organ which actively participates in the secretion of immunoglobulins, particularly IgA. Though the appendix is an integral component of the *gut-associated lymphoid tissue (GALT)* system, its function is not essential and appendectomy has not been associated with any predisposition to sepsis or any other manifestation of immune compromise. Lymphoid tissue first appears in the appendix about 2 weeks after birth. The amount of lymphoid tissue increases throughout puberty, remains steady for the next decade, and then begins a steady decrease with age. After the age of 60, virtually no lymphoid tissue remains within the appendix and complete obliteration of the appendiceal lumen is common.

INFLAMMATION OF THE APPENDIX

Acute Appendicitis

Historical Background

There is evidence in the literature that alchemists and physicians in the 1500s recognized the existence of a clinical entity associated with severe inflammation of the cecal region, known as “perityphlitis.” Although the first successful appendectomy was reported in 1736, it was not until 1886 that Reginald Fitz helped establish the role of surgical removal of the inflamed appendix as curative therapy for this disease, which was once thought to be fatal. In 1889, Charles McBurney presented his classic report before the New York Surgical Society on the importance of early operative intervention for acute appendicitis in which he described the point of maximal abdominal tenderness to be determined by the pressure of one finger placed one-third of the distance between the anterior superior iliac spine and the umbilicus. Five years later he devised the muscle-splitting incision which today bears his name.

Incidence

Appendicitis remains one of the most common acute surgical diseases. The incidence of acute appendicitis roughly parallels that of lymphoid development, with the peak incidence in early adulthood. Appendicitis occurs more frequently in males especially at the time of puberty. A review of over 2000 patients with appendicitis demonstrated an overall 1.3:1 male predominance.

A decline from 100 cases per 100,000 population to 52 cases per 100,000 population was demonstrated over a study period from 1975 to 1991. This degree of change does not seem to be explained by improved diagnosis, and the explanation for this phenomenon remains elusive. Currently, 84 percent of all appendectomies are performed for acute pathology. The rate of normal appendectomy averages 16 percent, with females comprising 68 percent of those patients found to have a normal appendix at exploration.

Etiology and Pathogenesis

Obstruction of the lumen is the dominant causal factor in acute appendicitis. Fecaliths are the usual cause of appendiceal obstruction. Less common are hypertrophy of lymphoid tissue; inspissated barium from previous x-ray studies; vegetable and fruit seeds; and intestinal worms, particularly ascarids.

The frequency of obstruction rises with the severity of the inflammatory process. Fecaliths are found in about 40 percent of cases of simple acute appendicitis, about 65 percent of cases of gangrenous appendicitis without rupture, and about 90 percent of cases of gangrenous appendicitis with rupture.

The probable sequence of events following occlusion of the lumen is as follows. A closed-loop obstruction is produced by the proximal block, and continuing normal secretion of the appendiceal mucosa rapidly produces distention. The luminal capacity of the normal appendix is only about 0.1 mL—there is no real lumen. Secretion of as little as 0.5 mL distal to a block raises the intraluminal pressure to about 60 cmH₂O. The human being is one of the few animals with an appendix capable of secreting at pressures high enough to lead to gangrene and perforation. Distention stimulates nerve endings of visceral afferent pain fibers, producing vague, dull, diffuse pain in the midabdomen or lower epigastrium. Peristalsis is also stimulated by the rather sudden distention, so that some cramping may be superimposed on the visceral pain early in the course of appendicitis.

Distention continues, not only from continued mucosal secretion, but also from rapid multiplication of the resident bacteria of the appendix. As pressure in the organ increases, venous pressure is exceeded. Capillaries and venules are occluded, but arteriolar inflow continues, resulting in engorgement and vascular congestion. Distension of this magnitude usually causes reflex nausea and vomiting, and the diffuse visceral pain becomes more severe. The inflammatory process soon involves the serosa of the appendix and in turn parietal peritoneum in the region, producing the characteristic shift in pain to the right lower quadrant.

The mucosa of the gastrointestinal tract, including the appendix, is very susceptible to impairment of blood supply. Thus its integrity is compromised early in the process, allowing bacterial invasion of the deeper coats. As progressive distention encroaches on the arteriolar pressure, the area with the poorest blood supply suffers most: ellipsoidal infarcts develop in the antimesenteric border. As distention, bacterial invasion, compromise of vascular supply, and infarction progress, perforation occurs, usually through one of the infarcted areas on the antimesenteric border.

This sequence is not inevitable; some episodes of acute appendicitis apparently subside spontaneously. Many patients who are found at operation to have acute appendicitis give a history of previous similar but less severe attacks of right lower quadrant pain. Pathologic examination of the appendices removed from these patients often reveals thickening and scarring, suggesting old healed acute inflammation.

Bacteriology

A variety of anaerobes, aerobes, or facultative bacteria have been cultured from peritoneal fluid, abscess contents, and appendiceal tissue in patients with gangrenous or perforated appendicitis. An average of 10 different organisms were recovered per specimen. *Bacteroides fragilis* and *Escherichia coli* were isolated from almost all specimens. Other frequent isolates were *Peptostreptococcus* (80 percent), *Pseudomonas* (40 percent), *Bacteroides splanchnicus* (40 percent), and *Lactobacillus* (37 percent).

A quantitative bacteriologic study of the appendix wall of children showed no significant differences between the flora of normal and of acutely inflamed appendices. *Bacteroides*, *E. coli*, and streptococci were the most common organisms isolated.

Cytomegalovirus-associated appendicitis has been reported in a patient with acquired immunodeficiency syndrome.

Clinical Manifestations

Symptoms

Abdominal pain is the prime symptom of acute appendicitis. Classically the pain is initially diffusely centered in the lower epigastrium or umbilical area, is moderately severe, and is steady, sometimes with intermittent cramping superimposed. After a period varying from 1 to 12 h, but usually within 4 to 6 h, the pain localizes in the right lower quadrant. This classic pain sequence, though usual, is not invariable. In some patients the pain of appendicitis begins in the right lower quadrant and remains there. Variations in the anatomic location of the appendix account for many of the variations in the principal locus of the somatic phase of the pain. For example, a long appendix with the inflamed tip in the left lower quadrant causes pain in that area; a retrocecal appendix may cause principally flank or back pain; a pelvic appendix, principally suprapubic pain; and a retroileal appendix may cause testicular pain, presumably from irritation of the spermatic artery and ureter. Malrotation is also responsible for puzzling pain patterns. The visceral component is in the normal location, but the somatic component is felt in that part of the abdomen where the cecum has been arrested in rotation.

Anorexia nearly always accompanies appendicitis. It is so constant that the diagnosis should be questioned if the patient is not anorectic. Vomiting occurs in about 75 percent of patients, but is not prominent or prolonged, and most patients vomit only once or twice.

Most patients give a history of obstipation from before the onset of abdominal pain, and many feel that defecation would relieve their abdominal pain. However, diarrhea occurs in some patients, particularly children, so that the pattern of bowel function is of little differential diagnostic value.

The sequence of symptom appearance has great differential diagnostic significance. In over 95 percent of patients with acute appendicitis, anorexia is the first symptom, followed by abdominal pain, which is followed in turn by vomiting (if vomiting occurs). If vomiting precedes the onset of pain, the diagnosis should be questioned.

Signs

Physical findings are determined principally by the anatomic position of the inflamed appendix as well as by whether the organ has already ruptured when the patient is first examined.

Vital signs are not changed very much by uncomplicated appendicitis. Temperature elevation is rarely more than 1°C; the pulse rate is normal or slightly elevated. Changes of greater magnitude usually mean that a complication has occurred or that another diagnosis should be considered.

Patients with appendicitis usually prefer to lie supine, with the thighs, particularly the right thigh, drawn up, because any motion increases pain. If asked to move, they do so slowly and gingerly.

The classic right lower quadrant physical signs are present when the inflamed appendix lies in the anterior position. Tenderness is often maximal at or near the point described by McBurney as being “located exactly between an inch and a half and two inches from the anterior spinous process of the ileum on a straight line drawn from that process to the

umbilicus.” Direct rebound tenderness is usually present, and referred or indirect rebound tenderness is frequently present, and the tenderness is felt maximally in the right lower quadrant, indicating peritoneal irritation. Rovsing’s sign—pain in the right lower quadrant when palpatory pressure is exerted in the left lower quadrant—also indicates the site of peritoneal irritation. Cutaneous hyperesthesia in the area supplied by the spinal nerves on the right at T10, T11, and T12 frequently but not always accompanies acute appendicitis. In patients with obvious appendicitis, this sign is superfluous, but in some early cases it may be the first positive sign. It is elicited either by needle prick or, better, by gently picking up the skin between the forefinger and thumb. This ordinarily is not unpleasant but is painful in areas of cutaneous hyperesthesia.

Muscular resistance to palpation of the abdominal wall roughly parallels the severity of the inflammatory process. Early in the disease, resistance, if present, consists mainly of voluntary guarding. As peritoneal irritation progresses, muscle spasm increases and becomes largely involuntary—true reflex rigidity as opposed to voluntary guarding.

Variations in the position of the inflamed appendix produce variations from the usual in physical findings. With a retrocecal appendix, the anterior abdominal findings are less striking, and tenderness may be most marked in the flank. When the inflamed appendix hangs into the pelvis, abdominal findings may be entirely absent, and the diagnosis may be missed unless the rectum is examined. As the examining finger exerts pressure on the peritoneum of the cul-de-sac of Douglas, pain is felt in the suprapubic area as well as locally. Signs of localized muscle irritation may also be present. The psoas sign indicates an irritative focus in proximity to that muscle. The test is performed by having patients lie on their left side; the examiner then slowly extends the right thigh, thus stretching the iliopsoas muscle. The test is positive if extension produces pain. Similarly, a positive obturator sign of hypogastric pain on stretching the obturator internus indicates irritation at that locus. The test is performed by passive internal rotation of the flexed right thigh with the patient supine.

Laboratory Findings

Mild leukocytosis, ranging from 10,000 to 18,000/mm³, is usually present in patients with acute, uncomplicated appendicitis and is often accompanied by a moderate polymorphonuclear predominance. If a normal white blood cell count with no left shift is present, the diagnosis of acute appendicitis should be reconsidered. It is unusual for the white blood cell count to be greater than 18,000/mm³ in uncomplicated appendicitis. White blood cell counts above this level raise the possibility of a perforated appendix with or without an abscess. Urinalysis can be useful to rule out the urinary tract as the source of infection. Although several white or red blood cells can be present from ureteral or bladder irritation as a result of an inflamed appendix, bacteriuria in a catheterized urine specimen will not be seen with acute appendicitis.

Plain films of the abdomen, although frequently obtained as part of the general evaluation of a patient with an acute abdomen, are rarely helpful in diagnosing acute appendicitis, although they can be of significant benefit in ruling out additional pathology. In patients with acute appendicitis, one often sees an abnormal bowel gas pattern, which is a nonspecific finding. The presence of a fecalith is rarely noted on plain films, but when present is highly suggestive of the diagnosis. A chest x-ray is sometimes indicated to rule out referred pain from a right lower lobe pneumonic process.

Graded compression sonography has been suggested as an accurate way to establish the diagnosis of appendicitis. The appendix is identified as a blind-ending, nonperistaltic bowel loop originating from the cecum. With maximal compression, the diameter of the appendix is measured in the anteroposterior dimension. A scan is considered positive if a noncompressible appendix 6 mm or greater in the anteroposterior direction is demonstrated (Fig. 27-1). The presence of an appendicolith establishes the diagnosis. Sonographic demonstration of a normal appendix, which is an easily compressible blind-ending tubular structure measuring 5 mm or less, excludes the diagnosis of acute appendicitis. The study is considered negative if the appendix is not visualized and there is no pericecal fluid or mass. When the diagnosis of acute appendicitis is excluded by sonography, a brief survey of the remainder of the abdominal cavity should be performed to establish an alternative diagnosis. In females of childbearing age, the pelvic organs must be adequately visualized either transabdominally or by endovaginal examination in order to exclude gynecologic pathology as a possible cause of acute abdominal pain. The sonographic diagnosis of acute appendicitis has a reported sensitivity of 78 to 96 percent and a specificity of 85 to 98 percent. Sonography is similarly effective in children and pregnant women, although its application is somewhat limited in late pregnancy.

Sonography has definite limitations and results are user-dependent. A false-positive scan can occur in the presence of periappendicitis from surrounding inflammation, a dilated fallopian tube can be mistaken for an inflamed appendix, inspissated stool can mimic an appendicolith, and, in obese patients, the appendix may not be compressible not because of an acutely inflamed appendix but because of overlying fat. False-negative sonograms can occur if appendicitis is confined to the appendiceal tip, the cecum is retrocecal in location, the appendix is markedly enlarged and mistaken for small bowel, or if the appendix is perforated and therefore compressible.

Additional radiographic techniques include computed tomography, barium enema, and radioisotope-labeled leukocyte scans. Although CT has been reported to be as, or more, accurate than sonography, it is significantly more expensive. Because of the cost and added radiation exposure, CT should be used primarily when an appendiceal abscess is suspected to ascertain the feasibility of percutaneous drainage. Diagnosis based on barium enema depends on the nonspecific findings of extrinsic mass effect on the cecum and nonfilling of the appendix, and is associated with an accuracy ranging from 50 to 84 percent. Radiographic evaluation of patients with suspected appendicitis should be reserved for patients in whom the diagnosis is in doubt and should not delay, or substitute for, prompt operative intervention when clinically indicated.

Laparoscopy can serve as both a diagnostic and therapeutic maneuver for patients with acute abdominal pain and suspected acute appendicitis. Laparoscopy is probably most useful for the evaluation of females with lower abdominal complaints, since appendectomy is performed on a normal appendix in as many as 30 to 40 percent of such patients. Differentiating acute gynecologic pathology from acute appendicitis is easily accomplished using the laparoscope.

Appendiceal Rupture

Immediate appendectomy has long been the recommended treatment of acute appendicitis because of the known progression to rupture. A study on the natural history of appendicitis demonstrated a rate of 14 percent normal, 70 percent inflamed, and 16 percent perforated appendices. This study suggested that delays in presentation were responsible for the majority of perforated appendices. There is no accurate way of determining when and if an appendix will rupture prior to resolution of the inflammatory process. Although it has been suggested that observation and antibiotic therapy alone may be an appropriate treatment for acute appendicitis, nonoperative treatment risks the morbidity and mortality associated with a ruptured appendix.

Appendiceal rupture occurs most frequently distal to the point of luminal obstruction along the antimesenteric border of the appendix. Rupture should be suspected in the presence of fever greater than 39°C (102°F) and a white blood cell count greater than 18,000/mm³. In the majority of cases rupture is contained and patients display localized rebound tenderness. Generalized peritonitis will be present if the walling-off process is ineffective in containing the rupture.

In 2 to 6 percent of cases, an ill-defined mass will be detected on physical examination. This could represent a phlegmon, which is matted loops of bowel adherent to the adjacent inflamed appendix, or a periappendiceal abscess. Patients who present with a mass have a longer duration of symptoms, usually at least 5 to 7 days. The ability to distinguish acute, uncomplicated appendicitis from perforation on the basis of clinical findings is often difficult, but it is important to make the distinction since their treatment differs. CT scan may be very beneficial in guiding therapy. Phlegmons and small abscesses can be treated conservatively with intravenous antibiotics; well-localized abscesses may be managed with percutaneous drainage; and complex abscesses should be considered for surgical drainage. If operative drainage is required, it should be performed using an extraperitoneal approach, with appendectomy reserved for cases in which the appendix is easily accessible. Interval appendectomy performed at least 6 weeks following the acute event has classically been recommended for all patients treated either nonoperatively or with simple drainage of an abscess. The reported incidence of recurrent appendicitis in patients not undergoing interval appendectomy ranges from 0 to 37 percent, and is highest during the first year. Because a perforated cecal carcinoma can be mistaken for an appendiceal abscess, all patients over the age of 50 years should undergo either barium enema or colonoscopic examination prior to interval appendectomy.

Differential Diagnosis

The differential diagnosis of acute appendicitis is essentially the diagnosis of the “acute abdomen” (see Chap. 22). This is because clinical manifestations are not specific for a given disease but are specific for disturbance of a physiologic function or functions. Thus an essentially identical clinical picture can result from a wide variety of acute processes within or near the peritoneal cavity that produce the same alterations of function as acute appendicitis.

Accuracy of preoperative diagnosis should be about 85 percent. If it is consistently less, some unnecessary operations are probably being done, and a more rigorous preoperative differential diagnosis is in order. On the other hand, an accuracy consistently greater than 90 percent should also cause concern, since this may mean that some patients with atypical but bona fide acute appendicitis are being “observed” when they should have prompt surgical intervention. The Haller group has shown, however, that this is not invariably true. Before their study, the perforation rate at the hospital where the study took place was 26.7 percent, and acute appendicitis was found at 80 percent of the operations. By a policy of intensive in-hospital observation when the diagnosis of appendicitis was unclear, the group raised the rate of acute appendicitis found at operation to 94 percent, while the perforation rate remained unchanged at 27.5 percent.

There are a few conditions in which operation is contraindicated, but in general the disease processes that are confused with appendicitis are also surgical problems or, if not, are not made worse by surgical intervention. The more frequent error is to make a preoperative diagnosis of acute appendicitis only to find some other condition (or nothing) at operation; much less frequently, acute appendicitis is found after a preoperative diagnosis of another condition. The most common erroneous preoperative diagnoses—accounting for more than 75 percent—in descending order of frequency are acute mesenteric lymphadenitis, no organic pathologic condition, acute pelvic inflammatory disease, twisted ovarian cyst or ruptured graafian follicle, and acute gastroenteritis.

Differential diagnosis of appendicitis depends upon three major factors: the anatomic location of the inflamed appendix; the stage of the process, that is, whether simple or ruptured; and the age and sex of the patient.

Acute Mesenteric Adenitis

This is the disease most often confused with acute appendicitis in children. Almost invariably an upper respiratory infection is present or has recently subsided. The pain is usually less or more diffuse, and tenderness is not as sharply localized as in appendicitis. Voluntary guarding is sometimes present, but true rigidity is rare. Generalized lymphadenopathy may be noted. Laboratory procedures are of little help in arriving at the correct diagnosis, although a relative lymphocytosis, when present, suggests mesenteric adenitis. Observation for several hours is in order if the diagnosis of mesenteric adenitis seems likely, since mesenteric adenitis is a self-limited disease, but if the differentiation remains in doubt, immediate operation is the only safe course.

Acute Gastroenteritis

This is very common in childhood but can usually be easily differentiated from appendicitis. Viral gastroenteritis, an acute self-limited infection of diverse causes, is characterized by profuse watery diarrhea, nausea, and vomiting. Hyperperistaltic abdominal cramps precede the watery stools. The abdomen is relaxed between cramps, and there are no localizing signs. Laboratory values are normal.

Salmonella gastroenteritis results from ingestion of contaminated food. Abdominal findings are usually similar to those in viral gastroenteritis, but in some cases the abdominal pain is intense, localized, and associated with rebound tenderness. Chills and fever are common. The leukocyte count is usually normal. The causative organisms can be isolated from essentially 100 percent of patients, but culturing may take too long to help the clinician in making a timely differential diagnosis in cases of abdominal pain. Similar attacks in other persons eating the same food as the patient greatly strengthen the presumptive diagnosis of salmonella gastroenteritis.

Typhoid fever is now a rare disease. This probably accounts for the frequency of missed diagnosis—it is rarely seen and rarely thought of. The onset is less acute than in appendicitis, with a prodrome of several days. Differentiation is usually possible because of the prostration, maculopapular rash, inappropriate bradycardia, and leukopenia. Diagnosis is confirmed by culture of *Salmonella typhosa* from stool or blood. Intestinal perforation, usually in the lower ileum, develops in about 1 percent of cases and requires immediate surgical therapy.

Diseases of the Male

Diseases of males must be considered in differential diagnosis of appendicitis, including torsion of the testis and acute epididymitis, since epigastric pain may overshadow local symptoms early in these diseases. Seminal vesiculitis may also mimic appendicitis but can be diagnosed by palpating the enlarged, tender seminal vesicle on rectal examination.

Meckel's Diverticulitis

This causes a clinical picture very similar to that of acute appendicitis. Preoperative differentiation is academic and unnecessary, since Meckel's diverticulitis is associated with the same complications as appendicitis and requires the same treatment—prompt surgical intervention. Diverticulectomy can nearly always be done through a McBurney incision, extended if necessary. If the base of the diverticulum is broad, so that removal would compromise the lumen of the ileum, then resection of the segment of ileum bearing the diverticulum with end-to-end anastomosis is done.

Intussusception

In contrast to Meckel's diverticulitis, it is extremely important to differentiate intussusception from acute appendicitis, because the treatment is quite different. The age of the patients is important: appendicitis is very uncommon under age 2, whereas nearly all idiopathic intussusceptions occur under age 2. Intussusception occurs typically in a well-nourished infant who is suddenly doubled up by apparent colicky pain. Between attacks of pain the infant appears quite well. After several hours, the patient usually passes a bloody mucoid stool. A sausage-shaped mass may be palpable in the right lower quadrant. Later, as the intussusception progresses distad, the right lower quadrant feels abnormally empty. The preferred treatment of intussusception, if seen before signs of peritonitis supervene, is reduction by barium enema, but treatment of acute appendicitis by barium enema may be catastrophic.

Regional Enteritis

The manifestations of acute regional enteritis—fever, right lower quadrant pain and tenderness, and leukocytosis—often simulate acute appendicitis. Diarrhea and the infrequency of anorexia, nausea, and vomiting favor a diagnosis of enteritis but are not sufficient to exclude acute appendicitis without celiotomy. In an appreciable percentage of patients with chronic regional enteritis, the diagnosis has been first made at the time of operation for presumed acute appendicitis. Acute ileitis should be distinguished from Crohn's disease. In the face of an acutely inflamed distal ileum with no cecal involvement and a normal appendix, appendectomy is indicated. Progression to Crohn's ileitis is uncommon.

Perforated Peptic Ulcer

Perforated peptic ulcer closely simulates appendicitis if the spilled gastroduodenal contents gravitate down the right gutter to the cecal area and if the perforation spontaneously seals fairly soon, thus minimizing upper abdominal findings.

Other Lesions

Diverticulitis or perforating carcinoma of the cecum or of that portion of the sigmoid that lies on the right side may be impossible to distinguish from appendicitis. Extensive diagnostic studies in an attempt to make a preoperative differentiation are not warranted.

Epiplaic Appendagitis

Epiplaic appendagitis probably results from infarction of the appendage(s) secondary to torsion. Symptoms may be minimal, or there may be continuous abdominal pain in an area corresponding to the contour of the colon, lasting several days. Pain shift is unusual, and there is no diagnostic sequence of symptoms. The patient does not look ill, nausea and vomiting are unusual, and appetite is commonly unaffected. Localized tenderness over the site is usual and is often marked on rebound but without rigidity. In 25 percent of reported cases, pain has persisted or recurred until the infarcted epiplaic appendages were removed.

Urinary Tract Infection

Acute pyelonephritis, on the right side particularly, may mimic a retroileal acute appendicitis. Chills, right costovertebral angle tenderness, pus cells, and particularly bacteria in the urine usually suffice to differentiate the two.

Ureteral Stone

If the calculus is lodged near the appendix, it may simulate a retrocecal appendicitis. Pain referred to the labia, scrotum, or penis; hematuria; and/or absence of fever or leukocytosis suggest stone. Pyelography usually confirms the diagnosis.

Primary Peritonitis

Primary peritonitis rarely mimics simple acute appendicitis but presents a picture very similar to diffuse peritonitis secondary to a ruptured appendix. The diagnosis is made by peritoneal aspiration. If nothing but cocci are seen on the Gram's-stained smear, peritonitis is primary and treated medically; if the flora are mixed, secondary peritonitis is indicated.

Henoch-Schönlein Purpura

This syndrome usually occurs 2 to 3 weeks after a streptococcal infection. Abdominal pain may be prominent, but joint pains, purpura, and nephritis are nearly always present also.

Yersiniosis

Human infection with *Yersinia enterocolitica* or *Y. pseudotuberculosis* is probably transmitted through food contaminated by feces or urine. *Yersinia* infections cause a variety of clinical syndromes, including mesenteric adenitis, ileitis, colitis, and acute appendicitis. Many of the infections are mild and self-limited, but some lead to a systemic septic course with a high fatality rate if untreated. The organisms are usually sensitive to tetracyclines, streptomycin, ampicillin, and kanamycin. A preoperative suspicion of the diagnosis should not delay operative intervention, since appendicitis caused by *Yersinia* cannot be clinically distinguished from appendicitis of other causation. About 6 percent of cases of mesenteric adenitis and 5 percent of cases of acute appendicitis are caused by *Yersinia* infection.

Campylobacter jejuni causes diarrhea and pain that mimics the pain of appendicitis. The organism can be cultured from stool.

Gynecologic Disorders

The rate of erroneous diagnosis of acute appendicitis is highest in young adult females. Rates of appendectomy being performed on a normal appendix of 32 to 45 percent have been reported in women 15 to 45 years old. Diseases of the female internal generative organs that may be erroneously diagnosed as appendicitis are, in approximate descending order of frequency, pelvic inflammatory disease, ruptured graafian follicle, twisted ovarian cyst or tumor, endometriosis, and ruptured ectopic pregnancy. Laparoscopy plays a significant role in establishing the diagnosis.

Pelvic Inflammatory Disease

The infection is usually bilateral but if confined to the right tube may mimic acute appendicitis. Nausea and vomiting are nearly always present in patients with appendicitis, but only in approximately half of those with pelvic inflammatory disease. The greatest value of these symptoms for establishing a diagnosis of pelvic inflammatory disease is their absence. Pain and tenderness are usually lower, and motion of the cervix is exquisitely painful. Intracellular diplococci may be demonstrable on smear of the purulent vaginal discharge. The ratio of appendicitis to pelvic inflammatory disease is low in the early phase of the menstrual cycle and high during the luteal phase. The clinical use of all the above-mentioned distinctions has resulted in a reduction of the incidence of negative findings on laparotomy in young women to 15 percent.

Ruptured Graafian Follicle

Not uncommonly, ovulation results in the spill of sufficient blood and follicular fluid to produce brief, mild lower abdominal pain. If the fluid is unusually copious and from the right ovary, appendicitis may be simulated. Pain and tenderness are rather diffuse. Leukocytosis and fever are minimal or absent. Since this pain occurs at the midpoint of the menstrual cycle, it is often called mittelschmerz.

Other Diseases

Diseases not mentioned in the previous sections that occur in patients of all ages and both sexes and that must be considered in the differential diagnosis of appendicitis are foreign body perforations of the bowel; closed-loop intestinal obstruction; mesenteric vascular occlusion; pleuritis of the right lower chest; acute cholecystitis; acute pancreatitis; hematoma of the abdominal wall; and numerous conditions too rare to mention.

Appendicitis in the Young

The establishment of a diagnosis of acute appendicitis in the young is even more difficult than in the adult. The inability of young children to give an accurate history, diagnostic delays by both parents and physicians, and the frequency of gastrointestinal upset in children are all contributing factors. The more rapid progression to rupture and the inability of the underdeveloped greater omentum to contain a rupture lead to significant morbidity rates in children. In a study of 1366 specimens from pediatric patients undergoing appendectomies, histologic analysis revealed 12 percent normal appendices, 68 percent nonperforated appendices, and 20 percent perforated appendices. Children under 8 years old had a twofold increase in the rate of perforation as compared to older children. The incidence of major complications was related to rupture, with an incidence of 1.2 percent in simple appendicitis compared to 6.4 percent in perforated appendicitis. The treatment regimen for perforated appendicitis generally includes immediate appendectomy, antibiotic irrigation of the peritoneal cavity, transperitoneal drainage through the wound, and a 10-day antibiotic treatment regimen. Laparoscopic appendectomy has also been shown to be safe and effective in children.

Appendicitis in the Elderly

Although the incidence of appendicitis in the elderly is lower than in younger patients, the morbidity and mortality are significantly increased in this patient population. Delays in diagnosis, a more rapid progression to perforation, and concomitant disease are all contributing factors. The diagnosis of appendicitis may be more subtle and less typical than in younger individuals, and a high index of suspicion needs to be maintained. In patients over 80 years old, perforation rates of 49 percent and mortality rates of 21 percent have been cited.

Appendicitis During Pregnancy

Appendicitis is the most frequently encountered extrauterine disease requiring surgical treatment during pregnancy. The incidence is approximately 1 in 2000 pregnancies. Acute appendicitis can occur at any time during pregnancy but is more frequent during the first two trimesters. As fetal gestation progresses, the diagnosis of appendicitis becomes more difficult as the appendix is displaced laterally and superiorly (Fig. 27-2). Nausea and vomiting after the first trimester or new-onset nausea and vomiting should raise the consideration of appendicitis. Abdominal pain and tenderness will be present, although rebound and guarding are less frequent due to laxity of the abdominal wall. Elevation of the white blood cell count above the normal pregnancy levels of 15,000 to 20,000/mm³ with a predominance of polymorphonuclear cells is usually present. When the diagnosis is in doubt, abdominal ultrasound may be beneficial. Laparoscopy may be indicated in equivocal cases, especially early in pregnancy. The performance of any operation during pregnancy carries a risk of premature labor of 10 to 15 percent, and the risk is similar for both negative laparotomy and appendectomy for simple appendicitis. The most significant factor associated with both fetal and maternal death is appendiceal perforation. Fetal mortality increases from 3 to 5 percent with early appendicitis to 20 percent with perforation. The suspicion of appendicitis during pregnancy should prompt rapid diagnosis and surgical intervention.

Appendicitis in Patients with AIDS or HIV Infection

The cause of appendicitis in HIV-positive patients and patients with AIDS is similar to the cause of appendicitis in the general population. In some cases, however, an underlying opportunistic infection, usually secondary to cytomegalovirus or Kaposi's sarcoma, may be responsible for the development of appendiceal inflammation. Although the clinical presentation of appendicitis in patients who have AIDS or are HIV-positive does not differ significantly from patients without AIDS or HIV infection, the leukocytosis usually noted in acute appendicitis may not be present. Cytomegalovirus enteritis and tuberculosis or lymphoma involving the distal ileum can mimic appendicitis. Diagnostic laparoscopy can be helpful, with laparoscopic appendectomy being indicated when an inflamed appendix is found. If appendectomy is performed prior to perforation, there is no increase in morbidity or mortality.

Treatment

Despite the advent of more sophisticated diagnostic modalities, the importance of early operative intervention should not be minimized. Once the decision to operate for presumed acute appendicitis has been made, the patient should be prepared for the operating room. Adequate hydration should be insured, electrolyte abnormalities corrected, and preexisting cardiac, pulmonary, and renal conditions should be addressed. Many trials have demonstrated the efficacy of preoperative antibiotics in lowering the infectious complications in appendicitis. It is common practice by most surgeons to routinely administer antibiotics to all patients with suspected appendicitis. If simple acute appendicitis is encountered, there is no benefit in extending antibiotic coverage beyond 24 h. If perforated or gangrenous appendicitis is found, antibiotics are continued until the patient is afebrile and has a normal white blood cell count. For intraabdominal infections of gastrointestinal tract origin of mild to moderate severity, the Surgical Infection Society has recommended single-agent therapy with cefoxitin, cefotetan, or ticarcillin-clavulanic acid. For more severe infections, single-agent therapy with carbapenems or combination therapy with a third-generation cephalosporin, monobactam, or aminoglycoside, plus anaerobic coverage with clindamycin and metronidazole, is indicated.

Open Appendectomy (Fig. 27-3)

Most surgeons employ either a McBurney (oblique) or Rocky-Davis (transverse) right lower quadrant muscle-splitting incision in patients with suspected appendicitis. The incision should be centered over the point of maximal tenderness or a palpable mass. If an abscess is suspected, a laterally placed incision is imperative to avoid generalized contamination of the peritoneal cavity. If the diagnosis is in doubt, a lower midline incision is recommended by some to allow a more extensive examination of the peritoneal cavity.

Several techniques can be used to locate the appendix. Since the cecum is usually visible within the incision, the convergence of the taeniae can be followed to the base of the appendix. A sweeping lateral to medial motion can aid in delivering the appendiceal tip into the operative field. Occasionally limited mobilization of the cecum is needed to aid in adequate visualization. Once identified, the appendix is mobilized by dividing the mesoappendix, taking care to ligate the appendiceal artery securely. The appendiceal stump can be managed by simple ligation or by ligation and inversion with either a purse-string or Z stitch as tradition dictates. As long as the stump is clearly viable and the base of the cecum not involved with the inflammatory process, the stump can be safely ligated with a nonabsorbable suture. The mucosa is frequently obliterated to avoid the development of a mucocele. The peritoneal cavity is irrigated and the wound closed in layers. If perforation or gangrene is found, the skin and subcutaneous tissue should be left open and allowed to heal by secondary intent or be closed in 4 to 5 days as a delayed primary closure. In children, who generally have little subcutaneous fat, primary wound closure has not led to an increased incidence of wound infection.

If appendicitis is not found, a methodical search for an alternative diagnosis must be performed. The cecum and mesentery should first be inspected. Next, the small bowel is examined in a retrograde fashion beginning at the ileocecal valve. In females, special attention should be paid to the pelvic organs. An attempt is also made to examine the upper abdominal contents. Peritoneal fluid should be sent for Gram's stain and culture. If purulent fluid is encountered, it is imperative that the source be identified. A medial extension of the incision (Fowler-Weir), with division of the anterior and posterior rectus sheath, is acceptable if further evaluation of the lower abdomen is indicated. If upper abdominal pathology is encountered, the right lower quadrant incision is closed and an appropriate upper midline incision performed.

Laparoscopy

Laparoscopy has emerged as a new technique for both the diagnosis and treatment of acute appendicitis. Laparoscopy can be of enormous assistance in the evaluation of young women of childbearing age in whom acute appendicitis is suspected. Laparoscopic appendectomy may be preferable in obese patients who would require a large incision for the open approach or in individuals who are particularly concerned about cosmesis. There are a number of theoretical advantages for the laparoscopic approach over the traditional open operation described over 100 years ago. These include decreased incidence of wound infection, less pain for the patient, reduced hospitalization, and a more rapid return to employment. The data have not demonstrated any significant economic benefit to laparoscopic appendectomy for the general population. Both operative time and supply costs are increased while duration of hospital stay is not significantly shortened. Nonetheless, laparoscopic appendectomy has been demonstrated to be a safe and effective treatment. Recently reported prospective randomized trials comparing open and laparoscopic techniques (Table 27-1) indicate that operative time is generally greater using the laparoscopic approach, but the time between the operation and return to activity, and the rate of wound infection, are decreased.

The superiority of laparoscopic appendectomy over the conventional approach continues to be an issue of some debate. Laparoscopy's most important role is in diagnostic evaluation of young females whose symptoms are not the classical symptoms of appendicitis and in patients in whom the diagnosis remains in question. It does provide visualization the entire abdominal cavity, unlike the limited exposure provided by a right lower quadrant incision. For properly trained personnel, laparoscopic appendectomy may be appropriate for most cases of appendicitis, with a conversion rate of approximately 10 percent, mostly in patients with ruptured appendices.

The principles behind laparoscopic appendectomies are similar to those for other laparoscopic procedures (Fig. 27-4). All patients should have an indwelling urinary catheter and nasogastric tube inserted prior to trochar insertion. The surgeon frequently stands to the patient's left with the video monitor at the foot of the table, or to the patient's right. Pneumoperitoneum is established and a 10-mm trochar cannula is inserted through the umbilicus. A 10-mm forward-viewing laparoscope is placed through the cannula and the peritoneal cavity is inspected. Next, a 10-mm trochar is introduced into the suprapubic region in the midline and additional 5-mm ports placed in either the right upper or lower quadrant. Exposure is facilitated by placing the patient in the Trendelenburg position, right side up. Generally the cecum is easily visualized and the appendix easily identified. Gentle traction can be applied to the mesoappendix by retracting the tip of the appendix with an atraumatic grasper placed through the right upper quadrant trochar. The mesoappendix is divided with a stapling device or by using electrocautery for dissection and clips or a ligating loop to secure the appendiceal artery. Division of the mesoappendix should be done as close to the appendix as possible. After the base of the appendix is adequately exposed, two ligating loops are placed proximally and one distally over the base. The appendix is divided with scissors or electrocauterization. Alternatively, the appendix could be divided using a stapling device. Invagination of the appendiceal stump is not routinely performed. The appendix is removed via the suprapubic trocar site.

The role of laparoscopic appendectomy for removal of the normal appendix has not been well defined. As for an open procedure, an appendectomy should be considered in patients explored for right lower quadrant pain with no identifiable pathology. Complication rates of 1 to 3 percent have been reported under these circumstances. If the appendix is normal, the same thorough search for an alternative diagnosis should be performed as with an open procedure.

Prognosis

Mortality

The mortality from appendicitis in the United States has steadily decreased from a rate of 9.9 per 100,000 in 1939 to 0.2 per 100,000 in 1986. Among the factors responsible are the significantly decreasing incidence of appendicitis; better diagnosis and treatment, attributable to the now- available antibiotics, intravenous fluids, blood, and plasma; and a higher percentage of patients receiving definitive treatment before rupture.

Principal factors in mortality are (1) whether rupture occurs before surgical treatment and (2) the age of the patient. The overall mortality rate in unruptured acute appendicitis is a little higher than the rate for a general anesthetic, which is 0.06 percent. The overall mortality rate in ruptured acute appendicitis is about 3 percent—a 30-fold increase. The mortality rate of ruptured appendicitis in the elderly is about 15 percent—a fivefold increase from the overall rate.

Death is usually attributable to uncontrolled sepsis—peritonitis, intraabdominal abscesses, or gram-negative septicemia. Sepsis may impose metabolic demands of such magnitude on the cardiovascular or respiratory systems that they cannot be met, in which case cardiac or respiratory insufficiency is the direct cause of death. Pulmonary embolism continues to account for some deaths. Aspiration causing the patient to drown in his or her own vomitus is a significant cause of death in the older age group.

Morbidity

Morbidity rates parallel mortality rates, being precipitously increased by rupture of the appendix and to a lesser extent by old age. In one report, complications occurred in 3 percent of patients with nonperforated appendicitis and in 47 percent of patients with perforations. Most of the serious early complications are septic and include abscess and wound infection. Wound infection is common but is nearly always confined to the subcutaneous tissues and promptly responds to wound drainage, which is accomplished by reopening the skin incision. Wound infection predisposes to wound dehiscence also. The type of incision is relevant; complete dehiscence rarely occurs in a McBurney incision. The efficacy of systemic antibiotics in reducing the incidence of wound infections has not been agreed on. But a significant reduction in morbidity has been shown in patients receiving metronidazole or the combination of systemic clindamycin and topical ampicillin.

The incidence of intraabdominal abscesses secondary to peritoneal contamination from gangrenous or perforated appendicitis has decreased markedly since the introduction of potent antibiotics. The sites of predilection for abscesses are the appendiceal fossa, pouch of Douglas, subhepatic space, and between loops of intestine. The latter are usually

multiple. Transrectal drainage is preferred for an abscess that bulges into the rectum.

Fecal fistula is an annoying but not particularly dangerous complication of appendectomy that may be caused by sloughing of that portion of the cecum inside a constricting purse-string suture, by the ligature's slipping off a tied but not inverted appendiceal stump, or by necrosis from an abscess encroaching on the cecum.

Intestinal obstruction, initially paralytic but sometimes progressing to mechanical obstruction, may occur with slowly resolving peritonitis with loculated abscesses and exuberant adhesion formation.

Late complications are quite uncommon. Adhesive band intestinal obstruction after appendectomy does occur but much less frequently than after pelvic surgical therapy. The incidence of inguinal hernia is three times greater in patients who have had an appendectomy. Incisional hernia is like wound dehiscence in that infection predisposes to it, it rarely occurs in a McBurney incision, and it is not uncommon in a lower right paramedian incision.

TUMORS

Appendiceal malignancies are rare, occurring in 0.5 percent of all appendectomies. The tumors are usually discovered at the time of laparotomy either as an incidental finding or in association with acute inflammation of the appendix. In a recent review of over 2000 appendectomy specimens, histologic confirmation of appendiceal neoplasms included carcinoid (0.27 percent), adenocarcinoma (0.14 percent), malignant mucocele (0.005 percent), and lymphoma (0.005 percent).

Carcinoid

The finding of a firm, yellow, bulbar mass in the appendix should raise the suspicion of an appendiceal carcinoid. The appendix is the most common site of gastrointestinal carcinoid followed by the small bowel and rectum. Carcinoid syndrome is rarely associated with appendiceal carcinoid unless widespread metastases are present, which occurs in 2.9 percent of cases. Symptoms attributable directly to the carcinoid are rare, though the tumor can occasionally obstruct the appendiceal lumen much like a fecalith and result in acute appendicitis.

The majority of carcinoids are located in the tip of the appendix. Malignant potential is related to size, with tumors less than 2 cm rarely resulting in extension outside of the appendix. In one report, 78 percent of appendiceal carcinoids were less than 1 cm, 17 percent were 1 to 2 cm, and only 5 percent were greater than 2 cm. Treatment rarely requires more than simple appendectomy. For tumors less than 2 cm with extension into the mesoappendix, and for all tumors greater than 2 cm, a right hemicolectomy should be performed.

Adenocarcinoma

Primary adenocarcinoma of the appendix is a rare neoplasm of three major histologic subtypes: mucinous adenocarcinoma, colonic adenocarcinoma, and adenocarcinoid. The most common mode of presentation for appendiceal carcinoma is that of acute appendicitis. Patients may also present with ascites or a palpable mass, or the neoplasm may be discovered during an operative procedure for an unrelated cause. The recommended treatment for all patients with adenocarcinoma of the appendix is a formal right hemicolectomy. Appendiceal adenocarcinomas have a propensity for early perforation, though not clearly associated with a worsened prognosis. The presence of pseudomyxoma peritonei secondary to mucinous adenocarcinoma does not adversely affect prognosis. Overall 5-year survival is 55 percent and varies with stage and grade. Patients with appendiceal adenocarcinoma are at significant risk for both synchronous and metachronous neoplasms, approximately half of which will originate from the gastrointestinal tract.

Mucocele

An appendiceal mucocele leads to progressive enlargement of the appendix from the intraluminal accumulation of a mucoid substance. Mucoceles are of four histologic types, and the type dictates the course of the disease and prognosis: retention cysts, mucosal hyperplasia, cystadenomas, and cystadenocarcinomas. A mucocele of benign etiology is adequately treated by a simple appendectomy.

In a small percentage of patients, the mucocele occurs along with gelatinous ascites known as pseudomyxoma peritonei. Pseudomyxoma peritonei can be associated with either ovarian or appendiceal mucinous tumors, usually of a malignant nature. When pseudomyxoma peritonei is present, survival is significantly decreased probably due to the association with the ascites and malignancy. The initial surgical procedure should include cytoreductive surgery along with a right hemicolectomy for cystadenocarcinoma of the appendix and bilateral oophorectomy, hysterectomy, and appendectomy for ovarian cystadenocarcinoma. A recent review found that even with aggressive surgical treatment, there is a 57 percent incidence of local recurrence of pseudomyxoma peritonei from an appendiceal primary site. Once a recurrence is detected, death usually ensues from progressive bowel obstruction and renal failure. Adjuvant therapy including radiation and intraperitoneal and systemic chemotherapy has been recommended, but its efficacy and role are unclear.

CHAPTER 28 - Liver

Seymour I. Schwartz

ANATOMY

The liver constitutes approximately one-fiftieth of total body weight. Its size reflects the complexity of its functions. True division into right and left lobes (hemilivers) is in line with the fossa for the inferior vena cava posteriorly and the gallbladder fossa anteroinferiorly (Cantlie's line) (Fig. 28-1). Based on the distribution of the intrahepatic branches of the hepatic artery, portal vein, and bile ducts, the right lobe is divided into an anterior section and a posterior section, and the left lobe is divided into a medial section and a lateral section. Couinad proposed a functional division of the liver related to the hepatic venous drainage (Fig. 28-2). The liver is divided into two "livers" (lobes) by the portal scissura in which the middle hepatic vein courses. The right lobe is divided into two "sectors" by the right hepatic vein. The right posterolateral "sector" contains segment VI anteriorly and segment VII posteriorly. The right anterolateral "sector" contains segment V anteriorly and segment VIII posteriorly. The left lobe is divided by a line containing the left hepatic vein. The left anterior sector is divided by the umbilical fissure into segment IV, the anterior part of which is the quadrate lobe, segment III, which is the anterior part of the left lobe. The posterior portion is segment II. The dorsal segment I, in regard to its vascularization, is independent of the portal division and the three main hepatic veins (Fig. 28-3).

Biliary Drainage

Each sector is drained by a major segmental duct formed by the confluence of subsegmental draining structures. The anterior and posterior sectoral ducts in the right lobe join to form the right hepatic duct, while the medial and lateral segmental ducts in the left lobe terminate in the left hepatic duct, which joins the right duct to form a common hepatic duct in the porta hepatis. This lies anteriorly in relation to other structures in the area.

Blood Supply

The afferent blood supply to the liver arises from two sources: (1) the hepatic artery, which carries oxygenated blood and accounts for approximately 25 percent of hepatic blood flow, and (2) the portal vein, which accounts for approximately 75 percent of hepatic blood flow and drains the splanchnic circulation. The common hepatic artery originates from the celiac axis and, after contributing the gastroduodenal and right gastric artery, ascends in the hepatoduodenal ligament to the left of the common bile duct and anterior in the portal vein. It bifurcates into a right and left branch to the left of the line dividing the right and left lobes. The major right hepatic artery originates from the superior mesenteric artery in 17 percent of people. This vessel usually courses to the liver in the hepatoduodenal ligament to the right of the common duct and anterior to the portal vein. Intrahepatic anastomoses between the right and left hepatic arteries do not occur. The cystic artery is usually an extrahepatic branch of the right hepatic artery.

The portal venous system contains no valves (Fig. 28-4). It returns to the liver the blood that the celiac, superior mesenteric, and inferior mesenteric arteries supply to the gastrointestinal tract, pancreas, and spleen. The vessel is formed behind the pancreas, at the level of L 1 to L2, by the confluence of the superior mesenteric and splenic veins and, at times, the inferior mesenteric vein. The portal vein resides posteriorly in relation to the hepatic artery and bile duct in the hepatoduodenal ligament but, in rare instances, is located anterior to the pancreas and first portion of the duodenum, in which circumstance it is frequently associated with a partial or complete situs inversus and is subject to injury during cholecystectomy or gastrectomy. In the porta hepatis, the vein divides into two branches, which course to each lobe. The average length of the main portal vein is 6.5 cm, and the average diameter is 0.8 cm.

The hepatic venous system (Fig. 28-5) begins in the liver lobules as a central vein into which the sinusoids empty. The central veins unite to form sublobular veins, which in turn fuse to form collecting veins. The collecting veins gradually increase in size by joining other large intrahepatic collecting channels, which coalesce to form the three major hepatic veins. The hepatic venous tributaries are intersectoral in position. The major hepatic veins are classified as right, left, and middle. The right hepatic vein drains the entire posterior portion as well as the superior area of the anterior portion of the right lobe. The left hepatic vein drains the entire area to the left of the umbilical fissure. The inferior areas of the medial and anterior portions of the two lobes are drained by the middle vein. In human beings there are no valves in the hepatic venous system. Total hepatic blood flow can be measured by means of hepatic vein catheterization and use of the Fick principle. The average value is 1500 mL/min/1.73 m 2 of body surface.

LIVER FUNCTION

The liver consists of four physiologic-anatomic units that are interrelated:

- (1) The circulatory system. A dual blood supply nourishes the liver and acts as a vehicle for material absorbed from the intestinal tract to be utilized in the metabolic pool. Blood vessels are accompanied by lymphatics and nerve fibers that contribute to the regulation of blood flow and intrasinuosoidal pressure.
- (2) Biliary passages. These serve as channels of exit for materials secreted by liver cells, including bilirubin, cholesterol, and detoxified drugs. This system originates with the Golgi apparatus adjacent to the microvilli of the bile canaliculi and eventually terminates in the common bile duct.
- (3) The reticuloendothelial system. This system has 60 percent of its cellular elements in the liver and includes the phagocytic Kupffer cells and endothelial cells.
- (4) The functioning liver cells (hepatocytes), which are capable of wide variation of activity. The metabolic pool in the liver serves the needs of the entire body. The cell performs both anabolic and catabolic activities, secretes, and stores. The large amount of energies required for these transformations result from the conversion of adenosine triphosphate (ATP) to adenosine diphosphate (ADP). A second source is the aerobic oxygenation in the metabolic pool via the tricarboxylic acid cycle of Krebs.

Function Tests

The so-called liver function tests (Table 28-1) evaluate liver activity by assessing the degree of functional impairment. They do not provide a pathologic diagnosis, and the extreme functional reserve of the organ occasionally produces normal results in the face of significant lesions. Many of these tests do not measure a specific function of the liver, and other organ systems may be implicated. False-positive results for each of the tests are found in about 10 percent of hospital controls. False-negative tests also occur in about 10 percent of most tests.

Proteins

Hepatic cells are responsible for the synthesis of albumin, fibrinogen, prothrombin, and other factors involved in blood clotting. A reduction of serum albumin is one of the most accurate reflections of the extent of liver disease and the effects of medical therapy. Because the half-life of albumin is 21 days, impairment of hepatic synthesis must be present for over 3 weeks before abnormalities are noted. The correlation between total protein and disease of the liver is not as close as that between the serum albumin level and liver disease, since albumin is produced only by hepatic cells and a reduction is frequently compensated for by an increase in the level of globulin.

Carbohydrates and Lipids

Glycogenesis, glycogen storage, glycogenolysis, and the conversion of galactose into glucose all represent hepatic functions. Hypoglycemia is a rare accompaniment of extensive hepatic disease, but the amelioration of diabetes in patients with hemochromatosis is considered an indication of neoplastic change. The more common effect of hepatic disease is a deficiency of glycogenesis with resulting hyperglycemia. A hepatic enzyme system is responsible for the conversion of galactose into glucose, and abnormal galactose tolerance tests are seen in hepatitis and active cirrhosis. In rare instances, a familial deficiency in this enzyme system accounts for spontaneous galactosemia accompanied by an obstructive type of jaundice that appears after the first week of life and subsides when lactose is removed from the diet.

Synthesis of both phospholipid and cholesterol takes place in the liver, and the latter serves as a standard for the determination of lipid metabolism. The liver is the major organ involved in the synthesis, esterification, and excretion of cholesterol. In the presence of parenchymal damage, both the total cholesterol and percentage of esterified fraction decrease. Biliary obstruction results in a rise in cholesterol, and the most pronounced elevations are noted with primary biliary cirrhosis and the cholangiolitis accompanying toxic reactions to phenothiazine derivatives.

Enzymes

The three enzymes that achieve abnormal serum levels in hepatic disease and have been studied widely are alkaline phosphatase, serum glutamic oxalacetic transaminase (SGOT), and serum glutamic pyruvic transaminase (SGPT). SGOT is present in the liver, myocardium, skeletal muscles, kidney, and pancreas. Cellular damage in any of the above-mentioned tissues results in elevation of the serum level. In reference to the liver, the most marked increases accompany acute cellular damage regardless of cause, and extremely high levels are noted in patients with hepatitis. SGOT is only moderately increased in cirrhosis and biliary obstruction. SGPT is more particularly applicable to the evaluation of liver disease, since the hepatic content greatly exceeds myocardial concentration. Elevations accompany acute hepatocellular damage. Lactic acid dehydrogenase (LDH) levels also may be elevated.

Serum alkaline phosphatase provides an elevation of the patency of the bile channels at all levels, intrahepatic and extrahepatic. Elevation is demonstrated in 94 percent of patients with obstruction of the extrahepatic biliary tract due to neoplasm and 76 percent of those in whom the obstruction is caused by calculi. Intrahepatic biliary obstruction and cholestasis also cause a rise in the enzyme level. In the presence of space- occupying lesions such as metastases, primary hepatic carcinoma, and abscesses, the alkaline phosphatase level is also increased. The overall correlation between metastatic carcinoma of the liver and an elevated enzyme level is as high as 92 percent. Sixty percent of patients with primary hepatic carcinoma also demonstrate a significant increase. Granulomatous and infiltrative lesions such as sarcoidosis, tuberculosis, and lymphoma are irregularly associated with mild to moderate increases in the alkaline phosphatase. Elevation of the serum level of this enzyme is also associated with diseases that have as a common denominator increased osteoblastic activity. 5[pr]-Nucleotidase is a phosphatase that catalyzes hydrolysis of nucleotides. Levels are elevated in hepatobiliary disease.

Dye Excretion

The hepatic removal of dyes from the circulation depends on hepatic blood flow, hepatocellular function, and biliary excretion. The presence of jaundice produces a disproportionate indocyanine green or sulfobromophthalein (Bromsulphalein) retention, and fever, shock, hemorrhage, and recent surgical treatment may all result in increased levels. An increased retention is associated with acute cellular damage and is also noted in patients with cirrhosis, carcinoma, and chronic passive congestion. Since the rate of disappearance from the blood is constant, hepatic blood flow can be determined by injecting the dye at a rate that will maintain a constant blood level and applying Fick's principle to the blood removed from a catheterized hepatic vein. An intestinal xenon technique has been shown to provide an accurate method of measuring portal vein and total hepatic blood flow. Determination of the fecal excretion of the radioactive material has been applied to the differential diagnosis of obstructive jaundice, particularly in the establishment of the diagnosis of congenital atresia of the bile ducts, in which case HIDA or DISIDA fails to appear in the stool.

Coagulation Factors

In liver disease, multiple coagulation defects may occur. Two mechanisms contribute to the deficiency of coagulation factors: (1) in obstructive jaundice, the bile source required for the absorption of the fat-soluble vitamin K results in a decreased synthesis of prothrombin, and (2) hepatocellular dysfunction is accompanied by an inability of the liver to synthesize prothrombin. Abnormal values for prothrombin time have been noted in a variety of hepatic diseases with parenchymal damage, and determination is particularly applicable in the evaluation of patients undergoing liver biopsy or surgical procedures. An increase in prothrombin time subsequent to the injection of parenteral vitamin K is used as an indication of hepatic function and suggests obstructive jaundice. Decreases in factors V, VII, and IX and fibrinogen also have been noted in hepatic disease. Cirrhosis also has been associated with an increased fibrinolysis due to defective synthesis of fibrinolytic inhibitors and delayed removal of plasminogen activators.

Quantitative Tests

Maximal rate of urea synthesis after an oral challenge with casein or an intravenous bolus of amino acids provides an assessment of hepatic function, as does the determination of galactose elimination capacity.

Bile Pigment Metabolism

See the section Jaundice in Chap. 22.

SPECIAL STUDIES

Needle Biopsy of the Liver

This is the one preoperative study that provides a pathologic diagnosis. It depends on an area of tissue measuring 1 to 4 cm in length and containing approximately 5 to 20 lobules representing a general anatomic change. Close to 100 percent accuracy has been demonstrated for both posthepatic and postnecrotic cirrhosis. Intrahepatic cholestasis, hepatitis, and cellular degeneration resulting from toxicity are all diffuse lesions and readily diagnosed. Focal lesions, such as neoplasms, granulomas, and abscesses, may be missed, but the correlation between needle biopsy and operative and autopsy findings is high. In the case of focal nodular hyperplasia, a needle biopsy often reports normal structure made up of normal hepatocytes and fails to diagnose the lesion because the classic central scar is missed. Occasionally, exsanguination has been reported, particularly in patients with hemangioma, and pain, pneumothorax, hemorrhage, and bile peritonitis are the complications to be considered. If hemangioma is a considered diagnosis, needle biopsy is contraindicated.

Ultrasonography, Computed Tomography, Magnetic Resonance Imaging, and Scintigrams

Preoperative *ultrasonography (US)* has its highest yield in defining hepatic abscesses, cystic lesions, and most hemangiomas. Intraoperative US detects lesions unidentified by preoperative studies and demonstrates the intraparenchymal vascular anatomy, thus facilitating resection. US and duplex scanning can determine the patency of a portasystemic shunt noninvasively.

Computed tomography (CT) is used with or without vascular enhancement. Intravenous contrast material improves the diagnostic yield over plain CT, but the best results in definition of parenchymal lesions are obtained with intraarterial infusion scans. A catheter is placed in the common hepatic artery, and the scan is taken while the artery is infused. The tumor lights up. The catheter is then positioned in the superior mesenteric artery, and a scan is taken while it is infused and again during the venous phase. Lesions present as radiolucencies. For most lesions, CT provides the best results.

Magnetic resonance imaging (MRI) is particularly applicable for assessing vascular lesions. The T₂ phase provides a characteristic demonstration of a hemangioma. Scintillation scanning also can detect intrahepatic focal lesions. Using tagged red cells or technetium (^{99m}Tc)-sulfur colloid, the diagnosis of hemangioma can be established.

A prospective analysis of laboratory tests and imaging studies has shown greater than 65 percent accuracy in the detection of hepatic lesions. No combination of laboratory tests increased this accuracy. If the laboratory tests were used with one of the imaging studies, the accuracy was increased to 76 percent. The use of all the liver imaging tests and laboratory tests lowers the accuracy and needlessly increases the expense.

Angiography

Since hepatic tumors, both primary and metastatic, depend on an arterial circulation, unusual vascular patterns are also detected by injection of the hepatic artery with radiopaque material. Unusual arrangements of the arteries and “tumor staining,” analogous to that found in cerebral and osseous neoplasms, may be noted. Angiography also demonstrates extrahepatic vascular anatomy and provides a “road map” for the surgeon. Angiography is currently used less frequently.

Measurements of Portal Pressure and Evaluation of Portal Circulation

See Portal Hypertension later in this chapter.

TRAUMA

(See Chap. 6, Trauma.)

HEPATIC ABSCESSES

Hepatic abscesses are related to two distinct groups of pathogens, pyogenic bacteria and *Entamoeba histolytica*. Distinctive features in the clinical manifestations and therapy of these two variations necessitate separate consideration.

Pyogenic Abscesses

Incidence

The lesion is present in 0.36 percent of autopsies. The highest percentage of cases occur in the sixth and seventh decades, and there is no predilection for either sex.

Etiology

Pyogenic abscesses of the liver result from (1) ascending biliary infection, (2) hematogenous spread via the portal venous system, (3) generalized septicemia with involvement of the liver by way of the hepatic arterial circulation, (4) direct extension from intraperitoneal infection, or (5) other causes, including hepatic trauma. Recently, the most frequent antecedent cause has been cholangitis secondary to calculi or carcinoma in the extrahepatic biliary duct system. In one series, over 80 percent of patients with a pyogenic liver abscess had an underlying hepatobiliary or pancreatic cancer. The second most common cause is related to generalized septicemia, while the portal venous route of infection has decreased in importance. Pylephlebitis occurs in 0.05 percent of cases of acute appendicitis and 3 percent of patients with perforated appendicitis. No segment of the intestine drained by the portal venous system can be excluded as a possible cause, and the incidence associated with acute diverticulitis is as high as that of appendicitis. There is an increased incidence in immunocompromised patients. There has been an increase in the percentage in which no cause is apparent. These account for about 20 percent of cases.

Cultures are positive in over 90 percent of cases in which they were obtained. *Escherichia coli*, *Klebsiella*, and *Streptococcus* are the organisms most commonly isolated. *Staphylococcus* and *Pseudomonas* are occurring more frequently, and mixed bacterial and fungal abscesses are noted in about 25 percent of patients.

Pyogenic abscesses may be solitary, multiple, and multilocular. Single and multiple abscesses occur with equal frequency. When a single abscess is present, it is usually located in the right lobe.

Clinical Manifestations

Since most pyogenic hepatic abscesses are secondary to other significant infections, it is difficult to delineate a pathognomonic symptom. Fever is the most common symptom, and a “picket fence” configuration of the temperature chart generally has been noted. Fever is frequently accompanied by chills, profuse sweating, nausea, vomiting, and anorexia. Pain is a late symptom and is more common with large, solitary abscesses. Liver enlargement is noted in 30 to 60 percent of cases. Hepatic tenderness is present in half the patients. Jaundice is related to the causative pathology.

Diagnostic Studies

Leukocytosis with white blood cell counts ranging between 18,000 and 20,000/mm³ is usual. Half the patients are anemic. Positive blood cultures are demonstrated in approximately 40 percent of patients, the most significant yields accompanying abscesses secondary to systemic septicemia. Liver function tests are not diagnostic, but elevation of the alkaline phosphatase level is the most frequent abnormality. Hypoalbuminemia is inconsistent. Characteristically, radiographs reveal an elevation and immobility or restriction of motion of the right leaf of the diaphragm. There is also obliteration of the right cardiophrenic angle on the posteroanterior chest film and the anterior costophrenic angle on the lateral film. Abscesses produced by gas-forming microorganisms are associated with air-fluid levels in the liver. The *CT* is the most accurate radiographic study (over 90 percent) as contrasted with ultrasound (80 percent) and radionuclide (70 percent) (Figs. 28-6 and 28-7).

Treatment

This is based on appropriate antibiotic therapy combined with drainage in selected cases. Intravenous antibiotics are usually administered for 2 weeks, followed by 1 month of oral therapy. The abscesses may be drained percutaneously under *US* or CT control. Several series have reported success rates of 80 percent using this technique. Equivalent results have been reported for percutaneous and surgical drainage. The route of surgical access depends on the position of the abscess and may be transthoracic or transabdominal (Figs. 28-8 and 28-9). Because of the availability of antibacterial agents, transperitoneal drainage is no longer associated with prohibitive morbidity or mortality. In a small group of patients with multiple abscesses confined to a lobe, treatment is best managed by resection (Fig. 28-10).

Prognosis and Complications

Percutaneous and surgical drainage have been associated with mortality rates ranging from 7.5 to 20 percent. With multiple abscesses, the rate is significantly increased. The likelihood of death for patients treated with antibiotics alone is approximately 50 percent.

Amebic Abscesses

Incidence

E. histolytica has been found wherever surveys have been made on the human population from northern Canada to the Straits of Magellan. Amebic abscess of the liver is a disease of the middle-aged adult and predominates in males with a 9:1 ratio. The concept of racial immunity is invalid.

Pathology

Amebas reach the liver by way of the portal venous system from a focus of ulceration in the bowel wall. Hepatic involvement is usually a large, single abscess containing liquefied material with a characteristic reddish brown “anchovy paste” fluid. The lesions are usually single and occur in the right lobe of the liver, either near the dome or on the inferior surface in juxtaposition to the hepatic flexure. The wall is only a few millimeters thick and consists of granulation tissue with little or no fibrosis. Microscopically, three zones are recognized: a necrotic center, a middle zone with destruction of parenchymal cells, and an outer zone of relatively normal hepatic tissue in which amebas may be demonstrated.

Clinical Manifestations

Abscesses become evident when they cause generalized systemic disturbances coupled with symptoms and signs of hepatic involvement. The chief complaints are fever and liver pain. Pain is present in 88 percent of patients, and the pattern is related to the location of the hepatic abscess. With pain and tenderness over the right lower intercostal spaces, there may be associated bulging and pitting edema of the subcutaneous tissue. Superior surface abscesses result in pain referred to the right shoulder, whereas abscesses in the bare area, which have no contact with the serosal surface, are latent as far as pain is concerned. Left lobe abscesses present as a painful epigastric swelling.

Fever accompanied by chills and sweating is present in over three-quarters of patients, but the temperature does not reach the levels resulting from pyogenic abscesses unless there is secondary infection. One-third to one- half of adults offer a history of antecedent diarrhea, whereas in children grossly bloody, mucous stool occurs more frequently. Tender hepatomegaly is an almost constant feature. Clinical jaundice is relatively rare.

Diagnostic Studies

Patients with acute disease show no anemia but an appreciable degree of leukocytosis, whereas those with prolonged illness have anemia with less marked leukocytosis. Amebas are found in the stool of only 15 percent of cases collected from the literature. Liver function tests are not helpful in establishing the diagnosis. The indirect hemagglutination test is almost always positive. Radiographic findings are similar to those described for pyogenic abscesses. Scintillography, *US*, and angiography also have helped to localize the lesion.

Diagnosis is frequently established by aspiration of the abscess cavity, a relatively innocuous procedure. Although the “anchovy paste” aspirate is considered pathognomonic, the abscess content may be creamy white, even though there is no secondary bacterial infection. Amebic trophozoites are demonstrated in the aspirate of fewer than one-third of patients.

Complications

The most common complication is secondary infection, which occurs in approximately 22 percent of patients. Rupture of the amebic abscess accounts for the next most common group of complications. The direction of rupture is reproduced in Fig. [28-11](#). Pleuropulmonary complications occur in 20 percent of patients. This is usually the result of direct extension of the hepatic process. The most serious route of rupture is into the pericardial cavity, and this is usually secondary to extension of an abscess in the left lobe. Rupture into the peritoneal cavity or into an intraabdominal viscus occurs in 6 to 9 percent of the patients.

Treatment

This consists of administration of amebicidal drugs combined with aspiration or surgical drainage when indicated. The initial approach is usually conservative and directed toward eradicating the parasite from the intestinal tract, liver, and abscess itself. In general, the patient is not considered for surgical treatment until the intestinal phase is controlled. Metronidazole, which acts in both the hepatic and intestinal sites, has replaced emetine and chloroquine. Both the hepatic and intestinal infections generally have been cured by 400 mg three times a day for 4 days, occasionally combined with closed aspiration. In endemic areas, most patients are managed with drugs alone and rarely require aspiration. A single dose of 2.5 g combined with aspiration also has had dramatic results.

Surgical Procedures

The indications for aspiration are (1) the persistence of clinical manifestations following a course of amebicidal drugs, (2) clinical or radiographic evidence of a hepatic abscess, and (3) absence of findings that would suggest secondary infection of a liver abscess. Drug therapy should be instituted several days prior to aspiration. In most instances, aspiration is not required, and the abscess will be resolved by the medication. There is no indication for injection of any drug directly into the abscess cavity. In the absence of localizing signs, the preferred route for percutaneous drainage is through the ninth or tenth interspace between the anterior and posterior axillary lines. Once an abscess has been demonstrated to be secondarily infected, open drainage is the treatment of choice.

Prognosis

This depends on the relative virulence of the organism and the resistance of the host, the stage of infection, the multiplicity of abscesses, and the presence of complications. In uncomplicated cases, the mortality rate is less than 5 percent, whereas with complications a 43 percent mortality has been reported.

CYSTS AND BENIGN TUMORS

Nonparasitic Cysts

These lesions may be single, multiple, diffuse, localized, unilocular, or multilocular. They include (1) blood and degenerative cysts, (2) dermoid cysts, (3) lymphatic cysts, (4) endothelial cysts, (5) retention cysts, consisting of (*a*) solitary retention cysts and (*b*) multiple retention cysts (polycystic disease), and (6) proliferative cysts (cystadenomas). Autopsy incidences of approximately 0.15 percent have been reported. One percent of *CT* scans reveal intrahepatic cysts. The clinically apparent nonparasitic solitary cysts occur more frequently in women in the fourth, fifth, and sixth decades, at an average age of 52 years. Polycystic hepatic disease also occurs much more frequently in women.

Pathology

Solitary nonparasitic cysts are usually located in the right lobe of the liver. The cyst content is a clear, watery material, and characteristically, the cysts have a low internal pressure, in contrast to the high tension in parasitic cysts. Occasionally, the fluid is yellowish brown, suggesting necrosis of adjacent parenchyma. Polycystic disease of the liver has a honeycomb appearance with multiple cavities, and the lesions commonly are distributed throughout the entire liver. At times, however, one lobe, more frequently the right, is preferentially involved. Unlike the solitary nonparasitic cyst, polycystic disease of the liver (Fig. [28-12](#)) frequently is associated with cystic involvement of other organs; 51.6 percent of polycystic livers are associated with polycystic kidneys. Conversely, the incidence of hepatic cysts in patients with known polycystic renal disease varies between 19 and 34 percent. Polycystic livers have been implicated as a rare cause of portal hypertension and also have been associated with atresia of the bile ducts, cholangitis, and hemangiomas.

Traumatic cysts are usually single, are filled with bile, and contain no epithelial lining. Cystadenomas are grossly smooth, encapsulated, and lobular and contain a mucoïd material. They are lined by a proliferative columnar epithelium.

Clinical Manifestations

Both solitary and polycystic lesions grow slowly and are relatively asymptomatic. A painless right upper quadrant mass is the most frequent complaint, and when symptoms occur, they are usually related to pressure on adjacent viscera, such as early satiety. Acute abdominal pain may accompany the complications of torsion, intracystic hemorrhage, or intraperitoneal rupture. Physical examination may reveal the mass, and the kidneys may be palpable. Jaundice is rare. Liver function tests usually demonstrate no abnormality. Scintillography, *CT* scan, *US*, and arteriography have been used to define the intrahepatic position of the mass, and peritoneoscopy may be diagnostic (Fig. [28-13](#)).

Treatment

Asymptomatic solitary nonparasitic cysts and polycystic disease of the liver require no treatment. Large, solitary symptomatic cysts usually can be managed electively unless there is rupture, intracystic hemorrhage, or torsion. Patients have been managed successfully with radiographically controlled percutaneous catheter drainage, at times reinforced with injection of a sclerosing solution such as alcohol. This procedure is frequently associated with recurrence. Permanent resolution can be effected by a simple operation in which the cyst is widely unroofed back to its junction with normal hepatic parenchyma. This can be accomplished laparoscopically. In the case of significant intracystic bleeding, cystectomy might be required. Internal drainage into the intestine is indicated only if there is erosion into a major hepatic duct that cannot be repaired.

In patients with significant symptoms attributed to the mass effect of polycystic liver, palliation can be achieved by nonanatomic resection and wide fenestration of the larger cysts.

Prognosis

The prognosis of polycystic disease is essentially that of the accompanying renal disease. Hepatic failure, jaundice, and the manifestations of portal hypertension are rare. The mortality rate for surgically treated nonparasitic cysts of the liver approaches zero.

Hydatid Cysts

Hydatid disease (*echinococcosis*) is characterized by worldwide distribution and frequent hepatic involvement. The incidence among human beings depends on the incidence in intermediate hosts, including sheep, pigs, and cattle. The southern half of South America, Iceland, Australia, New Zealand, and southern parts of Africa are regarded as intensive endemic areas. Most cases reported in the United States have occurred in immigrants from Greece and Italy.

Pathology

The most common unilocular hydatid cyst is caused by *Echinococcus granulosus*, whereas the alveolar type is caused by *E. multilocularis*. Approximately 70 percent of hydatid cysts are located in the liver, and in one-quarter to one-third of these cases there are multiple cysts. The right lobe is affected in 85 percent of patients. Cysts are usually superficial and are composed of a two-layer laminated wall, an inner germinative membrane, and an outer adventitia. The two membranes are in close contact with each other but are not linked. The fluid in the hydatid cyst has a high pressure of approximately 300 mL of water and is colorless, opalescent, and slightly alkaline. Inside the main hydatid vesicle, daughter cysts are usually found. Extension is commonly into the peritoneal cavity, but progressive intrahepatic expansion may result in the replacement of liver parenchyma.

In contrast to the unilocular hydatid cysts, the alveolar hydatid is a growth without a capsule and with a tendency toward multiple metastases. As growth progresses, the center becomes necrotic, and the periphery invades the blood vessels and lymph channels. The causative agent of this lesion is found more frequently in the colder regions of Alaska, Russia, and the Alps.

Complications

Intrabiliary rupture represents the most common complication and occurs in 5 to 10 percent of cases. Suppuration, the second most common complication, is caused by bacteria from the biliary tract. The formation of the purulent material results in death of the parasite and conversion into a pyogenic abscess. Intraperitoneal rupture results in the showering of hydatid fluid, brood capsules, and scolices into the peritoneum, leading to transient peritoneal irritation of varying intensity. Usually, the reproductive elements survive and initiate the formation of new cysts (*secondary echinococcosis of the peritoneum*). Cysts located in the superior portion of the liver tend to grow craniad into the pleural cavity and become intrathoracic. These can be differentiated from primary pulmonary cysts by the presence of daughter cysts and bile pigments. Empyema and bronchopleural fistula must result.

Clinical Manifestations

Patients with simple or uncomplicated multivesicular cysts are usually asymptomatic. When symptoms occur, they are caused by pressure on adjacent organs. Abdominal pain and tenderness are the most common complaints, followed by a palpable mass. A tumor, which is palpable in 70 percent of the patients, or diffuse hepatic enlargement in a patient who has lived in an endemic region is cause for suspicion. The so-called hydatid thrill and fremitus are quite rare. Jaundice and ascites are uncommon. With secondary infection, tender hepatomegaly, chills, and spiking temperatures occur. Urticaria and erythema offer evidence of a generalized anaphylactic reaction. With biliary rupture, the classic triad of biliary colic, jaundice, and urticaria may be noted. Vomiting with passage of hydatid membranes in the emesis (*hydatidemesia*) and passage of membranes in the stool (*hydatidenteria*) also may occur. The complication of intraperitoneal rupture is heralded by abdominal pain and signs of anaphylactic shock. Intrathoracic rupture is associated with shoulder pain and cough initially productive of a frothy blood-stained fluid that subsequently becomes stained with bile. Membranes are intermittently expectorated in 80 percent of these patients.

Diagnostic Studies

Radiographically, an unruptured cyst presents as a round, reticulated, calcified shadow in the liver (Fig. 28-14). Secondary infection with gas-producing organisms might be confused with daughter cysts. With intrabiliary rupture, gas is noted in the remaining cyst cavity. CT scans furnish useful information and correlate well with operative findings (Fig. 28-15). Eosinophilia is the least reliable of immunologic responses, being present in only 25 percent of all patients. The indirect agglutination test is positive in about 85 percent of patients; the complement fixation test is slightly less sensitive. This reaction becomes negative 2 to 6 months after removal of the cyst. Casoni's skin test is positive in approximately 90 percent of patients, and the reaction can be obtained years after surgical removal of the cyst or after the parasite has died.

Treatment

Small calcified cysts in patients with negative serologic test results need no treatment. Treatment is surgical, since there is no response to drug administration. Therapy consists of removal of the cyst contents without contaminating the patient, followed by appropriate management of any remaining cavity. Since the hydatid fluid is under high tension, evacuation and sterilization are carried out initially with a scolical agent such as hibitane, alcohol, or hypertonic saline. Following evacuation and irrigation, primary closure may effect cure. External drainage and marsupialization are accompanied by high complication rates and prolonged drainage. Removal of the parasite is accomplished by excision of the hydatid vesicle using the natural cleavage plane that exists between the germinative layer and adventitia. Omentoplasty provides a method of managing the cavity successfully (Fig. 28-16). Total removal of the cysts, including the adventitial layer, also may be performed. Partial hepatectomy with controlled hepatic resection has been advised for larger and multiple cysts. Marsupialization and partial hepatectomy are the alternatives for large or injected cysts. In uncomplicated cases, the results of surgical treatment are excellent, and the postoperative mortality is less than 5 percent. With intrabiliary rupture, marsupialization should be accompanied by drainage of the bile duct if there is associated obstruction. Rupture into the peritoneal cavity is treated by laparotomy and thorough cleansing, although it is frequently impossible to prevent secondary contamination. Intrathoracic rupture generally can be controlled by evacuating and draining the hepatic cysts. Alveolar disease of the liver was inevitably fatal, but more recently, satisfactory results have been obtained with extensive hepatic resection.

Benign Tumors

Hamartoma

Hamartomas are composed of tissues normally present in the organ but arranged in a disorderly fashion. The lesions vary from minute nodules to large tumors and are rarely of clinical significance. Large mesenchymal hamartomas have presented as rapidly growing abdominal masses in infants and children. US and CT are the most useful diagnostic tests. Grossly, the tumors are firm, nodular, and located immediately beneath the surface of the liver, and they may be solitary or multiple. They are generally well encapsulated and often cystic. With lesions of clinical significance, surgical excision is generally indicated. Deeply located lesions should be left alone after histologic diagnosis has been established because they do not grow rapidly and do not undergo malignant transformation.

Adenoma

Hepatic adenoma is a benign tumor that was rarely noted before the introduction of oral contraceptives in the 1960s. In an accumulation of data from many series, more than 60 percent of patients were exposed only to mestranol; an additional 20 percent of patients were exposed to a product that included mestranol. More than half the patients used oral contraceptives continuously for durations longer than 5 years; lesions have become manifest even after discontinuation of the drug. These lesions also develop during pregnancy, in patients with diabetes mellitus or glycogen storage disease, and rarely, as adenomatosis, which is defined as more than 10 adenomas in an otherwise normal hepatic parenchyma. Adenomatosis occurs with equal frequency in men and women.

In patients who were contraceptive users, hepatic adenomas tend to be larger and have higher rates of intratumoral and intraperitoneal hemorrhage. Bleeding also has occurred during pregnancy. Transformation of the adenomas into hepatocellular carcinoma has been documented; this occurs more frequently in patients with adenomatosis.

The diagnosis typically is made in women of childbearing age. Eighty percent are symptomatic, with pain or mass effect generally related to intratumoral or intraperitoneal bleeding. The latter may cause shock. The hepatic lesion usually can be identified by US or CT (Fig. 28-17). At times, a small lesion is not detected, but the diagnosis is suggested by a subglissonian hematoma. Percutaneous biopsy is contraindicated because it is associated with a high risk of bleeding.

Although regression and disappearance of hepatic adenomas have been reported after the discontinuation of contraceptives, the potential for bleeding and malignant transformation, along with the current safety of removing the lesions, favors routine resection. Deaths associated with elective resections are rare; an 8 percent mortality is reported for emergency resection. The lesions are readily identified by their pale yellow color and homogeneous appearance. They often can be removed by enucleation with a narrow rim of normal hepatic parenchyma. Because of the diffuse nature of adenomatosis and its potential for malignancy, transplantation has been used.

Focal Nodular Hyperplasia (FNH)

This is a benign lesion that usually occurs in women of reproductive age. Many believe that it is neither a neoplasm nor a hamartoma but a reaction to injury or a hyperplastic response to a preexisting spider-like vascular malformation. There is no consistent relationship to oral contraceptive use. US and CT frequently fail to define the lesion because it is isodense. The angiogram demonstrates a typical sunburst, hypervascular pattern. The patients are almost always asymptomatic, and the lesions frequently are detected at celiotomy. Spontaneous bleeding rarely occurs. The cut surfaces are tan and demonstrate a characteristic central stellate scar. To make a histologic diagnosis, a deep biopsy is necessary to define the scar because the hepatic cell structure is otherwise normal (Fig. 28-18). FNH was regarded as a possible precursor to fibrolamellar carcinoma, but unlike the latter, it contains no neurotensin. Resection is occasionally indicated for significant pain ascribed to the lesion and rarely for spontaneous rupture.

Hemangioma

Hemangioma is the most common nodule in the liver, and the liver is the internal organ most frequently affected with this lesion. The tumor occurs five times more frequently in women than in men. These are occasionally associated with FNH and cysts of the liver and pancreas. Malignant degeneration does not occur. The hemangioma must be distinguished from hemangioendothelioma or diffuse hemangiomatosis. The latter consists of widespread multicentric lesions accompanied by vascular involvement of the skin and occurs in children with clinical manifestations in the first week of life.

Most lesions are detected radiographically, are less than 5 cm in diameter, and are asymptomatic. Larger lesions can be painful and palpable. Platelet trapping in giant hemangiomas can result in thrombocytopenia. Growth of the lesions as a consequence of pregnancy or estrogen therapy has been varied. Most small lesions followed ultrasonographically during pregnancy grow minimally, but occasionally, significant increases in size occur. Rupture of a hemangioma is a rare event. In infants, large hemangiomas often are associated with high-output cardiac failure.

Hemangiomas can present a characteristic pattern on US and CT (Fig. 28-19 A). The diagnosis can be made on a T₂-weighted MRI or scintigram with ^{99m}Tc-labeled red blood cells. The arteriogram demonstrates pooling in small peripheral vessels (Fig. 28-19 B). Percutaneous biopsy often provides the histologic diagnosis but is rarely indicated because it is associated with the complication of bleeding.

In infants with high-output congestive heart failure, supportive therapy, at times with the addition of steroids, is effective, and the lesion regresses. In rare cases, hepatic artery embolization or ligation may be required to reverse cardiac failure. In adults, most hepatic hemangiomas should not be excised. Even large lesions followed for long periods show no notable increase in size or clinical manifestations. The potential for rupture is minimal and should not constitute an indication for excision. Pain, mass effect, significant growth, platelet trapping, and early rupture are indications for surgical excision. Few reports have documented reduction in size with radiation therapy, and hepatic arterial ligation is rarely effective in adults. Resection is the therapy of choice when indicated. Large lesions may necessitate anatomic resection, but enucleation is often feasible.

MALIGNANT TUMORS

Primary Carcinoma

Incidence

Although the disease is rare in people of western Europe and North America, primary carcinoma is remarkably common among the aboriginal inhabitants of Africa and in many parts of Asia. Postmortem rates in the United States average 0.27 percent, whereas in Africa the postmortem rate is 1.1 percent, hepatic carcinomas representing 17 to 53 percent of all cancers. In some Asian countries, the autopsy incidence is 2.5 percent.

Primary carcinoma of the liver occurs with greater frequency in males. In whites it is rare before age 40, whereas in Africans and Asians the affliction usually occurs before age 40. American blacks do not exhibit a predisposition toward the disease. By contrast, a higher incidence is present in Chinese subjects even after they have changed their habitation. In children, the first appearance of the neoplasm is usually before age 2, and primary carcinoma of the liver represents the most common carcinoma in the first few years of life. Hepatoblastoma usually affects children less than 2 years old; the male-to-female ratio is 6:1. This lesion also occurs in adults. Fibrolamellar carcinoma, a variant of hepatocellular carcinoma, has a propensity for adolescents and young adults, with an equal sex incidence.

Etiology

A number of etiologic factors have been implicated. Aflatoxins of the mold *Aspergillus flavus* contaminate the diet in African and Asian communities with a high incidence of hepatocellular carcinoma. Low protein intake and consequent kwashiorkor also may be factors. Just as almost every type of experimentally induced cirrhosis may be followed by carcinoma of the liver, so a definite association between cirrhosis and primary carcinoma has been noted in human beings. Postnecrotic cirrhosis is the type most commonly preceding hepatocellular carcinoma; cirrhosis is present in 60 percent of patients. Serologic markers for hepatitis B virus or antibodies to hepatitis C virus are detected in most patients with hepatocellular carcinoma in endemic areas. Hepatic malignant tumors occur in 4.5 percent of cirrhotic patients, and the incidence is increased in patients with hemochromatosis. Parasite infestation with the liver fluke *Clonorchis sinensis* has been considered a factor in the development of cholangiocarcinoma, but this is open to question. There is no increased risk for hepatic carcinoma following infectious hepatitis that does not progress to cirrhosis. In the pediatric age group, the tumor is rarely related to cirrhosis. Another factor associated with hepatocellular carcinoma is aberrant α_1 -antitrypsin-piZ.

Pathology

Liver cell (*hepatocellular*) carcinoma is the most common type; the tumor cells resemble the parenchymal cell. Bile duct carcinoma (*cholangiocarcinoma*) is apparently derived from bile duct epithelium. *Hepatoblastoma* represents an immature variant of hepatocellular carcinoma.

Grossly, each of these types may present as a single, large nodule, as extensive nodularity, or as a diffuse permeation throughout the organ. The anatomic distribution of fibrolamellar carcinoma is unusual in that 75 percent present as solitary, large left lobe tumors. They have a prominent central scar. The hepatocellular carcinomas have a trabecular structure, and vascularity is a prominent feature. These lesions frequently invade branches of the portal vein and occasionally the hepatic veins. The formation of giant cells is a feature of hepatocellular carcinoma and aids in distinguishing this lesion from secondary carcinoma of the liver. Fibrolamellar carcinoma is characterized by eosinophilic hepatocytes and abundant fibrous stroma arranged in parallel bands around tumor cells. The cell type of bile duct carcinoma is columnar, and its microscopic appearance may be impossible to distinguish from that of carcinoma of the gallbladder or extrahepatic biliary duct system. Bile is never seen in the acini or the cells, whereas mucus formation is common.

Hepatic tumors extend by four methods:

- (1) Centrifugal growth, which indicates nodular expansion leading to compression of the surrounding hepatic tissue.
- (2) Parasinusoidal extension, which refers to tumor invasion into the surrounding parenchyma, either through the parasinusoidal spaces or through the sinusoids themselves.
- (3) Venous spread or extension of tumor from small branches of the portal system in a retrograde fashion into larger branches and eventually into the portal vein. Invasion of hepatic vein tributaries is less common but may extend up to the inferior vena cava or right atrium.
- (4) Distant metastases, the result of invasion of lymph channels and vascular systems. The most frequently involved locations are regional lymph nodes and lungs.

Metastases occur in 48 to 73 percent of patients.

Clinical Manifestations

Weight loss and weakness occur in 80 percent of patients, whereas abdominal pain is present in half (75 percent of patients with fibrolamellar carcinoma). The pain is usually dull and persistent, but dramatic sudden onset may occur in patients with intraperitoneal hemorrhage secondary to rupture of a necrotic nodule or erosion of a blood vessel. Manifestations of portal hypertension, such as bleeding varices, are infrequent but foreboding symptoms.

The liver is almost always enlarged but not tender. Splenic enlargement is present in one-third of patients, as are other signs of portal hypertension. The incidence of jaundice varies from 20 to 58 percent. Ascites develops in one-half to three-quarters of patients. A rapid increase in the symptoms and signs associated with cirrhosis or hemachromatosis is highly suggestive of superimposed hepatic carcinoma. In these patients, the amelioration of diabetes and occasional hypoglycemic intervals also indicate neoplastic change.

In over half of pediatric patients, the first evidence is an abdominal mass. Hemihypertrophy and sexual precocity occur in an occasional pediatric patient with hepatoblastoma.

Diagnostic Studies

The most consistently altered liver function test is the alkaline phosphatase determination. The serum bilirubin level is usually normal; 5[pr]- nucleotidase is usually elevated.

The demonstration of *alpha-fetoprotein (AFP)* in the serum by immunodiffusion, immunoelectrophoresis, and immunoassay techniques is useful in the differential diagnosis and epidemiologic studies. This protein is normally present in the fetus but disappears a few weeks after birth. Positive AFP tests are noted in about 75 percent of Africans but in only 30 percent of patients in the United States and Europe. False-positive results occur with embryonic tumors of the ovary and testis. Resection of the tumor converts the test to "negative"; recurrence may be detected by the reappearance of AFP in the serum.

Selective hepatic arteriography has been used to demonstrate an arterial pattern within the tumor, characterized by pooling and increased vascularity (Fig. 28-20). Scintillation scanning also may identify the space- occupying lesion within the liver, but *CT* and *MRI* are more sensitive. Percutaneous needle biopsy can provide a definitive diagnosis. *US* is particularly helpful in differentiating cystic from solid tumors. Intraoperative US has added an important surgical refinement and permitted more limited resections.

Treatment

The only curative therapy for hepatocellular carcinoma is surgical excision. In most instances, this entails a lobectomy, but with an appreciation of segmental anatomy, lesser "anatomic" resections are being performed more frequently. A major resection is compromised by cirrhosis because of increased vascularity, increased morbidity, and an inability for the cirrhotic liver to regenerate. The use of intraoperative US has permitted limited resections particularly in cirrhotic patients. Limited resections, including segmentectomies and bisegmentectomies, have achieved success in cirrhotic patients. Resection has resulted in survival rates of over 40 percent in patients with small, unifocal, well-differentiated tumors without vascular invasion. Transarterial chemoembolization using gelatin sponges, iodized oil, and chemotherapeutic agents has achieved 1-, 2-, and 5-year survival rates of 51, 24, and 6 percent, respectively, while decreasing the tumor size in almost a third of patients. Unresectable hepatocellular carcinomas may be converted to resectable lesions with combined radiation chemotherapy. Percutaneous Ethanol injection has resulted in the disappearance of tumors less than 4.5 cm in diameter. Cryosurgery, using an intraoperatively placed probe that delivers liquid nitrogen, also has effected tumor necrosis and destruction. Transplantation and resection yield equivalent 5-year survival rates of approximately 50 percent, but the recurrent rate is lower in patients who were transplanted. Transplantation achieved the best results in patients with small uninodular or binodular lesions. Resection of extrahepatic recurrences of hepatocellular carcinomas has resulted in several 5-year survivals.

In the case of hepatoblastoma, particularly in children, lesions often deemed not resectable can be converted into resectable tumors that have potential for cure. A combination of preoperative chemotherapy followed by resection resulted in a cure rate of 90 percent in children.

Prognosis

The outlook for untreated primary carcinoma of the liver is extremely poor, and the duration of the disease is rarely longer than 4 months from the time of onset of symptoms. Death is the result of cachexia, hepatic failure, sequelae or portal vein thrombosis, intraperitoneal hemorrhage, and metastases. In the Mayo Clinic experience, the 5-year survival after curative resection of a primary hepatic malignancy was 27 percent. Cholangiocarcinoma, nodal metastases, cirrhosis, hypocalcemia, and increased alkaline phosphatase level and prothrombin time were associated with decreased survival. In Pittsburgh, the 5-year survival was 32 percent, with a more favorable prognosis noted for patients with fibrolamellar carcinoma. Similar survival rates were achieved with partial hepatic resection and by hepatectomy and orthotopic transplantation. In children under age 2 with hepatoblastoma, 21 of 27 who survived operation were alive and well with no evidence of disease for a mean of 53 months. By contrast, in children with hepatocellular carcinoma, the prognosis is poorer. Most tumors are not resectable, and 5-year cures are anecdotal.

Other Primary Neoplasms

The three major lesions are sarcoma, mesenchymoma, and infantile hemangioendothelioma. All hepatic mesenchymal lesions are considered malignant. Angiosarcoma is the most common primary sarcoma of the liver. Exposure to vinyl chloride and Thorotrast injection have been implicated as etiologic factors.

Angiosarcoma is characterized by a short illness, jaundice, and coma progressing rapidly to death. Infantile hemangioendotheliomas occur in children under the age of 5 and are associated with skin lesions and cardiac failure secondary to arteriovenous shunts within the tumor. Although most of these pediatric lesions are fatal, spontaneous regression has been recorded, as has success with partial hepatectomy.

Metastatic Neoplasms

Metastatic neoplasms represent the most common malignant tumors of the liver. The relative proportion of primary to secondary neoplasms is estimated to be 120, and there is no statistical difference between those with and those without cirrhosis. The liver is second only to regional lymph nodes as a site of metastases for tumors, and 25 to 50 percent of all patients dying of cancer have been found to have hepatic metastases. Fifty percent of patients with gastrointestinal tumors have hepatic metastases when autopsied.

Metastatic neoplasms reach the liver by four routes: (1) portal venous circulation, (2) lymphatic spread, (3) hepatic arterial system, and (4) direct extension.

Metastases appear in the liver at varying times in relation to primary lesions: (1) Precocious metastasis is evident when the primary lesion is not suspected (carcinoid of the ileum). (2) Synchronous metastases occur when the hepatic neoplasm is detected at the same time as the primary lesion. (3) Metachronous metastasis is one in which appearance is delayed following the successful removal of a primary tumor (ocular melanoma). The growth pattern of the metastatic tumor is frequently more rapid than the original lesion, and the mitotic count of metastatic hepatic neoplasms has been shown to be five times greater than that of the extrahepatic primary lesion.

Clinical Manifestations

Symptoms referable to the liver are present in 67 percent of patients with proven metastases. These include hepatic pain, ascites, jaundice, anorexia, and weight loss. On examination, hepatic nodularity is apparent in half the patients, and a friction rub is audible in 10 percent. Jaundice, ascites, and the signs of portal hypertension are present in approximately one-quarter to one-third of patients. With carcinoid tumors, hepatic metastases are of major importance in the pathogenesis of the flushing syndrome.

Diagnostic Studies

The alkaline phosphatase level is increased in over 80 percent of patients. The *SGOT* level is elevated in approximately two-thirds of patients, but the serum *AFP* determination is negative. The carcinoembryonic antigen (CEA) level may provide a marker for metastatic colon carcinoma. Enhanced *CT*, particularly that performed with selective arterial infusion via the hepatic artery, is the most sensitive means of defining intrahepatic metastases. *MRI*, scintigraphy, and arteriography also have been used. In the case of patients who have undergone resection of colorectal carcinomas, surveillance generally relies on sequential determinations of the CEA level. If elevation occurs, CT is performed. Intraoperative *US* has aided in the definition of resectable lesions.

Treatment

Surgical treatment of hepatic metastases should be considered only if (1) control of the primary tumor is accomplished or anticipated, (2) there are no systemic or intraabdominal metastases, (3) the patient's condition will tolerate the major operative procedure, and (4) the extent of hepatic involvement is such that resection and total extirpation of the metastasis is feasible. Resection of segments of the liver containing metastases has effected reasonable long-term survival without recurrence for patients with primaries in the colon and rectum and for those with Wilms' tumor. Rare survivors have been reported for other primaries.

A metastasis noted during a colon resection should be removed at that time if it is readily removable without anticipated blood loss. However, if it appears that a major hepatic resection will be required, the operation is delayed for months and is preceded by CT scan and angiography to assess resectability. Although 20 percent of patients with colorectal cancer have hepatic metastasis, only one-quarter of these are potentially resectable; half of these, in turn, have other metastases that would negate the value of resection.

A multi-institutional study of hepatic resection for colorectal metastases reported a 5-year actuarial survival of 33 percent and a 5-year actuarial disease-free survival of 21 percent. Single metastases and unilobar disease were associated with improved survival. Hepatic resection of greater than four metastatic lesions rarely was associated with prolonged survival. Forty percent of patients with recurrent disease after hepatic resection for metastatic colorectal tumors initially have only liver metastases. Reresection is followed by long-term survival in about one-third of carefully selected patients. Bismuth and associates have treated patients with colorectal hepatic metastases that were initially considered to be unresectable with doxorubicin, and this resulted in regression to a size that permitted resection. Cure rates equivalent to series of more favorable patients were achieved.

An implantable refillable pump has been used to intraarterially infuse floxuridine and other chemotherapeutic agents, but most series could demonstrate no improvement in survival or reduction in toxicity compared with intravenous administration of the drugs.

Patients with Wilms' tumor metastatic to the liver frequently can be cured by hepatic resection and adjuvant chemotherapy and radiation therapy. Resection of metastases from ocular melanoma, breast, stomach, uterus, cervix, ovary, and renal carcinomas rarely has achieved a cure (Table [28-2](#)).

Palliative cytoreductive surgical measures are indicated for marked pain associated with hepatic neoplasm and for the excision of metastases in patients with the flushing syndrome of carcinoid tumor. Resection of the major portion of the hepatic metastases (debulking procedure), even if residual tumor remains, has resulted in significant symptomatic improvement and reduction of the 5-hydroxyindoleacetic acid levels to normal. These subjective and objective changes have persisted for several years. Dearterialization and radiographically controlled embolization have achieved similar results.

HEPATIC RESECTION

The indications for hepatic resection include (1) trauma with resulting devascularization of hepatic tissue, (2) cysts, (3) granulomas, (4) primary neoplasms of the liver, and (5) secondary malignant tumors that involve the liver either by direct extension or as metastatic lesions.

Removal of up to 80 percent of the liver is compatible with life. Following excision of this amount, patients maintain normal blood ammonia levels and normal prothrombin times. Fibrinogen production is insignificantly impaired; clinical jaundice is a transient phenomenon. Following major resections, by the fifth postoperative day 95 percent of patients show clinical improvement in function, with the bilirubin and alkaline phosphatase levels returning to normal by the end of the third week. The most profound changes are noted in the serum albumin, which, by the third week, is usually restored to normal.

Regeneration results from marked hypertrophy of the remaining tissue. The remaining portion of the liver responds as rapidly and completely after second and third partial hepatectomies as after an initial insult. There is experimental evidence for hepatotropic substances in portal venous blood. Insulin may represent the major anabolic factor. Very little restoration occurs after partial hepatectomy of the cirrhotic liver.

Management of the Patient

Preoperative therapy is directed at maintaining optimal liver function and correcting any defects that may be present. A diet high in calories, proteins, and carbohydrates is utilized, and the administration of albumin may be required to achieve normal levels. Vitamin K is given routinely until a normal prothrombin time results. In the presence of jaundice, other fat- soluble vitamins are added. Fresh-frozen plasma will rapidly replenish coagulation factors. Since many patients have a reduced hematocrit, transfusion with fresh whole blood rich in platelets and coagulation factors is indicated. Major hepatic resection is attended by a prohibitive mortality rate in the patient with sulfobromophthalein retention greater than 35 percent, a serum albumin level lower than 2.0 g, and an increased prothrombin time that does not respond to parenteral vitamin K.

Postoperatively, infusion of 10% glucose is continued until the patient maintains an adequate oral intake to obviate severe hypoglycemia, which has been reported. Following more intensive resections, daily administration of 25 to 50 g albumin is usually required for 7 to 10 days to maintain the serum level above 3 g/dL. Antibiotics are administered prophylactically. Analgesics and hypnotics that are detoxified by the liver are used only sparingly. Intraabdominal abscess formation and sepsis are the most common complications of major hepatic resection, occurring in 20 to 30 percent of cases. Subphrenic abscesses usually can be managed with percutaneous drainage.

Operative Procedures

Control of Bleeding

This may be accomplished by (1) ligation or compression of blood vessels within the substance of the remaining liver segment, (2) efforts directed at the raw surface, including cautery and argon beam coagulation, and (3) control of the main blood vessels entering the porta hepatis.

Omental grafts, peritoneal grafts, Gelfoam, micronized collagen, and rapidly polymerizing adhesives have been applied to the raw surface as local hemostatic agents. Compression of the main vessels entering the liver facilitates the demonstration of bleeding sites along the raw surface. The hepatic artery and portal vein may be compressed for over an hour without affecting hepatic structure or function.

In order to obviate uncontrollable bleeding, total vascular occlusion can be helpful for lesions located close to the major hepatic veins and the inferior vena cava. After a vascular clamp is applied to the hepatoduodenal ligament, the vena cava above and below the liver is occluded. If the patient is loaded with fluids, 1 hour of total occlusion can be tolerated.

Techniques of Resection

On the basis of new concepts of segmental anatomy, the following classification of hepatic resection is applicable (Fig. [28-21](#)): (1) *Subsegmental*, or *wedge*, *resection* is removal of an area of the liver that is less than a segment and without an anatomic dissection plane. (2) *Left lateral segmentectomy* ("left lobectomy" in the old nomenclature) is excision of the liver mass to the left of the left segmental fissure along an anatomic plane. (3) *Left medial segmentectomy* is resection between the main interlobar fissure and the left segmental fissure. (4) *Left lobectomy* ("left hepatectomy") is excision of all hepatic tissue to the left of the main lobar fissure. (5) *Right lobectomy* ("right hepatectomy") is removal of the liver to the right of the main lobar fissure. (6) *Extended right lobectomy* is excision of the entire lobe plus the medial segment of the left lobe (*trisegmentectomy*), i.e., excision of all tissue to the right of the umbilical fossa, fossa for the ligamentum venosum, and the ligamentum teres.

Based on portal distribution, Couinaud has defined eight hepatic segments (see Fig. [28-2](#)). Segmental resection of one or two contiguous segments can be performed by a transparenchymatous approach following the anatomic scissura to the vascular pedicle (Fig. [28-22](#)).

The liver is mobilized initially by dividing the appropriate ligamentous attachments, i.e., ligamentum teres, falciform, and triangular and coronary ligaments. Dissection of the porta hepatis identifies the branches of the hepatic artery, portal vein, and biliary duct system supplying the segment or lobe to be removed (Fig. [28-23](#)). These are individually temporarily occluded. By rotating the liver, the hepatic veins may be isolated at their junctions with the inferior vena cava and ligated (Fig. [28-24](#)). Glisson's capsule is then incised along the surgical plane (Fig. [28-25 A](#)), and the cleavage plane of the hepatic parenchyma itself is best established by means of a scalpel handle or finger to permit exposure of the larger ducts and vessels, which may be individually clamped and ligated as they are encountered. This incision is continued posteriorly until the major hepatic vein or veins are identified (Fig. [28-25 B](#)), double ligated, and transected. The specimen is removed. The previously occluded structures in the porta hepatis are unclamped, and if bleeding or biliary drainage from the raw surface persists, the appropriate structure is ligated. The remaining raw surface may be covered with omentum. The blood flow to and from the remaining segments of the liver must be preserved carefully.

The majority of lobar resections, even right lobe resections, can be carried out transabdominally, and it is not necessary to proceed along the outlined sequence of events for surgical excision. Finger fracture is employed for trauma but is also applied in many instances for tumor. The sequence is summarized in Fig. [28-26](#). One can reduce the blood flow into the liver by temporarily cross-clamping the hepatoduodenal ligament; this procedure can be carried out for 60 min using a vascular clamp intermittently. Glisson's capsule is then incised anteroinferiorly, and the incision is carried down to the region of the porta hepatis. The vessels in the porta hepatis are then picked up in the parenchyma as they enter the liver. The parenchymal dissection is continued along anatomic planes, picking up vessels and ducts as they traverse the liver, until the hepatic venous structures are also picked up in the hepatic parenchyma. Intraoperative *US* is helpful in locating the intraparenchymal major vessels. The operative time is significantly reduced by this technique, and blood loss is only moderately increased. An ultrasonic disruption of the parenchyma can be used to isolate vessels as they traverse the resection plane. Trisegmentectomy necessitates anatomic dissection in order to avoid interrupting veins from the remaining segment.

PORTAL HYPERTENSION

Hypertension with the portal vein and its tributaries may accompany hepatic disease or disturbance in the anatomy of the extrahepatic vascular system. As a consequence of this elevated pressure, congestion of collateral pathways is established and may be manifested by esophagogastric varices, ascites, hypersplenism, or encephalopathy.

Etiology

The etiologic factors implicated in portal hypertension are listed in Table 28-3. Increased hepatopetal flow is an infrequent cause of portal hypertension. Hepatic arterial-portal venous fistula has been reported rarely, and the diagnosis can be established by CT, MRI, or angiography. Successful treatment has been effected by ligation of the hepatic artery or by direct closure of the fistula through an arteriotomy. Splenic arteriovenous fistula is also a relatively uncommon lesion. This has a predilection for women between the ages of 20 and 50 and may become asymptomatic during pregnancy. Calcification in the left upper quadrant is suggestive, and aortography may be diagnostic. Resection of the fistula or splenic artery and splenectomy are therapeutic.

An increase in forward blood flow in the portal venous system also has been proposed as the cause of portal hypertension in patients with tropical splenomegaly and myeloid metaplasia. In patients with increased hepatopetal flow related to splenomegaly, splenectomy alone may be therapeutic.

Since the hepatic veins constitute the sole efferent vascular drainage of the liver, obstruction or increased pressure within these vessels or their radicals results in an increased sinusoidal and portal pressure. This outflow obstruction (Budd-Chiari) syndrome is associated most frequently with an endophlebitis of the hepatic veins, which may be isolated or part of a generalized thrombophlebitis process. A web in the suprahepatic vena cava has been reported to cause the syndrome in Japanese people.

The clinical picture depends on the rapidity and degree of venous obstruction. With sudden and complete obstruction, the presentation is that of an abdominal catastrophe with severe abdominal pain, nausea, vomiting, and rapid enlargement of the abdomen by ascites. This rarely occurs. More commonly, obstruction to the hepatic venous system appears to be gradual and is associated with mild to moderate abdominal discomfort and ascites. Patients should be evaluated with an inferior vena cavagram to demonstrate occluded hepatic veins. If liver biopsy defines advanced cirrhosis, transplantation should be considered. If cirrhosis is absent, a mesenteric systemic venous shunt is the treatment of choice. A peritoneovenous shunt has provided temporary relief. Definitive treatment demands a side-to-side portal systemic anastomosis, since the portal vein must act as an efferent hepatic conduit. If the inferior vena cava is obstructed, a mesenteric-atrial shunt with a conduit may be required. In some patients, the manifestations have disappeared spontaneously.

Portal hypertension secondary to impaired flow in the extrahepatic portal venous system is unique in that the hypertension usually is not complicated by hepatocellular dysfunction. Congenital atresia or hypoplasia, as an extension of the obliterative process of the umbilical vein and ductus venosus, is rare. More commonly, there is a cavernomatous transformation of the portal vein that probably represents organization and recanalization of thrombi within the vessel. The most common etiologic factor in the development of extrahepatic portal venous obstruction in childhood may be some form of infection. Bacteria may be transmitted via a patent umbilical vein, but a history of neonatal omphalitis is rarely obtainable.

Extrahepatic obstruction also may be secondary to trauma and extrinsic compression caused by adhesions, inflammatory processes, and tumors. Isolated splenic vein thrombosis, usually a consequence of alcoholic pancreatitis, may cause esophagogastric varices. In this case, splenectomy cures the portal hypertension.

The overwhelming majority of cases of portal hypertension are related to an intrahepatic obstruction. This accounts for over 90 percent of patients with portal hypertension in most large series. A number of hepatic diseases have been implicated, but no single explanation of pathogenesis has proved totally satisfactory. The pathogenetic factors include (1) hepatic fibrosis with compression of portal venules, (2) compression by regenerative nodules, (3) increased arterial blood flow, (4) fatty infiltration and acute inflammation, and (5) intrahepatic vascular obstruction. The hepatic diseases associated with portal hypertension include nutritional cirrhosis, postnecrotic cirrhosis, schistosomiasis, biliary cirrhosis, hemochromatosis, Wilson's disease (hepatolenticular degeneration), congenital hepatic fibrosis, and infiltrative lesions.

Nutritional cirrhosis is the most common and has a worldwide distribution. In Western countries it is frequently associated with chronic alcoholism. As is true with all intrahepatic lesions, with the exception of congenital hepatic fibrosis and schistosomiasis, the major resistance to the flow of portal blood is located on the hepatic venous side of the sinusoid (postsinusoidal). Postnecrotic cirrhosis accounts for 5 to 12 percent of cases and represents progression of an acute viral hepatitis or toxic hepatic injury. Frequently, a history of viral infection is not obtainable. In the Orient, in most cases cirrhosis is a consequence of hepatitis. Both hepatitis B and C have been indicted. Biliary cirrhosis may be due to extrahepatic obstructions and secondary cirrhosis or to a primary hepatic lesion. Advanced portal cirrhosis is an almost invariable feature of hemochromatosis. Wilson's disease is characterized by alteration of hepatic function and structure and by mental deterioration. Congenital hepatic fibrosis may be related to dilatation of the intrahepatic bile ducts. It is usually an autosomal recessive disease. Clinical features include gross enlargement and firm consistency of the liver, accompanied by manifestations of portal hypertension and cholangitis. Hepatic function is not disturbed. As hepatic infestation with *Schistosoma mansoni* results in presinusoidal obstruction, there is no impairment of hepatic function until late in the course of the disease.

Pathophysiology

Portal hypertension refers to an elevated pressure within the portal venous system. This pressure reflects a dynamic, constantly fluctuating force. In addition to diurnal fluctuations, the pressure varies with changes of position, phases of respiration, and intraabdominal pressure. The normal portal pressure is less than 250 mmH₂O, with a mean value of 215 mmH₂O.

Portal pressure can be assessed by a variety of techniques. During an operative procedure, cannulation of an omental vein or the portal vein itself provides a direct recording. The pressure also can be determined by occlusive catheterization of the hepatic venule. This procedure is analogous to determination of pulmonary capillary pressure, in that it is based on the assumption that the occluding catheter creates a static column of blood extending from the hepatic vein to the junction of the hepatic arterial and portal venous streams as they converge in the sinusoidal bed. The procedure is carried out by cardiac catheterization technique and is particularly valuable in the diagnosis of extrahepatic portal obstruction. In this situation, the presinusoidal obstruction is associated with a normal occlusive hepatic venule pressure and an elevated splenic pulp pressure.

In all instances of portal hypertension, splenic pulp pressure is elevated. Intrasplenic pressure is essentially uniform throughout the pulp and is unrelated to the size of the organ. The pressure is usually 2 to 6 mmHg higher than the pressure within the portal vein per se, a function of the direction of venous flow. Splenic pulp manometry is carried out under local anesthesia but is contraindicated in patients with a bleeding tendency, thrombocytopenia, or severe jaundice.

Splenoportography or the venous phase of celiac and superior mesenteric angiography defines the pathologic features of the portal circulation. The studies provide a demonstration of collateral veins, particularly esophagogastric varices. They also provide graphic demonstration of the site of obstruction, i.e., intrahepatic or extrahepatic. Under normal circumstances, no collaterals are visualized and a good arborization is noted in the liver (Fig. 28-27). Whenever collaterals are apparent, the diagnosis of portal hypertension is suggested. Usually one can define the coronary vein contributing to esophageal varices by this technique (Fig. 28-28).

The umbilical vein also has been used to outline the portal system. In 80 percent of these cases, the obliterated vein can be isolated and dilated to permit passage of a catheter and injection of radiopaque material into the left portal vein. The portal and hepatic veins also can be visualized by percutaneous transhepatic cannulation.

Pathologic Anatomy

The collateral vessels (Fig. 28-29) that become functional in cases of portal hypertension are classified in two groups:

(1) Hepatopetal circulation occurs only when the intrahepatic vasculature is normal and obstruction is limited to the portal vein. In this situation, the accessory veins of Sappey, the deep cystic veins, the epiploic veins, the hepatocolic and hepatorenal veins, the diaphragmatic veins, and the veins of the suspensory ligaments carry a limited amount of portal venous blood to the liver.

(2) Hepatofugal flow is the type most commonly provided by the collateral circulation.

The vessels of the hepatofugal circulation include

(1) The coronary vein, which courses to the esophageal veins and then to the azygos and hemiazygos veins with eventual termination in the superior vena cava.

(2) The superior hemorrhoidal veins, which communicate by way of the hemorrhoidal plexus with hemorrhoidal branches of the middle and inferior hemorrhoidal veins and ultimately drain into the inferior vena cava.

(3) The umbilical and paraumbilical veins, which communicate with superficial veins of the abdominal wall and anastomose freely with the superior and inferior epigastric veins. Dilatation occurs in 22 percent of patients with portal cirrhosis, and the advanced stage is known as the *caput medusae*. The cephalad portion of the obliterated umbilical vein may remain patent in adult life or become recanalized, contributing to the Cruveilhier-Baumgarten syndrome.

(4) Retroperitoneally, the veins of Retzius, which form an anastomosis between the mesenteric and peritoneal veins and empty directly into the inferior vena cava.

In general, the collateral circulation does not effectively decompress the portal system, and the amount of blood shunted is relatively insignificant. Assuming the cross-sectional diameter of the normal portal vein to be 2 cm, then, according to Poiseuille's law, over 4000 collateral veins 0.5 cm in diameter will be needed to provide equivalent flow. The highest values of portal pressure are recorded in the group in which collateralization is more marked. In rare instances, spontaneous portal systemic shunts have effectively decompressed the portal system.

Esophagogastric Varices

As the veins become engorged, vessels in the submucosal plexus of the esophagus increase in size and become dilated. In the later stages, the overlying submucosa may disappear, and the walls of the vein actually may form a lining of the esophagus. The submucosal veins in the fundus and subfundal regions of the stomach also become varicose. Gastric varices occur predominantly in the cardiac end of the stomach but also have been found along the lesser curvature. Varices also have been demonstrated in the duodenum and ileum.

Although the presence of esophagogastric varices is, in itself, of minor consequence, rupture and bleeding from these vessels constitute the most alarming and serious complication of portal hypertension. The varices are almost always associated with portal hypertension but infrequently have occurred in patients with normal pressure. Over 90 percent of adult patients demonstrate intrahepatic disease, whereas in childhood the varices are usually related to extrahepatic portal obstruction. Precipitation of the bleeding episode has been ascribed to two factors: increased pressure within the varix and ulceration secondary to esophagitis. Regurgitation of gastric juice into the esophagus has been implicated, and ulcers of the esophagus have been demonstrated in 25 percent of nonintubated and 50 percent of intubated patients. The frequency and severity of bleeding also

are related to the degree of hepatocellular dysfunction.

Natural Course

Bleeding is to be anticipated in approximately 30 percent of cirrhotic patients with demonstrable varices. The elapsed time from the diagnosis of varices to the first hemorrhage varies between 1 and 187 weeks. Almost all hemorrhages occur within 2 years of the initial observation. It is difficult to predict bleeding in a patient with known varices. A prospective multicenter study using univariate analysis of endoscopic variables was able to identify patients at high risk. Etiology is a prime consideration. Varices secondary to extrahepatic portal obstruction must be considered separately, since it is rare for these patients to die of hemorrhage. By contrast, the mortality risk of repeated hemorrhage in patients with esophageal varices secondary to cirrhosis is extremely high. Approximately 70 percent of these patients die within 1 year of the first hemorrhage. Sixty percent of cirrhotic patients who have hemorrhaged once rebleed massively within 1 year.

Prophylactic sclerotherapy, propranolol, and a combination of the two modalities were of no benefit in preventing bleeding from varices in patients with alcoholic cirrhosis. A prophylactic shunt is not advised for a patient with varices that have not bled, since one cannot predict which patients will bleed; the survival is not improved, and encephalopathy may be induced. A cooperative Japanese study group has presented data suggesting that a prophylactic devascularization procedure or selective shunt can prevent bleeding without leading to a significant increase in mortality or morbidity in Child's A and B patients. There is also evidence of improved survival with prophylactic nondecompressive devascularizing procedures.

Acute Bleeding

In children, massive hematemesis almost always emanates from bleeding varices. Acute hemorrhage is usually the first manifestation of portal hypertension in children. Seventy percent of patients experience their first bleeding episode before age 7, and almost 90 percent hemorrhage before age 10.

In the adult, bleeding varices comprise one-quarter to one-third of cases of massive upper gastrointestinal tract bleeding. In cirrhotic patients, varices are the source of bleeding in approximately 50 percent, whereas gastritis is implicated in 30 percent and duodenal ulcers in 9 percent. It is now believed that peptic ulcer does not occur more frequently in cirrhotic patients. Correlation of the lesion with the severity of bleeding reveals that in the majority of cases bleeding from varices is severe hemorrhage, whereas bleeding from gastritis involves only mild to moderate blood loss.

Since the management of bleeding varices differs significantly from that of bleeding due to other causes, it is important to establish a diagnosis on an emergency basis. Physical examination may reveal the stigmata of cirrhosis. Splenomegaly is particularly suggestive of portal hypertension. Tests of hepatic function have been used but do not have uniform reliability. Barium swallow has a significantly high percentage of false-negative results. In a series of patients with proved varices, radiographic demonstration was present in only half. Celiac or superior mesenteric arteriography will rule out an arterial bleeding site, and the venous phase of the arteriogram will demonstrate collateral venous circulation. Bleeding from a varix is not visualized. Esophageal balloon tamponade has been used as a diagnostic measure, but varices are controlled in only two-thirds of the patients, and moreover, peptic ulcer may stop bleeding after the gastric balloon is inflated. Esophagoscopy represents the single most reliable technique, since it alone defines the bleeding point. On the other hand, esophagoscopy may fail to reveal varices because of variations in transvariceal blood flow. In addition, there is a significant observer variation in the endoscopic evaluation of varices.

Treatment

The therapeutic regimen is directed at promptly controlling bleeding without further disturbing an already impaired hepatic function. Rapid control is critical in order to avoid the injurious effects of shock on hepatic function as well as the toxic effects of absorption of blood from the gastrointestinal tract. The therapeutic approaches may be divided into nonoperative and operative methods that directly approach the bleeding site and techniques that act indirectly by decreasing portal pressure (Table 28-4).

Balloon tamponade has reduced the mortality and morbidity from bleeding varices in good-risk patients, particularly those in whom the varices were secondary to extrahepatic portal hypertension or compensated cirrhosis. Little change has been noted in the mortality rate for poor-risk patients, and reports have indicated failure to control hemorrhage in 25 to 55 percent of patients. Increasing awareness of the complications associated with this technique, including aspiration, asphyxiation, and ulceration at the site of the tamponade, has reduced its use. Either a four-lumen tube should be used or a small nasogastric tube should be positioned proximal to the esophageal balloon to provide suction and prevent aspiration.

Endoscopic injection of a sclerosing solution into varices also has controlled bleeding successfully. In a large series, bleeding was controlled in 93 percent of patients. There are significant risk factors associated with sclerotherapy. Endoscopic ligation of esophageal varices has resulted in control of bleeding equivalent to that of sclerotherapy, with fewer complications.

Drug therapy to reduce portal hypertension has employed surgical vasopressin, which acts by constricting the splanchnic arterial circulation and consequently reducing portal pressure and flow by approximately 40 percent. The drug is contraindicated in patients with angina, since generalized vasoconstriction results. Effective control has accompanied direct infusion of vasopressin, 0.2 unit/mL per minute. Isoproterenol may be given simultaneously to reduce the hemodynamic hazards of vasopressin related to its potential effect on the cardiac output. Somatostatin has been proved as effective as vasopressin in controlling acute bleeding and has less significant side effects. Paracentesis in a patient with bleeding varices and tense ascites will reduce portal pressure immediately.

Transjugular intrahepatic portal-systemic shunts (TIPS) using a self- expanding stent have reduced the portal-systemic gradient to about 10 mmHg and successfully stopped bleeding from esophagogastric varices. The procedure can be performed successfully in over 90 percent of patients. TIPS is followed by variceal rebleeding in 10 to 20 percent of patients. The incidence of shunt dysfunction ranges between 15 to 60 percent over a 6- to 12-month period. In the vast majority of cases, patency can be reestablished. TIPS is particularly applicable to control bleeding in patients with minimal hepatic reserve, in whom a transplant is indicated. The procedure obviates a portacaval shunt that compromises the transplant operation.

Surgical therapy includes transesophageal ligation and emergency portal- systemic shunt. The results of transesophageal ligation have improved significantly with stapling techniques, and results better than those with sclerotherapy have been reported. Devascularization procedures such as the Sugiura procedure have had variable success. Success rates from Western nations have not matched the Japanese success.

A more liberal use of emergency portacaval shunts to stop bleeding has been advised for the cirrhotic patients whose bleeding cannot be controlled by nonoperative measures. Emergency portal-systemic shunt remains an important option for selected patients with acute variceal bleeding. Recent experience of emergency shunt performed on 400 unselected patients within 8 h of initial contact indicated survival rates of 85, 78, and 71 percent at 30 days, 5 years, and 10 years, respectively. In most series, the mortality rate for patients with Child's class C disease remains high. The base figure that serves as a frame of reference for comparison is the mortality for patients with bleeding varices not subjected to emergency portacaval shunts, and this ranges between 66 and 73 percent. There is little question that an effective portal-systemic decompressive procedure almost always stops bleeding. No significance could be attributed to the presence or absence of jaundice, but ascites, when present, was associated with a marked reduction of survival rate.

In the pediatric age group and in adults with extrahepatic portal venous obstruction and normal liver function, despite the fact that the bleeding is often alarming, spontaneous cessation almost always occurs, and esophageal tamponade or vasopressin is rarely necessary. Hospitalization, bed rest, blood replacement, and sedation almost always suffice for patients with bleeding secondary to extrahepatic portal obstruction.

The majority of patients with acute bleeding varices is not in shock at the time of admission to the hospital, although the hematocrit is often reduced, and blood replacement may be necessary. Frozen red blood cells and fresh-frozen plasma should be employed for transfusing cirrhotic patients. This provides the clotting factors that are frequently diminished in the presence of hepatic disease and avoids the increased ammonia content and diminished platelet and prothrombin supply characteristic of old blood. There is a linearly progressive daily increment of 35 mg/dL ammonia nitrogen in banked blood, which can be responsible for exogenous hepatic coma. Therapy directed at preventing hyperammonemia and hepatic coma consists primarily of removing blood from the gastrointestinal tract. Catharsis, gastric lavage, and enemas are employed. If vasopressin has been administered, it will induce intestinal motility and effect a catharsis. A reduction in intestinal bacterial flora also contributes to the prevention of coma, and nonabsorbable antibiotic therapy is used to accomplish this.

Prevention of Recurrent Hemorrhage

Sclerotherapy has been used to eradicate varices subsequent to a major bleeding episode. This has been achieved in 80 to 90 percent of patients with an average of five injection sessions over a 9-month period. Endoscopic banding provides equivalent results. Somatostatin has been administered after bleeding was controlled initially by sclerotherapy to obviate future bleeding episodes.

The case for surgical intervention is based on the precept that a patient who has bled from esophageal varices is likely to rebleed and that subsequent bleeding episodes are associated with a higher mortality than an elective operative procedure.

Opinions differ about the role of decompressive procedures in children and in adults with portal hypertension due to extrahepatic portal venous thrombosis. Some children can be treated satisfactorily and safely without operation despite repeated episodes of variceal bleeding. The results of operation in terms of survival are significantly more encouraging in this population than in adults. Therefore, many series have suggested an aggressive approach in children with recurrent bleeding episodes. Central or distal splenorenal shunt or an anastomosis between the inferior vena cava and the superior mesenteric vein is applicable to this group of patients. The incidence of postoperative encephalopathy has been negligible. Devascularization operations such as the Sugiura procedure also have been used for these patients.

Presinusoidal obstruction (hepatic fibrosis, extrahepatic portal venous thrombosis, schistosomiasis) is characterized by portal hypertension and may be associated with normal hepatic function. In patients with hepatic fibrosis and extrahepatic portal venous obstruction, the results are gratifying; the surgical procedure generally will prevent subsequent bleeding and provide the patient with an essentially normal life expectancy. The patients with schistosomiasis are a unique group in that they are extremely liable to postshunt encephalopathy. A selective splenorenal shunt or devascularization procedure is the preferred operation.

Postsinusoidal portal hypertension is invariably complicated by impaired hepatic function. The role of decompressive procedures is least well defined for this group of cirrhotic patients. An elective procedure should be considered when the presence of an active intrahepatic process such as hyaline necrosis or acute fatty infiltration has been ruled out. Ascites that fails to respond to medical therapy, a prothrombin time that remains prolonged following parenteral administration of vitamin K, a serum bilirubin level above 3 mg/dL, a sulfobromophthalein retention greater than 20 percent, and a serum albumin level less than 2.5 g/dL are all associated with a poor postoperative prognosis. In these patients there

is immediate deterioration following portacaval shunting, but this is actually no greater than after other operations of comparable severity. Child's criteria and other assessments of hepatic function are not completely predictive and relate only to the immediate postoperative course.

In patients with end-stage liver disease and marked hepatocellular dysfunction, after the bleeding had been controlled with sclerotherapy or *TIPS*, orthotopic liver transplantation often is appropriate.

Ascites

Etiology

The mechanisms contributing to the formation of ascites are complex and incompletely understood. Portal hypertension is regarded as a contributory but minor factor, since there is no correlation between the degree of portal hypertension and the extent of ascites. Ascites is not a usual accompaniment of extrahepatic portal venous obstruction but has been noted occasionally. Impairment of hepatic venous outflow with subsequent congestion of the liver is accompanied by an increase in the size of lymphatic vessels and increased production of the hepatic lymph that extravasates through the capsule of the liver into the peritoneal cavity. In clinical cirrhosis, there is an increase in the size of hepatic channels and an augmented flow of thoracic duct lymph. Two distinct patterns of intrahepatic vasculature have been correlated with the presence or absence of ascites. With irreversible ascites, there is an absolute decrease in the hepatic venous bed and a concomitant increase in both the portal venous and hepatic arterial beds. By contrast, when cirrhosis is unaccompanied by ascites, there is a deficit in all vascular systems.

Reduced serum osmotic pressure related to hypoalbuminemia does exert some influence. The response of patients to albumin infusion is variable, and the reduced osmotic pressure may represent the result rather than the cause of fluid accumulation. The most profound biochemical change that accompanies the formation of ascites is the retention of sodium and water. There is evidence that adrenocortical hormone is a factor in the renal retention of sodium, and higher concentrations of antidiuretic substances have been noted in the urine of patients with cirrhosis and ascites.

Treatment

Bed rest reduces the functional demand on the liver. A diet high in calories with an excess of carbohydrates and proteins, supplemented by vitamins, is directed toward improving hepatic function, while low sodium (10 to 20 meq daily) intake is essential. Fluid is usually not restricted, and potassium supplements are provided routinely to treat the potassium depletion that accompanies the formation of ascites.

Chlorothiazide is usually used to initiate diuretic therapy, and approximately two-thirds of patients will respond to this medication. Potassium supplements are required. The aldosterone antagonists are employed for patients with incipient hepatic coma. Abdominal paracentesis as an initial procedure has diagnostic value, but repeated procedures are contraindicated because they deplete the body of protein and contribute to the development of systemic hyponatremia. Furosemide (Lasix) is the most frequently used drug. In some refractory cases, ethacrynic acid will help.

Emphasis on the importance of obstruction of hepatic venous outflow led to the proposal of side-to-side portacaval shunts as a method of therapy. These procedures were based on the hypothesis of providing a second outflow tract, with the portal vein acting as a hepatofugal conduit. At present, the operation is limited to patients with Budd-Chiari syndrome and to those patients who cannot be managed on a strict low-sodium diet and diuretic therapy, an unusual circumstance. Peritoneal venous shunts of the Leveen and Denver types have effectively controlled medically intractable ascites. The peritoneovenous shunt provides greater relief of ascites in a shorter period of time than does intensive medical therapy; also, ascites recurs more rapidly in medically treated patients. Improvement may be related to increased creatinine clearance and normalization of renin activity and aldosterone levels. Adverse consequence of the procedures include disseminated intravascular coagulopathy and initiation of variceal bleeding. Persistent patency of any peritoneal venous shunt is difficult to achieve.

Umbilical herniorrhaphy in a cirrhotic patient with marked ascites presents a significant risk, with hazards of leakage of ascitic fluid, infection, necrosis of the abdominal wall, and variceal bleeding due to interruption of collateral veins.

Hypersplenism

Splenomegaly, with engorgement of the vascular spaces, frequently accompanies portal hypertension. There is little correlation between the size of the spleen and the degree of hypertension. When hematologic abnormalities occur, they have been related to sequestration and destruction of the circulating cells by immune mechanisms mediated by the enlarged spleen or secretion by the hyperactive spleen of a substance that inhibits bone marrow activity. Patients may demonstrate reduction of any or all of the cellular elements of blood. The usual criteria for hypersplenism are a white blood cell count below 4000/mm³ and a platelet count below 100,000/mm³. Schistosomal fibrosis frequently induces hypersplenism.

No correlation exists between degree of anemia or leukopenia and the 5- year survival rate in patients. Splenectomy is rarely indicated and does not permanently reduce portal pressure. Removal of the spleen negates the possibility of performing a selective shunt. Decompression of the portal venous system is rarely indicated for treatment of hypersplenism alone. Significant hypersplenism in a patient undergoing elective surgical treatment for bleeding varices favors a splenorenal anastomosis, but both portacaval anastomosis and selective splenorenal shunt have been accompanied by reduction of the spleen and correction of the hypersplenism in about two-thirds of patients.

Encephalopathy and Coma

The development of neuropsychiatric symptoms and signs is related to natural and surgically created portal-systemic shunts and is identified by the term *portal-systemic encephalopathy*. This rarely occurs in patients with obstruction of the extrahepatic portal venous system without hepatocellular dysfunction. The neuropsychiatric syndrome usually is associated with cirrhosis and occurs in patients with marked hepatic dysfunction. Postshunt encephalopathy rarely occurs in patients with extrahepatic portal obstruction unaccompanied by hepatic dysfunction. Operative procedures that decompress the portal system also have been associated with varying incidences of encephalopathy in cirrhotic patients. With splenorenal anastomoses, the syndrome is demonstrated in 5 to 19 percent, whereas it has been reported in 11 to 38 percent following a portacaval anastomosis. The Warren distal splenorenal shunt has been associated with a reduced incidence of postoperative encephalopathy compared with portacaval and mesocaval shunts.

Hepatic coma has been related to hyperammonemia and ammonia intoxication. Both exogenous and endogenous sources contribute to the blood ammonia level. Dietary protein is the usual source of intestinal ammonia. In patients who bleed, blood within the intestinal tract is also converted into ammonia by bacteria. In the patient with hepatic disease, the ammonia formed within the intestine is carried to the liver but, because of hepatic dysfunction, cannot enter the Krebs-Henseleit (ornithine- citrulline-arginine) cycle. Endogenous urea produced within the gastrointestinal tract also represents an important source of ammonia, and gastric ammonia production from urea is a significant factor in patients with azotemia and cirrhosis. There was less deterioration of maximum urea synthesis following a selective splenorenal shunt than after total shunts.

In the cirrhotic patient with portal hypertension, the two factors implicated in the disturbed ammonia metabolism are impairment of hepatocellular function and portal-systemic collateralization. The blood ammonia level is also raised by increased ammonia production by the kidneys and by muscles that are actively contracting during delirium tremens.

The neuropsychiatric manifestations involve the state of consciousness, motor activity, and deep tendon reflexes. These have been divided into three stages: delirium, stupor, and coma. In the early stages there are mental confusion and exaggerated reflexes. The characteristic "liver flap" may be elicited. In the second stage there is an accentuation of muscular hypertonicity, to the extent of rigidity, and in the final stage there is complete flaccidity. The electroencephalogram is a sensitive indicator of portal-systemic encephalopathy, and the changes antedate clinical manifestations. Blood ammonia level does not define precisely the nature of material measured by standard tests. In patients with hepatic coma, the concentration of ammonia in the blood has correlated well with clinical progress in over 90 percent of patients. An elevated level, over 125 mg/dL, is usually associated with the clinical features of hepatic coma. Treatment with antibiotics negates the value of the test.

Treatment

Treatment is directed at (1) reducing nitrogenous material within the intestinal tract, (2) reducing the production of ammonia from the nitrogenous material, and (3) increasing ammonia metabolism. Since ammonia is an end product of protein metabolism, dietary protein must be reduced drastically to 50 g daily or less. Glucose is included in the diet, since it inhibits ammonia production by bacteria. Gastrointestinal hemorrhage frequently precipitates portal-systemic encephalopathy, with blood acting as a course of ammonia. A major factor in the prophylaxis of hepatic coma is prompt control of active bleeding. Potassium supplements are administered, particularly in patients who are receiving thiazide diuretics, because the rise in blood ammonia that accompanies diuresis has been related to hypokalemia.

The protein substrate on which bacteria can act may be reduced initially by using cathartics and enemas to purge the gastrointestinal tract. If active bleeding has occurred, infused vasopressin plays a dual role in temporarily stopping the bleeding as well as stimulating motility and evacuation of the intestine. Bacteria within the bowel are reduced by administering nonabsorbable antibiotics such as neomycin or kanamycin. In the presence of renal disease, kanamycin is preferred because there is less associated renal toxicity. For patients with severe renal impairment, chlortetracycline is more appropriate because it is not excreted primarily by the kidneys. Lactulose acts as a mild cathartic, and the products of its oxidation by bacteria include lactic and acetic acids, which lower the colonic pH and interfere with ammonia transfer across colonic mucosa. This drug has produced encouraging results in the treatment of hepatic encephalopathy.

Since the colon is the site of most ammonia absorption into the portal circulation, partial colectomy has been suggested as treatment of intractable encephalopathy but has not been effective.

Surgery of Portal Hypertension

The surgical therapy of portal hypertension may be divided into two major categories (1) procedures that directly attack a manifestation of portal hypertension, such as bleeding varices or ascites; and (2) procedures aimed at decreasing the portal hypertension and/or portal venous flow (Table [28-5](#)).

Transesophageal Ligation of Varices and Esophageal Transection

Using either a transthoracic or transabdominal approach, transesophageal ligation of varices and esophageal transection have been directed at controlling bleeding varices. The end-to-end stapler has facilitated the procedure. The procedures do provide temporary control, particularly in children with extrahepatic portal block who are too small to be considered for splenorenal anastomosis.

Technique

Transthoracic ligation (Fig. [28-30](#)) is performed through the eighth left intercostal space. The lower esophagus is freed, but the esophageal hiatus of the diaphragm is not disturbed. An umbilical tape is tightened around the esophagus just above the hiatus to minimize bleeding. A 7-cm longitudinal incision is made through all layers, and three tortuous columns

of veins, coursing longitudinally and communicating with one another, are obliterated with continuous locking sutures of 3-0 chromic catgut. The esophagotomy is closed in two layers with interrupted silk sutures, and the edges of the defect in the mediastinal pleura are reapproximated. Direct ligation of varices can be performed transabdominally.

For transection of the esophagus, the peritoneal cavity is entered, and the esophagogastric junction is exposed. The lower 3cm of the esophagus is mobilized, and care is taken to avoid the vagus nerves. The periesophageal veins are ligated. A high vertical incision is made in the anterior wall of the stomach, and the stapler is inserted, using the largest-size cartridge possible. The esophagus is tied over the center rod 2 cm above the gastric junction. The instrument is fired, resulting in simultaneous transection and reanastomosis of the esophagus (Fig. 28-31).

Esophageal Transection with Paraesophageal Devascularization

This procedure was introduced by Sugiura (Fig. 28-32), who found the perioperative mortality to be about 7 percent in elective cases and 25 percent in emergency cases. Hepatic function is not compromised, and postoperative encephalopathy does not occur. Unfortunately, American studies have not duplicated the Oriental results. The initial and late mortality rates were high, and over half the patients rebled. At least one Western report indicates that better results are achieved with a modified Sugiura procedure compared with portal-systemic results, citing better survival and a lower incidence of encephalopathy accompanied by only a slight increase in recurrent bleeding. However, the consensus is that best results are effected by a shunt. The procedure consists of esophageal transection and paraesophagogastric devascularization, splenectomy, and either selective vagotomy with pyloroplasty or highly selective vagotomy without pyloroplasty.

Procedures for Reduction of Portal Pressure

The operations directed at portal hypertension are based on the consideration that any reduction in portal pressure should decrease the potential for bleeding from varices. Splenectomy is effective only when portal hypertension is due to splenic vein thrombosis or increased flow, as in the massive splenomegaly of myeloproliferative disorders. Reduction of portal pressure by diffuse shunts between a high-pressure portal venous system and low-pressure systemic circulation was attempted. These procedures included omentopexy, posterior mediastinal packing, and transposition of the spleen into the thoracic cavity. Application of Poiseuille's law would suggest that any diffuse shunting would be less effective than a major portal-systemic shunt.

Functionally, portal-systemic shunts have been categorized as either totally or partially diverting portal venous flow away from the liver and also as decompressing or failing to decompress intrahepatic venous hypertension (Fig. 28-33). The end-to-side portacaval shunt prevents blood from reaching the liver by providing complete drainage of the splanchnic venous circulation to the vena cava. The associated alteration of hepatic blood flow is extremely variable, ranging from an increase of 34 percent to a decrease of 53 percent. This shunt also prevents the portal vein from serving as an efferent conduit from the liver. It has been shown that following the end- to-side shunt, the wedged hepatic vein pressure declines. Proponents of the end-to-side shunt have indicated this as the best method of preventing recurrent bleeding from varices, since it most completely decompresses the portal venous system's splanchnic circulation. In refutation, it has been shown that end-to-side and side-to-side portacaval shunts demonstrate equal flow and equivalent reductions of portal pressure.

The idea that the side-to-side portacaval shunt provides the liver with portal venous flow is erroneous in most circumstances. Injection of radioisotope into the distal portal vein results in minimal recovery in the portal vein cephalad to a side-to-side anastomosis. A variant of the side- to-side portacaval shunt uses a small-diameter (8 to 10 mm) portacaval H graft. Patients who maintained portal perfusion postoperatively had improved survival.

Accumulated evidence indicates that the side-to-side portacaval shunt converts the cephalad portion of the portal vein to an outflow from the liver. This is an important feature in patients with Budd-Chiari syndrome. Whether decompression of sinusoidal hypertension is greater with the side- to-side shunt than with the end-to-side shunt has not been defined. There is also concern as to whether the portal vein is beneficial or harmful as an efferent conduit because of a possible siphon effect that may reduce the blood available to the hepatic cell.

The classic end-to-side splenorenal shunt using the central end of the splenic vein also prevents the flow of portal venous blood to the liver if it adequately performs its prescribed function of decompressing esophagogastric varices. The other functional side-to-side shunts, including the end-to-side inferior vena cava–superior mesenteric artery shunt and the interposition of an H graft between these vessels, do not maintain hepatic perfusion with portal venous blood.

The distal splenorenal shunt proposed by Warren and associates is the one procedure that can be classified as truly selective because it decompresses esophagogastric varices while maintaining portal hypertension within the portal veins and hepatic sinusoids. Portal perfusion has been demonstrated in over 90 percent of patients with selective distal splenorenal shunts; the total hepatic blood flow has been shown to be unchanged, while the splenic venous circulation and esophagogastric veins have been reasonably decompressed. Angiographic and other studies have demonstrated that the distal splenorenal shunt loses its selectivity a few months after the operation. Prospective, randomized trials comparing the distal splenorenal shunt with nonselective (portacaval or mesocaval) shunts demonstrate no difference in survival, postoperative complications, or ascites. It is generally believed that the selective shunt is associated with a lower incidence of encephalopathy.

Selection of Procedure

Before a major shunt is performed, the presence of portal hypertension should be defined manometrically. Infrahepatic vena caval pressure should be measured to rule out caval hypertension that would interfere with splanchnic venous decompression. A splenoportogram or a selective superior mesenteric arteriogram with a venous phase should be obtained to determine the status of the major veins. Portal vein thrombosis occurs as a complication in approximately 2 percent of patients with portal cirrhosis. However, lack of visualization of the portal vein in and of itself does not establish this diagnosis, and collateral veins of Sappey must be visualized. If a selective or central splenorenal shunt is being considered, the anatomy of the left renal vein and its relation to the splenic vein should be identified.

Estimations of hepatic blood flow are fraught with errors in interpretation, particularly in cirrhotic patients. Pressure determinations and differentials within the portal venous system, measurements of the estimated hepatic blood flow, and splenoportographic findings did not approximate true flow, and these findings could not be related to the subsequent development of postshunt encephalopathy. The increase in hepatic arterial flow subsequent to the creation of a portacaval shunt has offered a hemodynamic correlate with the patient's prognosis.

The end-to-side portacaval shunt is the procedure most commonly performed, since it is technically easiest and has been associated with the lowest incidence of thrombosis. The presence of a large caudate lobe is less compromising to this procedure than to a side-to-side shunt. For some patients with extensive adhesions from previous operative procedures in the right upper quadrant, splenorenal and mesocaval shunts are preferred. Thrombosis with or without recanalization of the portal vein (cavernomatous transformation) generally precludes a portacaval anastomosis. The Budd- Chiari syndrome, related to endophlebitis of the hepatic veins, dictates a side-to-side shunt to decompress the liver.

In reference to the factor of ascites as a determinant of the decompressive procedure, in one series 39 percent of patients with end-to-side shunts who had preoperative ascites experienced postoperative relief; in 12 percent ascites appeared after the shunt, while all patients with side-to-side shunts and ascites had permanent relief. The splenorenal shunt, which is a functional side-to-side shunt, failed to relieve ascites in 12 percent of patients, and ascites appeared after the shunt in 16 percent. It is therefore thought that ascites per se cannot be considered a significant factor in determining the shunt to be performed. Some series have indicated that the selective splenorenal shunt is not ascitogenic.

Similarly, whether previous encephalopathy and the presence of asterixis are important determinants of the type of shunt has not been resolved. In general, the selective splenorenal shunt is associated with a lower incidence of encephalopathy than other decompressive procedures, but patients with minimal hepatocellular dysfunction rarely develop encephalopathy regardless of the shunt used; devascularization operations rarely cause encephalopathy. Another consideration in shunt selection is the anticipation of performing an orthotopic transplant on the patient in the future. In this circumstance, it is preferable to perform a distal splenorenal shunt.

Selection of Patients

Ascites that failed to respond to medical therapy, a prothrombin time that remained prolonged after parenteral administration of vitamin K, serum albumin level less than 3 g/dL, serum bilirubin level greater than 1 mg/dL, and sulfobromophthalein retention greater than 10 percent are all associated with poor postoperative prognosis. Child divided patients into three groups, including those with good hepatic function (A), those with moderate hepatic function (B), and those with advanced disease and poor reserve (C). In group A are patients with a serum bilirubin level below 2 mg/dL, albumin level above 3.5 g/dL, no ascites, no neurologic disorders, and excellent nutrition. Patients in group B have bilirubin levels between 2 and 3 mg/dL, albumin levels between 3 and 3.5 g/dL, easily controlled ascites, minimum neurologic disorder, and good nutrition. In the C group, the bilirubin level is above 3 mg/dL, the albumin level is below 3 g/dL, and the ascites is poorly controlled, with advanced coma and wasting. Operative mortality following portacaval shunts in group A was zero, in group B was 9 percent, and in group C was 53 percent. There is general agreement that hepatic function is more important than the type of shunt in determining prognosis.

Portacaval Shunt Technique

This shunt (Fig. 28-34) generally is performed through a subcostal incision, but in the presence of extreme hepatomegaly or obesity, a thoracoabdominal approach may be used. The liver is retracted craniad, and a Kocher maneuver is performed to permit mobilization of the duodenum. Dissection is begun in the hepatoduodenal ligament, and the portal vein, which resides posteriorly in relation to the common bile duct, is dissected free along the entire course. Attention is then directed to dissection of the inferior vena cava. The incision in the retroperitoneum is extended, and the anterior and lateral aspects of the inferior vena cava are exposed from the renal veins to the point where the vessel passes retrohepatically. Atraumatic clamps are applied to the portal vein just above its origin and just below its bifurcation, after which the vein is transected as far craniad as possible. The hepatic end is either ligated or oversewn. A sidearm, nonocclusive clamp is positioned along the anterior aspect of the inferior vena cava, and an incision is made in the inferior vena cava wall. This should be approximately one and one half times as long as the diameter of the portal vein. Employing vascular suture techniques, an anastomosis is made between the portal vein and the side of the inferior vena cava, utilizing a continuous suture that is interrupted at the two ends. Following mobilization of the portal vein and inferior vena cava, a side-to-side shunt may be performed. After the anastomosis is completed, the clamp is removed from the inferior vena cava, and then the clamp occluding the portal vein is removed. Pressure should be recorded directly from the portal vein.

Central Splenorenal Shunt

In the cirrhotic patient with postsinusoidal obstruction, the splenorenal anastomosis is not as hemodynamically efficient as the portacaval shunt and is associated with a higher incidence of recurrent bleeding. Proponents of this procedure indicate that in their experience the prevention of recurrent bleeding is similar to that resulting from a portacaval shunt, and the incidence of portal-systemic encephalopathy and persistent hypersplenism is reduced. The operation is generally employed in patients with obstruction of the extrahepatic portal venous system in which the portal vein is not available for shunting. In the pediatric age group, it is preferable to postpone this procedure until the child is 10 years old and the splenic vein is large enough to maintain its patency.

Technique

(Fig. 28-35).

An oblique subcostal incision or thoracoabdominal approach may be used. The transverse colon and splenic flexure are mobilized and retracted caudad, and the short gastric vessels are doubly ligated and transected. The splenophrenic splenorenal ligaments are then transected, and dissection is continued in the hilus until an ultimate pedicle of splenic artery and vein remains. The splenic vein is freed as it courses along the pancreas. The posterior peritoneum is incised just medial to the hilus of the kidney, and the left renal artery and vein are dissected free. Tapes are passed around the main renal vein and the major branches in the hilus of the kidney. Traction on these tapes establishes control of bleeding and minimizes the number of clamps interfering with the anastomosis. The splenic artery is double ligated and transected, and an atraumatic clamp is applied to the central end of the splenic vein. The splenic vein is then transected as close to the hilus of the spleen as possible and brought down to an appropriate site on the anterosuperior aspect of the renal vein. The renal artery is occluded temporarily with a bulldog clamp, and an incision is made in the renal vein. An end-to-side anastomosis is performed by initially securing two stay sutures and completing the posterior layer as a continuous suture. Anastomosis of the anterior layer is accomplished with either horizontal mattress sutures or a continuous suture.

Superior Mesenteric Vein-Inferior Vena Cava Shunt

This operation is generally used for patients with extrahepatic vein obstruction and is particularly applicable to the patient in whom a previous splenorenal shunt failed or to a small child in whom a splenorenal anastomosis is doomed to failure because of the size of the splenic vein. The operation is also advised for patients with cirrhosis if there is associated thrombosis of the portal vein or extensive scarring in the right upper quadrant that precludes safe dissection of the portal vein or marked enlargement of the caudate lobe of the liver.

Interruption of the inferior cava, which is required for the end-to-side shunt, results in venous stasis in the lower extremity, and in the immediate postoperative period the foot of the bed must be elevated to reduce potential edema. The procedure is well tolerated by young patients, in whom postoperative chronic dependent edema of the legs is uncommon. In older patients, any edema may be readily controlled with elastic stockings.

Technique

(Fig. 28-36).

The peritoneal cavity is entered through a midline or right paramedian incision extending from the xiphoid process to well below the umbilicus. Upward traction on the transverse colon exposes the superior mesenteric vessels. The peritoneum is incised in the region of the superior mesenteric arterial pulse, and the superior mesenteric vein is identified and dissected free. The lateral reflection of the ascending colon is then incised along its entire length to permit medial displacement of the transverse and ascending colons and medial reflection of the ascending mesocolon. This exposes the inferior vena cava and the third portion of the duodenum. The inferior vena cava is mobilized from its origin up to the entrance of the right renal vein. The paired lumbar veins are ligated and transected. After the entire inferior vena cava has been freed, vascular clamps are applied immediately below the renal veins and at the junction of the iliac veins. The inferior vena cava is transected as far distal as possible, and the caudal stump is ligated. The right iliac vein may be left attached to the vena cava to achieve greater length. A “window” is created in the mesentery of the small intestine between the ileocolic vessels and the origin of the main ideal trunk to permit approximation of the end of the inferior vena cava to the right posterolateral aspect of the superior mesenteric vein. The anastomosis between the inferior vena cava and the superior mesenteric vein is usually performed proximal to the right colic vein, utilizing a continuous arterial suture interrupted at both ends.

Decompression is more commonly accomplished by the construction of an H graft using a 19- to 22-mm prosthesis interposed between the superior mesenteric vein and the inferior vena cava (Fig. 28-37). A high incidence of immediate and long-term thrombosis of the graft has been reported from some institutions, but this is not uniform.

Selective Splenorenal Shunt

The indications for the selective distal splenorenal shunt include a substantial portal venous flow to the liver, favorable anatomic features related to the site and patency of the splenic vein and the site and size of the left renal vein, and satisfactory liver function in the absence of marked ascites.

Technique

The operative procedure is shown in schematic fashion in Fig. 28-38. Decompression is effected through the short gastric vessels in the spleen. The spleen is not removed, and the distal or splenic side of the splenic vein is used for an anastomosis to the left renal vein. This technique can be modified by transecting the left renal vein close to the hilus of the kidney, turning and anastomosing the caval side of the renal vein to the side of the splenic vein, and ligating the splenic vein close to the confluence with the superior mesenteric vein. Included in the procedure is ligation of the coronary vein and devascularization of the stomach by ligating all vessels with the exception of the right gastric artery and the short gastric veins. Both Inokuchi and Warren have devised modifications of splenopancreatic disconnection to prevent future portal malcirculation.

Complications of Portal-Systemic Shunts

The complications uniquely associated with portal-systemic shunting procedures occur intraoperatively or during the postoperative period. The intraoperative complications include bleeding and a nonshuntable situation, whereas the postoperative complications include rebleeding, hepatic failure, changes in cardiorespiratory dynamics, the hepatorenal syndrome, and delayed complications of hemosiderosis, peptic ulcer, and portal-systemic encephalopathy.

The complication of intraoperative bleeding can be reduced by correction of coagulation defects and by continuing the infusion of vasopressin during the operative procedure. A nonshuntable situation may be related to extension of cavernomatous transformation of the portal vein to involve the superior mesenteric vein and the splenic vein. In these patients, the so-called makeshift shunt, using large collaterals, is generally doomed to failure. The circumstance of caval hypertension caused by hypertrophy and nodularity of the caudate lobe encroaching on the infrahepatic vena cava has been referred to previously. Attempts have been made to shunt between the superior mesenteric vein and the atrium.

Early postoperative bleeding is usually related to thrombosis of a reconstructed shunt. This can be defined by splenoportography in the case of a portacaval shunt. The rapid onset of ascites during the early postoperative period may be managed by restriction of sodium intake and the administration of diuretic agents. In this circumstance, the early institution of a peritoneal-venous shunt has provided dramatic relief. Renal failure following a portal-systemic shunt is not predictable, and treatment consists of supportive measures. The early postoperative development of hepatic coma is an ominous sign.

Portacaval Shunt for Glycogen Storage Disease and Hypercholesterolemia

In 1963, Starzl and associates performed a portacaval transposition on an 8-year-old child with type III glycogen storage disease, which resulted in resumption of weight gain and growth rate. Since then, several investigators have reported clinical improvement following an end-to-side portacaval shunt in children with type I glycogen storage disease in which the enzyme glucose 6-phosphatase is deficient or absent. Intravenous hyperalimentation for 2 to 3 weeks prior to surgery is advised to reduce liver size, restore bleeding time to normal, correct acidosis and hypoglycemia, and promote a favorable outcome of the shunting procedure. Children who have undergone diversion of portal flow have shown no evidence of encephalopathy. Portacaval shunts also have been applied with success to a few patients with homozygous hypercholesterolemia and to an occasional patient with heterozygous type 2 hypercholesterolemia.

FULMINANT HEPATIC FAILURE

Fulminant hepatic failure refers to the clinical syndrome characterized by sudden, severe impairment of hepatic function generally as a consequence of massive necrosis of liver cells. In most instances, the cause is acute hepatitis of viral origin. Massive necrosis and dysfunction have been reported with Reye's syndrome, as a rarity in pregnancy, and following exposure to a variety of drugs. Circulatory necrosis of hepatic cells has been reported following vasopressor therapy and following the inadvertent intraarterial infusion of vasopressin into the hepatic artery.

General supportive therapy is directed at reducing hyperammonemia. A number of intercessions are all aimed at removing so-called noxious elements from the affected patient and preserving life long enough for the liver to regenerate sufficiently. Included in this category are hemodialysis and peritoneal dialysis, exchange transfusion, plasmapheresis, asanguineous hypothermic total-body perfusion, ex vivo perfusion of a liver of the same or different species, and cross-circulation with a human being or a subhuman primate. Orthotopic liver transplantation has led to the survival of several moribund patients and is now the treatment of choice.

Patients in fulminant hepatic failure who are categorized at the comatose level with spasticity have a mortality of between 85 and 90 percent; this approaches 100 percent when the flaccidity stage is reached. The effect of any form of therapy is difficult to evaluate because spontaneous recovery occurs in 10 to 20 percent of patients.

CHAPTER 29 - Gallbladder and Extrahepatic Biliary System

Seymour I. Schwartz

ANATOMY

Duct System

The extrahepatic biliary system begins with the hepatic ducts and ends at the stoma of the common bile duct in the duodenum. The right hepatic duct is formed by the intrahepatic confluence of dorsocaudal and ventrocranial branches. The former enters with a sharp curve, which accounts for the fact that calculi are less common in this segment. The left hepatic duct is longer than the right and has a greater propensity for dilatation as a consequence of distal obstruction. The two ducts join to form a common hepatic duct that is 3 to 4 cm in length. It is then joined at an acute angle by the cystic duct to form the common bile duct (Fig. 29-1).

The common bile duct is approximately 8 to 11.5 cm in length and 6 to 10 mm in diameter. The upper portion is situated in the free edge of the lesser omentum, to the right of the hepatic artery and anterior to the portal vein. The middle third of the common duct curves to the right behind the first portion of the duodenum, where it diverges from the portal vein and hepatic arteries. The lower third of the common bile duct curves more to the right behind the head of the pancreas, which it grooves, and enters the duodenum at the hepatopancreatic ampulla (of Vater), where it is frequently joined by the pancreatic duct. The portions of the duct are referred to according to their relationship to intestinal viscera—*suprapancreatic*, *intrapancreatic*, and *intraduodenal*.

The union of the bile duct and the main pancreatic duct follows one of three patterns. The structures may: (1) unite outside the duodenum and traverse the duodenal wall and papilla as a single duct; (2) join within the duodenal wall and have a short, common, terminal portion; or (3) exit independently into the duodenum. Separate orifices have been demonstrated in 29 percent of autopsy specimens, and injection into cadavers reveals reflux from the common bile duct into the pancreatic duct in 54 percent. Radiographically, reflux from the common bile duct into the pancreatic duct is present in about 16 percent of cases. The sphincter of Oddi surrounds the common bile duct at the ampulla of Vater. This provides control of the flow of bile and, in some cases, pancreatic juice. An ampullary sphincter that is present in one-third of adults may produce a common channel for the terminal common and pancreatic ducts.

Gallbladder

The gallbladder is located in the bed of the liver in line with that organ's anatomic division into right and left lobes. It is a pear-shaped organ with an average capacity of 50 mL and is divided into four anatomic portions: the fundus, the corpus or body, the infundibulum, and the neck. The fundus is the rounded, blind end that normally extends beyond the liver's margin. It may be unusually kinked and present the appearance of a “phrygian cap.” It contains most of the smooth muscle of the organ, in contrast to the corpus or body, which is the major storage area and contains most of the elastic tissue. The body tapers into the neck, which is funnel-shaped and connects with the cystic duct. The neck usually follows a gentle curve, the convexity of which may be distended into a dilatation known as the infundibulum, or Hartmann's pouch.

The wall of the gallbladder is made up of smooth muscle and fibrous tissue, and the lumen is lined with a high columnar epithelium that contains cholesterol and fat globules. The mucus secreted into the gallbladder originates in the tubular alveolar glands in the globular cells of the mucosa lining the infundibulum and neck.

The gallbladder is supplied by the cystic artery, which normally originates from the right hepatic artery behind the cystic duct. It is approximately 2 mm in diameter and courses above the cystic duct for a variable distance, until it passes down the peritoneal surface of the gallbladder and branches. Venous return is carried through small veins, which enter directly into the liver from the gallbladder, and a large cystic vein, which carries blood back to the right portal vein. Lymph flows directly from the gallbladder to the liver and drains into several nodes along the surface of the portal vein. The nerves of the gallbladder arise from the celiac plexus and lie along the hepatic artery. Motor nerves are made up of vagus fibers mixed with postganglionic fibers from the celiac ganglion. The preganglionic sympathetic level is at T8 and T9. Sensory supply is provided by fibers in the sympathetic nerves coursing to the celiac plexus through the posterior root ganglion at T8 and T9 on the right side.

The gallbladder is connected with the common duct system via the cystic duct, which joins the common hepatic duct at an acute angle. The segment of the cystic duct adjacent to the gallbladder bears a variable number of mucosal folds that have been referred to as the “valves of Heister” but do not have any valvular function. Immediately behind the cystic duct resides the right branch of the hepatic artery. The length of the cystic duct is highly variable, though the average is around 4 cm. Variations of the cystic duct and its point of union with the common hepatic duct are surgically important (Fig. 29-2). The cystic duct may run parallel to the common hepatic duct and actually be adherent to it. It may be extremely long and unite with the hepatic duct at the duodenum. It may be absent or very short and have a high (cephalad) union with the hepatic duct, in some cases joining the right hepatic duct instead. The cystic duct may spiral anteriorly or posteriorly in relation to the common hepatic duct and join it on the left side. Congenital biliary atresia is discussed in Chap. 37.

Anomalies

The classic description of the extrahepatic biliary passages and their arteries applies in only about one-third of patients. There are surgically important anomalies in the gallbladder's position and form, and even its number (Fig. 29-3). Isolated congenital absence of the gallbladder is extremely rare; autopsy incidences of 0.03 percent have been reported. Before the diagnosis is made, the presence of an intrahepatic vesicle or left-sided organ must be ruled out. Duplication of the gallbladder with two separate cavities and two separate cystic ducts has an incidence of approximately 1 in 4000. The accessory gallbladder may be situated on the left side, and its cystic duct may empty into the left hepatic duct rather than the common duct. Pathologic processes such as cholelithiasis and cholecystitis may involve one organ while the other is spared.

The gallbladder may be found in a variety of anomalous positions. The so-called “floating gallbladder” occurs when there is an increase in the peritoneal investment. The organ may be completely invested by peritoneum with no mesentery. In other instances, the gallbladder may be suspended from the liver by a complete mesentery, or the neck may have a mesentery in which the cystic artery lies, while the fundus and body are free. This condition occurs in about 5 percent of patients and predisposes to torsion and resulting gangrene or perforation of the viscus. A left-sided gallbladder with the cystic duct entering directly into the left hepatic duct or common duct is extremely rare, as is the situation known as *retrodisplacement*, in which the fundus extends backward in the free margin of the gastrohepatic omentum. The gallbladder may also be totally intrahepatic, a situation that occurs in many animals. In human beings, the partial or complete intrahepatic gallbladder is associated with an increased incidence of cholelithiasis.

Anomalies of the cystic duct were described earlier (see Fig. 29-2). Accessory hepatic ducts are present in approximately 15 percent of cases. Large ducts are usually single and drain a portion of the right lobe of the liver joining the right hepatic duct, common hepatic duct, or infundibulum of the gallbladder. Small ducts (of Luschka) may drain directly from the liver into the body of the gallbladder. When these ducts go unrecognized and are not ligated or clipped at cholecystectomy, an accumulation of bile (biloma) may occur in the subhepatic area.

Anomalies of the hepatic artery and the cystic artery are present in about 50 percent of cases (Fig. 29-4). A large accessory left hepatic artery, originating from the left gastric artery, occurs in about 5 percent of cases. In about 20 percent of cases, the right hepatic artery originates from the superior mesenteric artery, and in about 5 percent of cases there are two hepatic arteries: one originating from the common hepatic and other from the superior mesenteric artery. The right hepatic artery is vulnerable during surgical procedures, particularly when it parallels the cystic duct and is adherent to it or when it resides in the mesentery of the gallbladder. A “caterpillar hump” right hepatic artery may be mistaken for the cystic artery. The right hepatic artery may course anteriorly to the common duct. In 10 percent of cases, the cystic artery originates from the left hepatic artery or from the junction of the left or right hepatic arteries with the common hepatic artery. In about 15 percent of cases, the cystic artery passes in front of the common hepatic duct, rather than to the right of or posterior to this duct. Double cystic arteries occur in about 25 percent of cases, and they may both arise from the right hepatic artery, or one may have another origin.

Cystic Disease of the Extrahepatic Biliary Tract (Choledochal Cyst)

Congenital cystic abnormalities may occur throughout the entire biliary system, i.e., from intrahepatic biliary radicles to the terminal common duct. Intrahepatic cystic dilatation is discussed in Chap. 28. Choledochal cysts are discussed in Chap. 37. There are three major varieties (Fig. 29-5): cystic dilatation involving the entire common bile duct and common hepatic duct with the cystic duct entering the choledochal cyst; a small cyst usually localized to the distal common bile duct; and diffuse fusiform dilatation of the common bile duct.

Congenital biliary atresia is discussed in Chap. 37.

PHYSIOLOGY

Bile Formation

The normal adult with an intact hepatic circulation and consuming an average diet produces within the liver 250 to 1000 mL bile per day. This is, in large part, an active process that takes place within the hepatocytes and is dependent on a supply of oxygen. The secretion of bile is responsive to neurogenic, humoral, and chemical control. Vagal stimulation increases secretion, whereas splanchnic nerve stimulation results in decreased bile flow, probably related to vasoconstriction. The release of secretin from the duodenum after the stimulus of hydrochloric acid, breakdown products of proteins, and fatty acids increases bile flow and the production of an alkaline solution by the canaliculi. Bile salts are also choleretic and augment bile secretion by the liver.

The active transport of bile acids from the hepatocytes into the canaliculi creates an osmotic gradient that causes water to diffuse into those canaliculi. In addition, there is a “bile acid-independent” active transport of electrolytes and other solutes into the canaliculi with consequent passive diffusion of water and solutes.

Composition of Bile

The main constituents of bile are water, electrolytes, bile salts, proteins, lipids, and bile pigments. Sodium, potassium, calcium, and chloride have the same concentration in bile as in extracellular fluid or plasma. As secretion increases, there is an increase in the concentration of bicarbonate and in pH, and a slight increase in chloride. The pH of hepatic bile is usually neutral or slightly alkaline and varies with diet; an increase in protein shifts the pH to the acidic side.

Cholesterol and phospholipids are synthesized in the liver. The rate of cholesterol synthesis, subject to a negative feedback mechanism, is inhibited by high cholesterol intake. Bile acids, produced endogenously or taken orally, reduce cholesterol synthesis and increase cholesterol absorption from the intestine. The synthesis of phospholipids is also regulated by bile acids. The concentrations of cholesterol and phospholipids are both lower in hepatic bile than in plasma.

The principal bile acids, cholic and deoxycholic acids, are synthesized from cholesterol within the liver; they are conjugated there with taurine and glycine and act within the bile as anions that are balanced by sodium. The concentration of these salts within liver bile is 10 to 20 mEq/L. Proteins are present in bile in lesser concentrations than in plasma, with the exception of mucoproteins and lipoproteins that are not present in plasma. Liver bile also contains unesterified cholesterol, lecithin, and neutral fats.

The color of the bile secreted by the liver is related to the presence of the pigment bilirubin diglucuronide, which is the metabolic product of the breakdown of hemoglobin and is present in bile in concentrations 100 times greater than in plasma. After this pigment has been acted upon by bacteria within the intestine and converted into urobilinogen, a small fraction of the urobilinogen is absorbed and secreted into the bile.

Gallbladder Function

The gallbladder provides storage and concentration of bile. The selective absorption of sodium, chloride, and water results in a concentration of bile salts, bile pigments, and cholesterol ten times higher than in liver bile. The gallbladder mucosa has the greatest absorptive power per unit area of any structure in the body. This rapid absorption prevents a rise in pressure within the biliary system under normal circumstances. The absorption of fluid by the gallbladder is driven by an energy-dependent active transport of sodium and a consequent passive transport of water.

Secretion of mucus, approximately at the rate of 20 mL/h, protects the mucosa from the lytic action of bile and facilitates the passage of bile through the cystic duct. This mucus makes up the colorless, “white bile” present in hydrops of the gallbladder resulting from obstruction of the cystic duct. The gallbladder also secretes calcium in the presence of inflammation or obstruction of the cystic duct.

Motor Activity

The passage of bile into the duodenum involves the coordinated contraction of the gallbladder and relaxation of the sphincter of Oddi. Some bile flows from the gallbladder continuously and there are rhythmic contractions occurring two to six times per minute and mediating pressures less than 30 mmH₂O. The gallbladder's emptying, however, is mainly a response to the ingestion of food and the release of *cholecystokinin (CCK)* by the duodenum. CCK also relaxes the terminal bile duct, the sphincter of Oddi, and the duodenum. After the intravenous injection of CCK, the gallbladder is two-thirds evacuated within 30 min. CCK exerts its contractile effects mainly through action directly on the gallbladder smooth muscle cells, but also via interaction with cholinergic nerves. There is a feedback inhibition of CCK secretion by bile acids and proteases. Somatostatin has a direct inhibitory action against CCK-induced gallbladder contraction.

The vagus nerve stimulates contraction of the gallbladder, and splanchnic sympathetic stimulation is inhibitory to its motor activity. Although vagotomy for duodenal ulcer increases the size and volume of the gallbladder, the rate of emptying is unchanged. Parasympathomimetic drugs contract the gallbladder, whereas atropine leads to relaxation. Magnesium sulfate is a potent evacuator of the gallbladder. Emptying of the gallbladder takes place 30 min after ingestion of a fatty meal. There is an increased risk of gallbladder disease in patients on prolonged total parenteral nutrition (TPN) because of the lack of intestinal stimulus and consequent stasis of bile within the organ.

Gallbladder filling occurs when the pressure in the bile duct is greater than that within the gallbladder. This is correlated with reduced CCK levels but is also affected by vasoactive intestinal polypeptide (VIP), pancreatic polypeptide (PP), and peptide YY (PYY).

The common bile duct can be shown to have waves of peristalsis. During starvation, the sphincter of Oddi maintains an intraductal pressure that approximates the maximal expulsive pressure of the gallbladder, i.e., 30 cmH₂O, thereby preventing emptying. During the interdigestive periods, the hormone motilin regulates sphincteric pressure to allow continuous flow of small amounts of bile into the duodenum. After the ingestion of food, the sphincteric pressure is reduced to 10 cmH₂O. When pressure within the extrahepatic bile ducts is greater than 36 cmH₂O, secretion of bile is suppressed.

Biliary dyskinesia lacks objective findings. The term has been used to describe disturbances of biliary tract motility that occur in the absence of anatomic changes. It has been applied as a primary condition and as a complication of biliary tract surgery. Pain has been noted to occur after the ingestion of fatty foods and the injection of CCK at the time that contraction of the gallbladder is induced. Biliary tract pain has also been ascribed to spasm of the sphincter of Oddi. The concept of hyperplastic cholecystosis, characterized by hyperconcentration and excessive emptying of the gallbladder manifest on a cholecystogram, is questionable, but cholecystectomy has been reported to be curative in symptomatic patients.

Enterohepatic Circulation

After the bile enters the duodenum, over 80 percent of the conjugated bile acids are absorbed in the terminal ileum, and the remainder is deconjugated by bacterial activity and absorbed in the colon. Eventually, almost 95 percent of the bile acid pool is absorbed and returns via the portal venous system to the liver. Only 5 percent is excreted in the stool, thereby permitting a relatively small pool of bile acids to have maximal effectiveness. A negative feedback mechanism regulates the hepatic synthesis of bile acids. When the distal ileum has been resected, there is usually adaptation, but occasionally the lack of a feedback mechanism persists and causes significant diarrhea.

DIAGNOSIS OF BILIARY TRACT DISEASE

(See also Jaundice in Chap. [22](#).)

Radiologic Studies

Abdominal Ultrasonography

Ultrasound imaging is the most widely applied diagnostic technique for biliary tract disease in elective and emergent situations. It provides anatomic and pathologic information with great flexibility and portability, and at low cost. The technique may be limited by obesity and large amounts of intestinal gas. Ultrasonography employs a high-frequency vibration in which alternate compression and rarefaction waves travel through the tissue and are reflected off of tissues or items that differ in acoustic impedance. The reflected portion of the sound beam returns to a transducer to create an image. There is variability in the quality of images, and the technique is operator dependent. The gallbladder is readily imaged because echo-free bile contrasts with the organ's wall and the liver parenchyma. The intrahepatic and extrahepatic major bile ducts are also defined. Calculi can be demonstrated in more than 95 percent of cases in which they are present. The discrimination of ductal dilatation has an accuracy of 90 percent.

Ultrasonography is the most cost effective and reliable method for demonstrating gallstones. They appear as reflective foci within the gallbladder or ducts and cast acoustic shadows (Fig. [29-6](#)). A stone impacted in the gallbladder neck or cystic duct may be difficult to detect because the walls themselves return strong echoes. Ultrasonography has been used to guide lithotripsy.

Ultrasound imaging also provides diagnostic information for acute and chronic cholecystitis. The characteristic signs include edema and thickening of the gallbladder wall, occasionally gas in the wall, and absence of visualization of the organ. Thickening and edema of the wall is particularly useful in establishing the diagnosis of acalculous cholecystitis when they are coupled with tenderness over the organ evoked by pressure of the ultrasound probe. Ultrasonography also can establish the diagnoses of hydrops, porcelain gallbladder, adenomas, and carcinomas.

Ultrasound is the first radiologic step in the evaluation of jaundice because it provides a sensitive method for detecting intrahepatic and extrahepatic ductal dilatation. The level of obstruction can be defined by tracing the dilatation down to a point or termination. It can distinguish between intraductal calculi and tumors as the causative agent. Postoperatively it readily defines bilomas and subhepatic abscesses.

Abdominal Radiography

Plain x-ray films of the abdomen are of limited value in assessing patients with gallstones or with jaundice. Supine and upright films of the abdomen may be useful in excluding other causes of abdominal pain, such as a perforated viscus or a bowel obstruction. The presence of significant amounts of calcium within gallstones, which occurs in 15 to 20 percent of patients, causes stones to appear as opacified objects located in the right upper quadrant on plain x-ray films (Fig. [29-7](#)). There are a number of unusual circumstances in which complications from gallstones may be suggested by specific radiographic findings. The presence of gas within the biliary tree outlining its anatomy occurs in patients with a cholecystenteric fistula (abnormal communication between the gallbladder and duodenum, which typically occurs as a consequence of chronic cholecystitis). Opacification of the gallbladder, or of parts of it, occurs in patients with a “porcelain” gallbladder. Gas bubbles may be present in the wall of the gallbladder in patients with emphysematous cholecystitis (infection secondary to anaerobic, gas-producing organisms).

Oral Cholecystography

Oral cholecystography, a relatively simple and effective test for diagnosing gallstones, was introduced by Graham and Cole in 1924. While this test may permit visualization of gallstones within the gallbladder, the critical function that is assessed is the absorptive ability of the gallbladder. A radiopaque iodine containing halogenated dye is orally ingested by the patient. The dye is first absorbed by the gastrointestinal tract and extracted in the liver. The liver excretes the dye into the biliary ductular system, and the dye then passes through the cystic duct into the gallbladder. Ultimately, if the gallbladder has normal mucosal function, the dye becomes concentrated through the physiologic absorption of water and solutes. A “positive” study—one suggestive of gallstones or gallbladder pathology—occurs when stones are noted as filling defects in a visualized, opacified gallbladder (Fig. [29-8](#)) or when the dye is not adequately concentrated and the gallbladder cannot be visualized. When nonvisualization occurs, a second, double dose of contrast medium is frequently administered. Although the accuracy of this modality has been reported to be as high as 95 percent, a number of important limitations have reduced its use. False positives may occur when patients have been noncompliant or have been unable to ingest the tablets because of nausea and emesis or general medical conditions; when the tablets have not been absorbed through the gastrointestinal tract or have not been excreted into the biliary tract as a result of hepatic dysfunction; or when there is some technical problem with the equipment. Oral cholecystography has been largely replaced by the development and refinement of abdominal ultrasonography.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) is used to assess biliary dilatation and calculi (Fig. [29-9](#)), but because both can be studied more readily by ultrasound imaging, CT is not routinely performed. CT is inferior to ultrasonography for the detection of stones. The major application of CT is to define the course and status of the extrahepatic biliary tree and adjacent structures. Intravenous contrast enhancement of the biliary tract is mandatory in this study. Use of CT is an integral part of the differential diagnosis of obstructive jaundice. Magnetic resonance imaging currently has little application in biliary disease. With the introduction of new contrast agents, its applicability may be expanded.

Biliary Scintigraphy

After technetium 99m-labeled derivatives of iminodiacetic acid (HIDA) are injected intravenously, they are cleared by the Kupffer's cells in the liver and excreted in the bile. Normally, after injection, peak activity is detected in the liver in 10 min, and the biliary ducts can be identified shortly thereafter. The gallbladder is visualized within 60 min in fasting subjects (Fig. [29-10](#)). The test is particularly applicable when the diagnosis of acute cholecystitis is being considered. Evidence of cystic duct obstruction, as indicated by nonvisualization of the gallbladder, is highly diagnostic. The isotopic visualization of the gallbladder essentially precludes the diagnosis. The accuracy of the test in diagnosing acute cholecystitis is about 97 percent.

Percutaneous Transhepatic Cholangiography (PTC)

With fluoroscopic guidance, a small needle is introduced under local anesthesia through the abdominal wall and into the substance of the liver. After position in a bile duct has been confirmed, a guide wire is introduced and a catheter can be placed. PTC facilitates diagnosis by providing a cholangiogram and permits therapeutic intervention, as necessary, based on the clinical situation. The technique has little role in the management of patients with uncomplicated gallstone disease, but it has been particularly useful for patients with more complex biliary problems, including strictures and tumors (Fig. [29-11](#)). PTC is the preferred approach for patients in whom ultrasonography demonstrates intrahepatic ductal dilatation and no extra hepatic ductal dilatation, e.g., Klatskin's tumor at the confluence of the right and left hepatic ducts. As with any invasive procedure, there are potential risks: bleeding, cholangitis, bile leak, and other catheter-related problems. Hematobilia occurs often but is usually self-limiting and of little consequence.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

Using a side-viewing endoscope, the biliary tract and pancreatic duct can be intubated and visualized. This procedure is generally performed with the patient under light intravenous sedation. Advantages of ERCP include direct visualization of the ampullary region and direct access to the distal bile duct, which facilitates diagnosis and therapeutic intervention. This test is generally not required when dealing with patients who have benign gallbladder disease, though it has been of enormous benefit for patients with common bile duct disease (benign and malignant). This is particularly true for the evaluation and treatment of patients with obstructive jaundice when there is dilatation of the common duct or gallbladder (Fig. [29-12](#)).

Choledochoscopy

Rigid and flexible choledochoscopes inserted into the supraduodenal common duct to visualize the lumen of the extrahepatic ducts have been used to determine the presence or absence of calculi; an accuracy of over 90 percent has been reported. The technique is used as an adjunct to operative cholangiography when the common duct is explored. Choledochoscopy can also aid in the removal of stones and bile duct tumors, and in inspecting and obtaining biopsy samples from stenoses.

TRAUMA

Penetrating and Nonpenetrating Injuries of the Gallbladder

Injuries of the gallbladder are uncommon, occurring in 2 to 8 percent of patients with major abdominal trauma. Penetrating injuries are usually caused by gunshot wounds or stab wounds; they also occur rarely during a needle biopsy procedure of the liver. Nonpenetrating injuries are extremely rare. Fewer than 100 cases have been reported, and in only 20 percent was the trauma isolated to the gallbladder.

The types of traumatic injuries to the gallbladder include contusion, avulsion, laceration, rupture, and traumatic cholecystitis. Contusion is difficult to verify but may be associated with vague or temporary symptoms that require no specific therapy. The contused area may undergo necrosis and perforate. Avulsion of the gallbladder from its liver bed occurs as a result of nonpenetrating injury. When the gallbladder's attachments are torn the organ usually hangs by its neck but may be attached only by the cystic duct and artery. Volvulus of the gallbladder may result. Traumatic cholecystectomy, in which the cystic duct, cystic artery, and gallbladder attachments are transected, has been reported. Laceration is the most common type of injury following penetrating wounds but also may result from blunt trauma. Delayed rupture of the gallbladder can occur days to weeks following injury. Traumatic cholecystitis is an unusual condition that occurs as a result of blunt trauma. Bleeding into the gallbladder, from injury of the gallbladder or of the liver, precipitates cholecystitis and sometimes gangrene of the gallbladder. The retained blood may clot and block the cystic duct, in which case the patient presents with the manifestations of hematobilia, including intermittent jaundice, colicky pain, hematemesis, and melena.

Effects of Intraperitoneal Bile

The effects of extravasation of bile into the peritoneal cavity depend on whether or not the bile is infected. When infected bile escapes into the peritoneal cavity, a fulminating and often fatal peritonitis results. When bile is sterile, however, it is well tolerated and results in a chemical peritonitis that may be relatively mild. In the majority of gallbladder injuries, the organ is normal and the bile is sterile. The fact that sterile bile is relatively innocuous is borne out by the very low mortality rate associated with nonpenetrating wounds of the gallbladder. Continuous leakage of noninfected bile, however, is not innocuous. The extravasated bile may produce ascites or become encysted, and extensive chemical peritonitis causes an outpouring of fluid into the peritoneal cavity from the general circulation that may result in shock. There is also some evidence that large amounts of bile salts may be toxic.

Clinical Manifestations

Bile leakage through the penetrating wound suggests the possibility of damage to the biliary system, but duodenal laceration may have a similar manifestation. With blunt trauma, manifestations may be delayed for 36 h or more, in part because typically there are other serious injuries that mask injury of the biliary tract, and sterile bile itself causes only minimal symptoms. The presence of severe shock and pain in the right upper quadrant or lower part of the right side of the chest should raise clinical suspicion of gallbladder injury. The manifestations of bacterial peritonitis may ensue, or if the bile leakage is minimal, the patient may appear to recover but subsequently develop ascites or an intraperitoneal cyst. The finding of bile-stained fluid during diagnostic paracentesis is suggestive, but a negative tap does not exclude gallbladder injury. In most instances the diagnosis is made at celiotomy, emphasizing the need for careful examination of the biliary system after abdominal trauma.

Treatment

The injured gallbladder has been successfully treated by simple suture of the laceration, cholecystostomy, and cholecystectomy. In general, it is preferable to remove the traumatized gallbladder. Cholecystectomy is usually quite easy to perform, since the gallbladder is rarely diseased, and it must be performed if the gallbladder has been avulsed or the cystic artery torn. In the severely ill patient, cholecystostomy may be used for treatment of the extensive laceration or traumatic cholecystitis in order to reduce the time of operative procedure and avoid injury to the common duct. Prognosis is directly related to the incidence of associated injuries.

Injury of the Extrahepatic Bile Ducts

Rare cases of solitary penetrating wounds involving the bile duct have been reported, but there is usually associated trauma to other viscera. Approximately 120 cases of traumatic rupture of the extrahepatic bile duct have been reported, and in 20 cases complete transection occurred. The clinical manifestations are similar to those described for gallbladder injury.

Treatment consists initially of meticulous exploration, particularly if injury to the gallbladder has been excluded and bile has been demonstrated retroperitoneally or within the peritoneal cavity. A Kocher maneuver should be performed to rule out perforation of the common duct behind the duodenum. The presence of hematoma in this region should raise the surgeon's suspicions. Tangential injuries may be treated by primary repair. Complete transection of the common hepatic duct or the common bile duct (e.g., by a penetrating knife wound) may be treated by debridement and an end-to-end anastomosis over a T tube, which should be left in place for several weeks. In most cases of complete transection and injuries caused by blunt trauma, however, the proximal end of the duct should be anastomosed to a Roux-en-Y limb of jejunum. The patient should be placed on an appropriate regimen of antibiotics.

Operative Injury of the Bile Ducts

The great majority of injuries of the extrahepatic biliary duct system are iatrogenic, occurring in the course of laparoscopic or open cholecystectomy. In over 70 percent of cases, the cholecystectomy had apparently been carried out without incident.

Diagnosis

In approximately 15 percent of the cases, ductal injuries are recognized and treated at the time of operation. The remaining 85 percent become manifest by either increasing obstructive jaundice or profuse and persistent drainage of bile through a fistula. Jaundice usually becomes manifest in 2 to 3 days, but in some instances it does not develop for weeks. It may be continuous or intermittent; if intermittent, it is frequently accompanied by attacks of chills and fever, suggesting ascending cholangitis. Hepatomegaly almost always accompanies jaundice if it has been persistent for several weeks, and splenomegaly also may occur if secondary biliary cirrhosis has evolved. Some patients do not display the signs or symptoms of partial or complete blockage until months or years after surgical treatment. Blockage in such cases is the result of increasing fibrosis and narrowing of the channel or of repeated episodes of cholangitis, which in turn leads to fibrosis. *ERCP* or *PTC* most clearly defines the site of obstruction or leak.

Treatment

Patients with jaundice or persistent fistula require a vigorous preoperative regimen that includes a high-protein, low-fat diet and intravenous administration of fat-soluble vitamins, particularly vitamin K. Concomitant portal hypertension with bleeding varices may preclude repair of the common duct; the portal hypertension is usually best treated by a splenorenal shunt because of extensive scarring in the right upper quadrant.

Operative Approach

Injury of the bile duct recognized during surgical operation should be corrected with an immediate reconstructive procedure. Restoration of the continuity of the duct with an end-to-end anastomosis over a T tube may be feasible after a sharp transection, but stricture develops in about half the cases. Direct anastomosis is usually impractical for acute injuries and chronic strictures where the proximal end of the duct should be anastomosed to a Roux-en-Y of jejunum. A mucosa-to-mucosa approximation provides the best long-term results. If this is not feasible, a lateral-lateral anastomosis between the left hepatic duct and a Roux-en-Y limb of jejunum (Hepp- Soupault) is preferable to the Smith transhepatic mucosal pull-through technique. The Longmire operation, with transection of the left lobe of the liver and anastomosis of the jejunum to a large intrahepatic bile duct, has been associated with discouraging results.

The operative mortality of patients with chronic stricture is reported to be 3 to 5 percent. A satisfactory result is obtained in about 70 percent of patients after one or more operative procedures. If the patient is symptom-free 4 years after reconstruction, the cure is almost always permanent.

GALLSTONES

Composition

The major elements involved in the formation of gallstones are cholesterol, bile pigment, and calcium. Other constituents include iron, phosphorus, carbonates, proteins, carbohydrates, mucus, and cellular debris. In Western cultures, most stones are made up of the three major elements and have a particularly high content of cholesterol, averaging 71 percent. Pure cholesterol stones are uncommon, usually large with smooth surfaces, and solitary. Bilirubin pigment stones are also uncommon, with a characteristic smooth, glistening, green or black surface. The pigment stones may be "pure" or consist of calcium bilirubinates. The "pure" pigment stones are usually associated with hemolytic jaundice or situations in which the bile is abnormally concentrated. Increased red blood cell destruction after cardiac valve replacement has resulted in production of gallstones. Calcium

bilirubinate stones are prevalent in Asia, where they constitute 30 to 40 percent of all gallstones.

Formation

Gallstones form as a result of solids settling out of solution. The solubility of cholesterol depends on the concentrations of conjugated bile salts, phospholipids, and cholesterol in bile. Lecithin is the predominant phospholipid in bile, and, although insoluble in aqueous solutions, it is dissolved by bile salts in micelles. Cholesterol is also insoluble in aqueous solution but becomes soluble when incorporated into the lecithin-bile salt micelle. By plotting the percentages of cholesterol, lecithin, and bile salts on triangular coordinates (Fig. 29-13), the limits of micellar liquid in which bile is less than saturated with cholesterol may be defined. Above these limits, the bile is either a supersaturated liquid or a two-phase system of liquid bile and solid crystalline cholesterol.

Perhaps no more than 30 percent of biliary cholesterol is transported in micelles, and of that the majority is carried in a vesicular form. These vesicles are made up of lipid bilayers similar to those found in cell membranes. The vesicles are able to solubilize more cholesterol than are micelles, and the stability of these structures is believed to be the key determinant of cholesterol saturation and precipitation. Current theory suggests that there is an equilibrium between the physicochemical phases of these vesicles such that the formation of liquid crystals may or may not result in actual gallstones. When crystals achieve macroscopic size during a period of entrapment in the gallbladder, gallstones form. The basic secretory defect in nonobese patients is decreased bile salt and phospholipid secretion. Conversely, in obese subjects cholesterol secretion is greatly increased without any reduction in bile salt or phospholipid secretion.

Nucleation is the process by which cholesterol monohydrate crystals form and aggregate. The time required for nucleation is shorter in patients with gallstones than in those without stones. Specific heat-labile glycoproteins within cholesterol-saturated bile induce vesicular aggregation and consequent stone growth. Factors that have been implicated in the formation and precipitation of cholesterol include constitutional elements, bacteria, fungi, reflux of intestinal and pancreatic fluid, hormones, and bile stasis. Constitutional elements are best exemplified in the Pima Indians, of whom 70 percent of females by age thirty and 70 percent of males by age sixty have gallstones. The Masai of Kenya, in contrast, do not have gallstones. Evidence in favor of infection as a cause includes the isolation of such organisms as *Escherichia coli*, *Salmonella typhi*, and *Streptococcus* species from gallbladder walls and from the center of stones in a high percentage of cases, and the demonstration of slow-growing actinomycetes recovered from over half the stones examined in one series. Given that gallstones develop in the absence of infection or inflammation, infection appears not to be a universal factor. In Asians, concretions are known to form about liver flukes and other parasites within the bile ducts.

The reflux factor receives support from the findings of pancreatic enzymes in the gallbladders of patients with cholelithiasis. Trypsin disturbs colloidal balance, and pancreatic phospholipase A can convert lecithin into toxic lysolecithin. Hormones have been implicated in an unproved correlation between calculi and parity, diabetes, hyperthyroidism, and the predominance in females.

Stasis, which includes temporary cessation of bile flow into the intestine and stagnation in the gallbladder, has also been assigned a major role in stone formation. Temporary bile stasis may be due to functional disorders or to a mechanical blockage in the region of the choledochoduodenal junction or the gallbladder. The interruption of bile flow to the intestine is associated with an interruption in enterohepatic circulation, which in turn is accompanied by a decrease in the output of bile salts and phospholipids, reducing the solubility of cholesterol. When more than 20 percent of bile is diverted, the bile salt pool cannot be maintained. Bile salt secretion is also diminished by reduction of the distal third of the intestine, explaining the development of stones in patients with ileal resection or disease. Cholecystectomy causes a greater fraction of the bile salt pool to cycle around the enterohepatic circulation, thereby increasing bile salt and phospholipid secretion.

Solubility has been investigated as a possible regimen to prevent the development of stones in patients at risk as well as to dissolve stones already formed. Chenodeoxycholic acid and ursodeoxycholic acid, which replenish the bile acid pool and reduce cholesterol synthesis and secretion, administered to potential stone formers may return supersaturated bile to its normal composition, preventing stone formation. In one series the drug was administered for 2 years; complete dissolution of radiolucent stones occurred in 13.5 percent of patients. Partial dissolution occurred in 41 percent. The effects were more frequent in women, in thin patients, and in patients with serum cholesterol levels greater than 227 mg/dL. Clinically significant hepatotoxicity was rare.

The direct instillation into the gallbladder of agents that are capable of dissolving cholesterol gallstones has become a reality largely as a result of advances in interventional radiologic technology. Although experience is limited, infusion of a potent cholesterol solvent, methyl- *tert*-butyl ether (MTBE), into the gallbladder via a percutaneously placed catheter has been shown to be effective in selected patients in achieving gallstone dissolution. This procedure is invasive and is therefore associated with some specific risks, including hemorrhage and catheter-related and drug-regulated problems. The major disadvantage of this technology is the high recurrence rate, which approaches 50 percent at 5 years. Lithotripsy has successfully fragmented biliary calculi but generally is not regarded as appropriate therapy because a diseased organ remains to form new stones and the flushing effected by normal bile flow is not equivalent to that of urinary flow.

Pigment stones can be further classified as either “brown” or “black” stones. Brown stones have a characteristic appearance and consistency and are typically found in Asia. These stones presumably occur as a result of infection and are quite similar to primary bile duct stones. Black stones, by contrast, typically are not associated with infected bile. These stones are found in patients with hemolytic disorders or cirrhosis. Altered solubilization of unconjugated bilirubin with precipitation of calcium bilirubinate and insoluble salts is presumed to be the common final pathway for the formation of all pigment stones, regardless of the clinical setting.

Asymptomatic Gallstones

The liberal use of cholecystography and ultrasonography has resulted in the diagnosis of calculi in patients without symptoms referable to the biliary tract. In several large series of asymptomatic patients with gallstones who were followed without surgical treatment, symptoms developed in 50 percent, and serious complications occurred in 20 percent. By contrast, McSherry and associates reported that only 10 percent of patients developed symptoms during a mean 5-year follow-up. Similarly, Gracie and Ransohoff reported a 15-year cumulative probability of developing symptoms of 18 percent for 123 patients with asymptomatic gallstones, and no deaths from gallbladder disease.

The relationship of cholelithiasis and carcinoma of the gallbladder is also of some significance. A review of several series showed that the incidence of calculi in cancer of the gallbladder ranged from 65 to 100 percent, with a mean of 90 percent. Conversely, the incidence of cancer of the gallbladder in patients with symptomatic gallstones ranged from 1 to 15 percent, with a mean of 4.5 percent. Comfort and associates reported no carcinoma among 112 patients with asymptomatic cholelithiasis.

In general, patients with asymptomatic gallstones should not be treated. Dyspepsia, eructations, and flatulence are not regarded as specific symptoms. With the advent of laparoscopic cholecystectomy, the number of cholecystectomies performed has increased. Cholecystectomy for asymptomatic stones may be appropriate for elderly patients with diabetes and for individuals who will be isolated from medical care for an extended period.

Cystic Duct Obstruction

Temporary obstruction to the outflow of bile from the gallbladder is responsible for the most common manifestation of calculous disease, which is biliary colic. This consists of the intermittent spasmodic pain in the right upper quadrant, often radiating to the shoulder or scapula, and precipitated by a fatty or fried meal. The attacks are self-limiting but have a tendency to recur in an unpredictable manner. Significant temperature elevation or leukocytosis are uncommon. The bilirubin and alkaline phosphatase levels are normal or slightly elevated because of an inflammatory process, and hyperamylasemia may be present. The treatment is cholecystectomy, preferably by the laparoscopic approach, and is best performed during that hospitalization but not as an emergent procedure.

Calculi, usually of the cholesterol type, may become impacted in the cystic duct or the neck of the gallbladder, resulting in what is called *hydrops of the gallbladder*. The bile is absorbed, and the gallbladder becomes filled and distended with mucinous material. The gallbladder is generally palpable and tender, and the impacted stone with the resulting edema may encroach on the common duct and cause mild jaundice. Although hydrops may persist with few consequences, early cholecystectomy is generally indicated to avoid the complications of biliary tract infection, empyema, or perforation of the gallbladder. In questionable cases, isotopic scanning of the gallbladder following intravenous CCK can define cystic obstruction or patency.

Choledocholithiasis

Common duct stones may be single or multiple and are found in 4 to 12 percent of cases subjected to cholecystectomy. Most common duct calculi are formed within the gallbladder and migrate down the cystic duct into the common bile duct. Less commonly, stones are thought to form within the ducts. These are classified as *primary stones*, in contradistinction to the *secondary stones* formed in the gallbladder. Primary stones are usually soft, nonfaceted, yellowish brown, and friable. In patients infected with tropical parasites such as *Clonorchis sinensis* and in the Asian population of the Far East, stones may form within the hepatic ducts or the common bile duct itself. Although small stones may pass via the common duct into the duodenum, the distal duct with its narrow lumen (2 to 3 mm) and thick wall frequently obstructs their passage. Edema, spasm, or fibrosis of the distal duct secondary to irritation by the calculi contribute to biliary obstruction. Both extrahepatic and intrahepatic bile ducts become dilated, and there is evidence of laking in the biliary radicles of the liver. There is also thickening of the duct walls and inflammatory cell infiltration. Chronic biliary obstruction may cause secondary biliary cirrhosis with bile thrombi, bile duct proliferation, and fibrosis of the portal tracts. Also associated with chronic obstruction is the development of infection within the bile duct, giving rise to ascending cholangitis and occasionally extending up to the liver, resulting in hepatic abscesses. The offending organism is almost always *E. coli*.

Gallstone pancreatitis is generally associated with the presence or passage of common bile duct stones. The best evidence for this is the frequency with which stones can be found if the stool is filtered at the time of an attack. The frequency with which stones are found in the common duct varies from 1 percent to 70 percent, depending on the time of the operation. At the time of exploration, the pancreas may appear entirely normal, or it may demonstrate edema and rarely necrosis (necrotizing pancreatitis).

Clinical Manifestations

The manifestations of calculi within the common duct are variable. Stones may be present within the extrahepatic duct system for many years without causing symptoms. Characteristically, the symptom complex consists of colicky pain in the right upper quadrant radiating to the right shoulder with intermittent jaundice accompanied by pale stools and dark urine. Biliary obstruction is usually chronic and incomplete but may be acute or complete. If obstruction is complete, jaundice progresses but is rarely intense. In contrast to patients with neoplastic obstruction of the common bile duct or the ampulla of Vater, the gallbladder is usually not distended because of associated inflammation (Courvoisier's law). Liver function tests demonstrate the pattern of obstructive jaundice, and the alkaline phosphatase level usually becomes elevated earlier and remains abnormal for longer periods than the serum bilirubin level. The prothrombin time is frequently prolonged because the absorption of vitamin K is dependent on bile entering the intestine, but a normal level can usually be achieved with parenteral vitamin K. Tests of hepatocellular function generally have normal results. In patients with ascending cholangitis, Charcot's intermittent fever accompanied by abdominal pain and jaundice is characteristic. The diagnosis may be established by *ERCP* or *PTC*.

Treatment

The indications for the removal of common duct stones are: (1) their presence as defined preoperatively in a symptomatic patient or by palpation or cholangiographically at the time of operation; (2) a dilated extrahepatic duct; (3) jaundice; (4) recurrent chills and fevers suggestive of cholangitis; and (5) gallstone pancreatitis.

Common duct stones can be removed by *ERCP*, and the performance of an adequate destruction of the sphincter of Oddi will permit stones that were not extracted or form at a later date to pass into the duodenum without obstruction in the extrahepatic ducts. In a patient undergoing an elective cholecystectomy in whom common duct stones are thought to be present, a preoperative ERCP and sphincterotomy can be followed by laparoscopic cholecystectomy. In some elderly patients ERCP and sphincterotomy have constituted definitive treatment and the gallbladder was not removed.

If common duct stones are detected during laparoscopic cholangiogram, they can be removed by subsequent *ERCP* or during the procedure by trans-cystic duct retrieval or pushing them into the duodenum. Alternatively, the common duct can be opened, the stones extracted, and a T tube inserted. If common duct stones are suspected or detected during open cholecystectomy, the same alternatives apply. The use of the choledochoscope and ureteral baskets facilitates the procedure. In the patient population as a whole, concomitant choledochostomy at the time of cholecystectomy increases the operative mortality by less than 1 percent. In addition, in the face of dilated common duct and multiple stones, a choledochoduodenostomy can provide definitive treatment.

Retained Common Duct Stones

If stones are noted to be present when a T-tube cholangiogram is performed postoperatively (Fig. 29-14), several approaches can be entertained. Small stones, particularly those located in the branches of the hepatic duct, may be disregarded; the majority will remain asymptomatic, and for those that do generate symptoms operative extraction is not associated with significantly increased morbidity. Another approach employs either flushing or chemical dissolution. Capmul 8210, a mono- octanoin, is the agent of choice. The use of heparin, 250,000 units in a 250-mL solution infused every 8 h for 5 days, has been successful.

The mechanical extraction of the retained stone can be performed under radiographic control. Mazzariello reported a 96 percent success rate for 1086 cases, and Burhenne and associates reported a 91 percent success rate for 612 patients managed at 38 hospitals, with no deaths and no significant complications. The T tube is generally left in place for at least 4 weeks after the operation; it is then extracted and a polyethylene catheter is used to instill radiopaque material into the common duct. A Dormia basket is then advanced through the catheter to entrap the stone (Fig. 29-15).

The most commonly used approach is transduodenal papillotomy with extraction of the stone under endoscopic visualization (Fig. 29-16). The success rate for extraction or spontaneous passage after this procedure was 86 percent for 731 collected cases. A complication rate of 7 percent was noted, but two-thirds of complications were treated conservatively. The mortality rate related to the technique was 1.25 percent. Operative intervention is indicated in some cases if there is evidence of obstruction or cholangitis, or if nonoperative methods fail.

Some calculi remain within the liver and may cause irreversible damage. The most common location is a left main hepatic duct that forms a cisterna, and successful treatment is best achieved in this circumstance by resection of the left lobe of the liver. In occasional patients with recurrent hepatic duct stones, a Roux-en-Y limb can be anastomosed to the hepatic duct (usually the left main duct) and positioned so that it can be entered under radiographic guidance to permit stone extraction.

Biliary Enteric Fistula and Gallstone Ileus

A stone in the ampulla of the gallbladder (Hartmann's pouch) can encroach upon and erode the common bile duct. This is known as Mirizzi's syndrome. Operative management depends on the extent to which the common duct has been compromised. If there is only a pressure effect, cholecystectomy is sufficient. If the common duct segment is partially or completely destroyed, a reconstructive procedure is mandated and may require a Roux-en-Y limb anastomosis to the proximal normal duct. When biliary enteric fistulas develop, they usually run between the gallbladder and the duodenum, but 15 percent are cholecystocolic fistulas. Mechanical obstruction of the gastrointestinal tract caused by gallstones is a relatively infrequent occurrence. Gallstone ileus causes 1 to 2 percent of mechanical small-intestine obstructions; the mortality rate is less than 10 percent.

Since cholelithiasis occurs three to six times more commonly in the female than in the male, a higher incidence of gallstone ileus in the female is to be anticipated. Preponderance in the female is actually higher than one would expect, and in several series all patients were female. It is characteristically a disease of the aged, with an average age of sixty-four, and is unusual under the age of fifty.

The process usually begins with formation of the stone within the gallbladder, but cases have been reported in which the gallbladder was not present, having been removed several years prior to the intestinal obstruction. After the gallstone has left the gallbladder, it may obstruct the alimentary tract in one of two ways. Typically, *intraluminal obstruction* is produced by the entrance of the stone into the gastrointestinal tract. Rarely, the stone enters the peritoneal cavity, causing kinking or inflammation and *extrinsic obstruction* of the intestine. The stone may enter the duodenum via the common duct, but this is unusual, and almost always the offending calculus enters through a cholecystenteric fistula. The fistulous tract may connect the gallbladder with the stomach, duodenum, jejunum, ileum, or colon. In addition, internal biliary fistulas may communicate with the pleural or pericardial cavities, tracheobronchial tree, pregnant uterus, ovarian cyst, renal pelvis, and urinary bladder. In a series of 176 fistulas caused by gallstones, the duodenum was involved in 101, the colon in 33, the stomach in 7, and multiple sites in 11.

The fistula probably originates with a stone obstructing the cystic duct, acute cholecystitis, empyema, and the formation of adhesions between the gallbladder and adjacent viscera. Perforation then occurs between the intimately adherent organs, and the stone traverses the fistula. The cholecystenteric fistula then frequently closes, and only a fibrous remnant remains. Having entered the alimentary tract, the gallstone, which is usually single, may be vomited or passed spontaneously via the rectum. The size of the stone is important, since stones smaller than 2 to 3 cm usually pass. When obstruction occurs, the site is usually at the terminal ileum, which is the narrowest portion of the small intestine. Of 154 cases, the duodenum was obstructed in 6, the jejunum in 14, the proximal ileum in 6, the middle ileum in 31, the terminal ileum in 88, the colon in 3, and the rectum in 2. When a gallstone blocks the small intestine, the morbid anatomic and physiologic effects of a mechanical obstruction obtain. There are very large losses of fluid into the intestine. Edema, ulceration, or necrosis of the bowel may occur, and perforation may result.

Clinical Manifestations

A past history suggestive of cholelithiasis is present in 50 to 75 percent of patients. Symptoms of acute cholecystitis immediately preceding the onset of gallstone ileus occur in one-quarter to one-third of the cases. A history of jaundice is present in about 10 percent of the cases. Occasionally, there may be an initial episode of pain suggestive of biliary colic, but major pain is usually not experienced until the intestinal colic results. There is associated cramping, nausea, and vomiting, which may be intermittent. When complete small intestinal obstruction occurs, the vomiting increases and obstipation results. Vomiting is present in almost 100 percent, cramps in 90 percent, distention in 90 percent, obstipation in 78 percent, and feculent vomiting in 67 percent. Serum electrolyte levels reveal the pattern of lower intestinal obstruction with marked hypochloremia, hyponatremia, hypokalemia, and an elevated carbonate level.

The correct preoperative diagnosis is infrequently made, ranging between 13 and 30 percent in several series. The usual diagnosis is that of intestinal obstruction of unknown cause. Radiologic examination may be diagnostic if gas is demonstrated within the biliary tract (Fig. 29-17). Flat, upright, and lateral films plus spot films over the liver are indicated if the diagnosis is considered. The plain x-ray film reveals the pattern of small-intestine obstruction, and a stone is visualized in less than 20 percent of the cases. The diagnosis has also been based on the migration of a previously observed radiopaque gallstone.

Treatment

Biliary enteric fistulas are managed by cholecystectomy and closure by primary repair of the intestinal opening. The patient with gallstone ileus often requires fluid and electrolyte replacement in order to correct deficiency, and a nasogastric tube is used to decompress the stomach. Definitive therapy consists of locating the stone or stones, enterotomy proximal to the stone, and removal of the offending calculi with closure of the intestine. The recurrence rate of gallstone ileus is 5 to 9 percent, and it is important to palpate the entire small intestine, gallbladder, and common duct for retained stones, particularly if the obstructing stone is faceted. Either concomitant or planned interval cholecystectomy and closure of the fistula, if patent, is indicated, since recurrent symptoms or complications develop in one-third of the patients. Carcinoma of the gallbladder has also been present or developed 5 to 16 years after removal of the obstructing gallstone. Performance of concomitant cholecystectomy is determined by the patient's general condition. Many of these patients are extremely ill and depleted, and prolongation of the operative procedure may be contraindicated.

INFLAMMATORY AND OTHER BENIGN LESIONS

Acute Cholecystitis

Acute cholecystitis is usually associated with an obstruction of the neck of the gallbladder or cystic duct caused by stones impacted in Hartmann's pouch. Direct pressure of the calculus on the mucosa results in ischemia, necrosis, and ulceration with swelling, edema, and impairment of venous return. These processes in turn increase and extend the intensity of the inflammation. The ulceration may be so extensive that the mucosa is frequently hard to define on microscopic examination, and segmented leukocytes are found infiltrating all layers. The results of necrosis are perforation with pericholecystic abscess formation, fistulization, or bile peritonitis. In the past, acute cholecystitis secondary to systemic infection occurred most commonly with typhoid fever, but this is now rare. A bacterial cause has been proposed and positive bile cultures have been noted in 60 percent of patients. *E. coli*, *Klebsiella* species, streptococci, *Enterobacter aerogenes*, salmonellae, and clostridia have all been implicated.

Acute cholecystitis, caused by generalized sepsis or by stasis or impaction of a calculus, may occur while the patient is recovering from trauma or an operation. Among other causes of acute cholecystitis are the vascular effects of collagen disease, terminal states of hypertensive vascular disease, and thrombosis of the main cystic artery. Acute cholecystitis in which the gallbladder is devoid of stones is known as acalculous cholecystitis. Less than 1 percent of acutely inflamed gallbladders contain a malignant tumor that may play a role in causing obstruction. The incidences of common duct calculi are similar in acute and in chronic cholecystitis, averaging 7 to 15 percent.

Clinical Manifestations

Most attacks of acute cholecystitis occur in patients who give a history compatible with chronic cholecystitis and cholelithiasis. Acute cholecystitis can occur at any age, but the greatest incidence is between the fourth and eighth decades, and patients over the age of sixty comprise between one-quarter and one-third of the group. Caucasians are afflicted more frequently than blacks, and women more than men.

The onset of acute symptoms is frequently related to a vigorous attempt of the gallbladder to empty its contents, usually after a heavy, fatty, or fried meal. Moderate to severe pain is experienced in the right upper quadrant and epigastrium and may radiate to the back in the region of the angle of the scapula or in the interscapular area. The patient is often febrile, and vomiting may be severe. Tenderness, usually along the right costal margin, often associated with rebound tenderness and spasm, is characteristic. The gallbladder may be palpable, or a palpable mass in the region may be the result of omentum wrapped around the gallbladder. Mild icterus may be present and may be caused by calculi within the ampulla and edema encroaching on the common duct. Moderate to marked jaundice, particularly with a serum bilirubin level greater than 6 mg/dL, suggests the presence of

associated choledocholithiasis but can occur with isolated cholecystitis.

The differential diagnosis includes perforation or penetration of peptic ulcer, appendicitis, pancreatitis, hepatitis, myocardial ischemia or infarction, pneumonia, pleurisy, and herpes zoster involving an intercostal nerve.

The hemogram usually demonstrates leukocytosis with a shift to the left. Radiographs of the chest and abdomen are indicated to rule out pneumonia. A radiopaque calculus is noted in less than 20 percent of cases. The serum bilirubin level may determine the presence of common duct obstruction. Although an elevated amylase level is generally regarded as evidence of acute pancreatitis, levels as high as 1000 Somogyi units have been associated with acute cholecystitis uncomplicated by pancreatitis. To rule out myocardial ischemia, an electrocardiogram should be performed on any patient over the age of forty-five being considered for surgical treatment. Acute cholecystitis may be responsible for some electrocardiographic changes. Oral cholecystography is of limited value because of impaired absorption of dye. An ultrasonogram may demonstrate calculi and/or a thickened wall of the gallbladder and is the diagnostic procedure of choice. Radionuclide scanning with DISIDA (diisopropyl iminodiacetic acid) or PIPIDA (N-para-isopropyl-acetanilide-iminodiacetic acid) is the most effective diagnostic study in this situation.

Treatment

There have been conflicting opinions on the management of acute cholecystitis, particularly on the optimal time for surgical intervention. For the purposes of discussion, early operation is defined as one performed within 72 h after the onset of symptoms; intermediate operation is one carried out between 72 h and the cessation of clinical manifestations; delayed operative management permits the acute inflammatory process to subside; and scheduled elective surgery is performed after an interval of 6 weeks to 3 months. Most surgeons now favor early operation, i.e., with 24 to 48 h. The mortality rate for emergent cholecystectomy ranges from 0 to 5 percent. In the majority of cases, laparoscopic cholecystectomy is successful, but the incidence of conversion to open cholecystectomy is greater in this group of patients when compared to those without acute inflammation. In rare instances of extremely ill patients, cholecystostomy under local anesthesia is applicable.

Emphysematous Cholecystitis

Emphysematous cholecystitis is a rare form of acute, usually gangrenous, cholecystitis, associated with the presence of gas in the gallbladder (Fig. 29-18). Unlike ordinary acute cholecystitis, which is more prevalent among women, emphysematous cholecystitis is more often found in men, with incidences of 75 percent for males and 25 percent for females. Pathogenesis is related to acute inflammation of the gallbladder, which often begins aseptically, complicated by a secondary infection with gas-forming bacilli. These may reach the gallbladder by bile ducts, bloodstream, or lymphatic channels and grow in an anaerobic environment. The clinical manifestations are similar to those of acute cholecystitis. In approximately half the patients, a history of previous gallbladder attacks can be elicited. Cholelithiasis is also present in half the patients, who are frequently diabetic.

The diagnosis is usually made on the basis of radiographs that show a globular, gas-filled shadow in the region of the gallbladder. Later, intramural or submucosal gas may appear, and gas may also appear in the pericholecystic area, denoting extension of the pathologic process outside the confines of the gallbladder. The treatment of choice is early operation, since the incidence of free perforation is reported to be 40 to 60 percent. Cholecystectomy is indicated, but if it is not feasible, cholecystostomy should be performed. In 9 percent of cases, choledocholithiasis is present, and exploration of the common duct may be required. Although positive bile cultures are found in only half the cases, antibiotics directed toward the clostridial and coliform organisms are indicated. The mortality rate is significantly greater than that for nonemphysematous cholecystitis.

Chronic Cholecystitis

Chronic inflammation of the gallbladder is generally associated with cholelithiasis and consists of round cell infiltration and fibrosis of the wall. Buried crypts of mucosa (Rokitansky-Aschoff sinuses) may be seen dipping into the mucosa (Fig. 29-19). Obstruction by gallstones of the neck of the cystic duct may produce a mucocele of the gallbladder (hydrops). The bile is initially sterile but may be secondarily infected with coliform bacilli, *Klebsiella* species, streptococci, and occasionally clostridia or *Salmonella typhi*. Secondary effects of cholecystitis include obstruction of the common duct, cholangitis, perforation of the gallbladder with formation of a pericholecystic abscess or a cholecystenteric fistula, bile peritonitis, and pancreatitis. There may be associated carcinoma of the gallbladder.

Clinical Manifestations

The patients generally present with moderate intermittent abdominal pain in the right upper quadrant and epigastrium, occasionally radiating to the scapula and interscapular region. There is usually a history of intolerance of fatty or fried foods, and the patient may have noted intermittent nausea and anorexia. If the patient is not experiencing acute pain, there may be no diagnostic findings on physical examination. Occasionally tenderness is elicited over the gallbladder. Diagnosis is usually established by ultrasound scanning or an oral cholecystogram, which demonstrates either the absence of filling of the gallbladder or the presence of stones.

Hyperplastic Cholecystoses

Hyperplastic cholecystoses are characterized by the proliferation of normal tissue elements. The two most common of these lesions are cholesterolosis and adenomyomatosis. In patients with cholesterolosis there is evidence of cholesterol deposition within the epithelial cells of the lamina propria. The bile of these patients contains significantly more cholesterol than that of normal adults, and the abnormality presumably arises from some aberration in cholesterol transport and absorption by the gallbladder epithelium. The deposition of cholesterol within the wall gives rise to the gross description of the "strawberry gallbladder." Adenomyomatosis is characterized by hyperplasia of the muscle and mucosa of the gallbladder. Malignant degeneration is unusual, and it is unclear whether these disorders can truly be the source of symptoms. Cholecystectomy should be offered to these patients only if warranted by symptoms.

Treatment

The treatment of chronic cholecystitis and cholelithiasis is cholecystectomy, and the results are usually excellent. Laparoscopic cholecystectomy is the procedure of choice. Early cholecystectomy is particularly important for the diabetic patient. Operative mortality of less than 1 percent has been reported for large series. Seventy-five percent of patients undergoing cholecystectomy for cholelithiasis are completely relieved of all preoperative symptoms, and the remaining 25 percent have only mild symptoms that are apparently unrelated to the biliary system.

Acalculous Cholecystitis

Acute and chronic inflammatory disease of the gallbladder can occur without stones. Acute acalculous cholecystitis frequently is a complication of burns, sepsis, multiple system failure, cardiovascular disease, diabetes, prolonged illness, or a major operation.

The incidence of chronic acalculous cholecystitis is difficult to establish. It is present in over 50 percent of children and 35 percent of Nigerians with gallbladder disease, and the accepted incidence of adults in the United States is less than 5 percent of cases of cholecystitis. Possible causes include (1) anatomic conditions such as kinking, fibrosis, and obstruction of the cystic duct by tumor or anomalous vessels; (2) thrombosis of major blood vessels, producing ischemia and gangrene; (3) spasm or fibrosis of the sphincter of Oddi in patients with a "common channel" with or without associated pancreatitis; (4) systemic diseases such as diabetes mellitus and collagen diseases; (5) specific infections such as typhoid fever, actinomycosis, and parasitic infestation; and (6) scarlet fever and a wide variety of febrile illnesses in young children. The DISIDA or PIPIDA scan and the ultrasound scan are occasionally normal in these patients, but characteristically the ultrasound demonstrates thickening of the wall. Percutaneous cholecystostomy has been used successfully (80 percent) for diagnosis and treatment of acalculous cholecystitis.

Treatment

Cholecystectomy is preferable, but in one series the patient's condition mandated cholecystostomy in 14 of 16 cases. In children with acute febrile illness, cholecystostomy has been particularly effective, and subsequent cholecystectomy has not been required in many of these patients.

Cholangitis

Infection within the biliary duct system is most frequently associated with choledocholithiasis but also has accompanied choledochal cysts and carcinoma of the bile duct, and has followed sphincteroplasty. Infection and inflammatory changes may extend up the duct system into the liver and give rise to multiple hepatic abscesses. Clinically, the condition is characterized by intermittent fever, upper abdominal pain, exacerbation of jaundice, pruritus, and at times rigor.

In patients with common duct stones in whom there is ascending cholangitis, a broad-spectrum antibiotic directed particularly at *E. coli*, which is the most common offending organism, should be given for several days before surgical treatment. Antibiotics usually control the infection, but if the patient's temperature does not fall, surgical drainage should not be delayed. This can be accomplished percutaneously by the transduodenal or transhepatic routes or operatively.

Acute Suppurative Cholangitis

Suppurative cholangitis, in which there is gross pus within the biliary tract, constitutes one of the most urgent causes for laparotomy in patients with obstructive jaundice. The condition was first described in 1877 by Charcot, who suggested a diagnostic triad of jaundice, chills and fever, and pain in the right upper quadrant. To these, Reynolds and Dargan added shock and central nervous system depression as specific identifying features of the condition.

The disease occurs almost exclusively in patients over 70 years of age. All patients are febrile, and a majority are jaundiced. Hypotension, confusion, or lethargy occurs in about 20 percent of cases. A white blood cell count of less than 12,000/mm³ has been reported in over half the patients, probably related to the age and lack of marrow response. Bilirubin, SGOT, and alkaline phosphatase levels are characteristically elevated, but the serum amylase level is usually normal. The correct diagnosis has been made in less than one-third of the patients. Patients have been managed emergently by establishing initial drainage via *ERCP* or *PTC* followed by definitive operation.

At operation, all patients demonstrate gross distention of the common bile duct, with frank pus, frequently under considerable pressure, and choledocholithiasis or a tumor obstructing the distal bile duct. If the gallbladder is present, it is invariably distended and inflamed. Spontaneous perforation of the bile ducts has been reported. Surgical treatment is directed at rapid decompression of the duct system and is combined with large doses of antibiotics, particularly those that achieve high levels in the bile. In a review of the literature, it was reported that all patients who were not operated on died, and mortality following drainage or surgical procedures ranged from zero to 88 percent, averaging 33 percent.

Cholangiohepatitis

Cholangiohepatitis, which is also known as recurrent pyogenic cholangitis, is found almost exclusively among the Chinese, with the largest number of cases seen among Cantonese living in the Pearl River delta in China. In Hong Kong it is the most commonly encountered disease of the biliary passages and is the third most common abdominal surgical emergency after appendicitis and perforated ulcer. It has also been encountered in Great Britain, in Australia, and in the Chinese population in the United States. Cholangiohepatitis

occurs most frequently in the third and fourth decades but has been reported at all ages and occurs with equal frequency among men and women.

The etiology of cholangiohepatitis is summarized in Fig. 29-20. The pyogenic element probably originates from the bowel and is caused by *E. coli*, *Klebsiella* species, *Bacteroides* species, or *Enterococcus faecalis*. In most instances, positive cultures are obtainable from the bile and the portal venous blood. The Chinese liver fluke, *C. sinensis*, was thought to be an important contributing factor. Other factors that have been implicated as contributing causes of cholangiohepatitis include ascariasis and hemolysis associated with malaria.

Pathology

The gallbladder wall is thickened but not grossly inflamed. The common bile duct is also usually grossly distended and contains large stones. The stones are produced by precipitation of bile pigments, desquamation of epithelium, and products of inflammation; the nucleus of the stone may contain an adult *Clonorchis* worm, an ovum, or an ascarid. Acute or hemorrhagic pancreatitis occurs in less than 1 percent of cases. The most marked changes occur in the liver, where the intrahepatic bile ducts are both dilated and constricted. Inflammatory changes are present in the periductal tissue and may progress to frank abscess formation.

Clinical Manifestations

In highly endemic areas, cholangiohepatitis is the first consideration in patients with jaundice, pain, and pyrexia. Pain is usually located in the right upper quadrant and epigastrium and may be colicky or constant. In most acute attacks there is fever accompanied by chills and rigors, and 50 percent of the patients are jaundiced, while the remainder have an elevation of the serum bilirubin level. Recurrence of symptoms is one of the most characteristic features of the disease.

Most patients appear to be in a toxic condition, with temperatures up to 40°C. There is tenderness and guarding in the right upper quadrant. The white blood cell count is usually about 15,000/mm³, and the serum bilirubin level is generally above 2mg/dL, with accompanying bilirubinuria. There may be evidence of impairment of hepatocellular function. In the majority of cases calculi are not demonstrable on routine x-ray films. An occasional finding of significance is the presence of gas in the biliary tree, which may be due to a secondary gas-forming organism or a fistula between the duct and duodenum. *ERCP* or *PTC* may establish the diagnosis. Manifestations of portal hypertension may be present.

Treatment

Patients are generally prepared with antibiotics. Surgical therapy, however, should not be delayed for the patient who is jaundiced and has pain and pyrexia. The operation consists of removal of the stones and debris from the extrahepatic bile ducts followed by establishment of open drainage between the involved ducts and intestine, usually with a Roux-en-Y limb. Anchoring the Roux-en-Y limb to the anterior abdominal wall facilitates subsequent repeated dilatation and stone extractions.

If large hepatic abscesses are noted, drainage should be performed. Left hepatic lobectomy has been carried out on occasion, when there has been gross dilatation of the ducts and abscess formation in the left lobe while the right was apparently normal.

The prognosis is generally guarded, since recurrence is not uncommon. In one study, common duct exploration, transhepatic intubation, and hepatotomy were associated with recurrence rates of 24, 37, and 75 percent, respectively. Hepatic resection had a failure rate of only 4 percent, and none of the patients had recurrent stones. In advanced cases, particularly with multiple abscesses, the prognosis is poor, and the patient eventually succumbs to liver failure, septicemia, or cholangiocarcinoma.

Sclerosing Cholangitis

Sclerosing cholangitis is an uncommon disease that involves all or part of the extrahepatic biliary duct system and often affects the intrahepatic biliary radicals as well. The disease has also been called *obliterative cholangitis* and *stenosing cholangitis*, in reference to a progressive thickening of the bile duct walls encroaching upon the lumen. It may be associated with gallstones, but several series have been presented in which there were no stones in the gallbladder or the common duct. A significant number of cases have been associated with ulcerative colitis, Crohn's disease, Riedel's struma, retroperitoneal fibrosis, and porphyria cutanea tarda.

The cause of sclerosing cholangitis is unknown. Histologic sections in several cases failed to reveal any granulomatous lesion, metaplasia, or neoplasia. In several series, none of the patients had previous surgical treatment, and therefore local trauma was excluded as an etiologic agent; irritation of the common duct by passage of calculi is unlikely given that there are usually no stones present in either the common duct or the gallbladder. It has been suggested that the disease may be caused by local response to viral infection, since a relative lymphocytosis with atypical lymphocytes has been noted. Immune response and collagen disease have also been considered as possible causes. A positive cellular immune response to biliary antigens has been demonstrated. The disease has been noted in patients with HIV infection.

Pathology

Grossly, there is diffuse thickening of the wall of the extrahepatic biliary tract and sometimes of the intrahepatic ducts, with a concomitant encroachment on the lumen, resulting in marked luminal narrowing. The duct system may be completely involved, or the hepatic ducts may be spared and the disease restricted to the entire length of the common duct. The gallbladder is usually not involved, but the lymph nodes in the region of the common duct and foramen of Winslow are usually markedly enlarged and succulent. Microscopic analyses of the affected duct show that the walls are as much as eight times thicker than normal. The areas of inflammation and fibrosis are in the submucosal and subserosal portions, with an edematous field between them. The mucosa is intact throughout. Biopsy examination of the liver may reveal bile stasis or, in long-standing cases, biliary cirrhosis. The histologic evaluation is critical, since it is difficult to differentiate this disease from sclerosing carcinoma of the bile ducts.

Clinical Manifestations

The diagnosis is to be considered in patients (particularly middle-aged men) with a clinical and laboratory picture of extrahepatic jaundice. Jaundice is usually associated with intermittent pain in the right upper quadrant, nausea, vomiting, and occasionally chills and fever. In long-standing cases with biliary cirrhosis, the manifestations of portal hypertension, such as bleeding varices and ascites, may be apparent. The diagnosis has been established by *ERCP*. At operation a dense inflammatory reaction in the region of the gallbladder and gastrohepatic ligament is noted. Palpation of the duct reveals a cordlike structure that may feel like a thrombosed blood vessel, but the wall of the common duct is obviously thickened and cuts with difficulty. The edges of the incision characteristically pout out. Usually only a fine probe or small Bakes dilator can be inserted into the lumen. Cholangiography may vividly demonstrate the extensive narrowing of the lumen (Fig. 29-21).

Treatment

The appropriate management of sclerosing cholangitis remains unclear. No drug therapy has achieved consistent, or even usual, success.

The asymptomatic anicteric patient is not treated and is not studied with repeated cholangiograms if jaundice or cholangitis does not develop. The pruritic and icteric patient is treated for 4 to 6 weeks with prednisone; if there is no improvement, or if cholangitis is present or develops, an operation is performed with a preoperative cholangiogram as a guide. If there is minimal intrahepatic involvement and dilatation of a segment of the common duct or common hepatic duct proximal to marked stenosis, the stenotic segment is excised as a biopsy section to rule out cholangiocarcinoma, and a direct mucosa-to-mucosa anastomosis is effected between the dilated segment of duct and a Roux-en-Y limb of jejunum, preferably without a stent. Stricture of the confluence of the hepatic ducts is managed by excision of the distal ducts for pathologic evaluation and anastomosis of the hepatic ducts to the Roux-en-Y limb of jejunum by the mucosa-to-mucosa technique. If the hepatic ducts are sufficiently dilated, no stent is used. If these ducts are small, transhepatic stents are used, but no attempt is made to dilate intrahepatic ducts.

Data from several large centers suggest that selected patients with primarily extrahepatic disease can be successfully managed with hepaticojejunostomy and long-term stenting. In patients with more diffuse or advanced parenchymal disease, hepatic transplantation has become the procedure of choice. The role of transplantation might be extended as we begin to understand more fully the risk of cholangiocarcinoma developing in patients with sclerosing cholangitis.

Fibrosis or Stenosis of the Sphincter of Oddi

In 1884 Langenbuch, only 2 years after reporting the first successful removal of a gallbladder, suggested transduodenal division of the "diverticulum" of Vater in cases of cicatricial stenosis for chronic inflammation. In 1901 Opie called attention to the "common channel" theory as the cause of pancreatitis, and in 1913 Archibald suggested sphincteroplasty as the treatment for pancreatitis.

The pathogenesis of fibrosis or stenosis of the sphincter of Oddi and the papilla of Vater is not fully understood. Long-standing spasm may play an important role, and infection of the biliary tract or pancreas has also been implicated. Irritation from stones within the common duct may also lead to fibrosis. In a series of 50 patients in whom sphincteroplasty was performed because a small Bakes dilator could not be passed through the sphincter of Oddi, biopsy analysis revealed no abnormalities in 18, while 18 showed inflammatory infiltration, 17 had minimal fibrosis, and 2 had diffuse fibrosis. No definite correlation could be found between the various manifestations of biliary tract disease and the histologic changes.

Clinical Manifestations

The main symptom of fibrosis or stenosis of the sphincter of Oddi is abdominal pain, usually colicky and frequently associated with nausea and vomiting. The pain begins in the right upper quadrant and radiates to the shoulder, and it may be intermittent. Over half the patients give a history of intermittent jaundice, and many indicate that they have had previous cholecystectomy without relief of symptoms.

Treatment

The diagnosis is generally made when there is difficulty in passing a No. 3 Bakes dilator through the ampulla of Vater. Cholangiography and pressure studies on the common bile duct have theoretical application. If a 3-mm dilator cannot be easily passed through the ampulla, a transduodenal exploration should be carried out. Thomas and associates compared the results of transduodenal sphincteroplasty and choledochoduodenostomy in 30 patients with stenosis or stricture of the sphincter. The procedures were equally and highly effective, and neither was associated with a significant incidence of subsequent cholangitis. Sphincteroplasty is preferable if the common duct is small, and a transduodenal approach is indicated if an ampullary tumor is suspected. Endoscopic papillotomy has been used successfully, particularly in Europe, where the disorder is more frequently diagnosed.

Papillitis

In 1926 DelValle first described a benign inflammatory and fibrous process of the ampulla of Vater and indicated that it was a factor in producing stenosis. It was postulated that acute and subacute inflammatory changes occur and that stenosis is the final and irreversible result of these changes. Acosta and Nardi have presented 61 cases of papillitis, 21 of which were chronic ulcerative papillitis, 20 chronic sclerosing papillitis, 15 chronic granulomatous papillitis, and 5 chronic adenomatous papillitis. The acute stage, which is characterized by edema, papillary dilatation, hemorrhage, and infiltration, may be reversible, whereas sclerosing papillitis and chronic granulomatous papillitis are considered

irreversible in view of their inevitable evolution into scar tissue.

The clinical and pathologic features associated with papillitis include the postcholecystectomy syndrome in 30 percent, dilatation of the common duct in 50 percent, biliary disease without stones in 25 percent, obstructive jaundice in 60 percent, pancreatitis in 70 percent, and liver damage in 25 percent. There has been no correlation between the specific clinical syndromes and the pathologic changes. A pancreatic evocative test, using morphine-neostigmine or secretin-CCK, has been used. Elevation of at least one serum pancreatic enzyme level by a factor of four over the normal level, coupled with reproduction of the patient's pain, is considered a positive test result. The efficacy of this test has been disputed. Since the majority of patients with papillitis have irreversible lesions, sphincteroplasty is generally employed.

TUMORS

Carcinoma of the Gallbladder

Carcinoma of the gallbladder accounts for 2 to 4 percent of gastrointestinal malignancies. Its occurrence in random autopsy series is about 0.4 percent, and approximately 1 percent of patients undergoing biliary tract operations have carcinoma either as an anticipated diagnosis or found incidentally.

Etiology

Approximately 90 percent of patients with carcinoma of the gallbladder have cholelithiasis, but the pathogenesis has not been defined. There is also an association with polypoid lesions of the gallbladder. Areas of dysplasia have been noted in juxtaposition to larger (greater than 2.5 cm) stones and in adenomas. Malignant changes have been noted more frequently in polypoid lesions greater than 10 mm. The calcified "porcelain" gallbladder is associated with a 20 percent incidence of gallbladder carcinoma.

Pathology

Approximately 80 percent of the tumors are adenocarcinomas (75 percent of these are scirrhous, 15 percent polypoid, and 10 percent mucoid). Squamous carcinomas, adenoacanthomas, and melanomas occur rarely. The routes of metastasis include spread along the lymphatics to the choledochal, peripancreatic, and periduodenal nodes. There is often localized invasion of vessels within the wall of the gallbladder, and the tumor frequently extends transmurally into the parenchyma of the liver. When metastases are present, the liver is involved in two-thirds of patients, the regional lymph nodes in about one-half, and the omentum, duodenum, colon, or porta hepatis in about one-fourth. Early reports suggest more frequent and rapid recurrences of carcinomas of the gallbladder after laparoscopic cholecystectomy. By 1995, 15 cases of trocar-site metastases from unsuspected gallbladder carcinoma following laparoscopic cholecystectomy were reported.

Clinical Manifestations

Signs and symptoms of carcinoma of the gallbladder are generally indistinguishable from those associated with cholecystitis and cholelithiasis. These include abdominal discomfort, right upper quadrant pain, nausea, vomiting, and weight loss. Half the patients are jaundiced, and two-thirds of those with clinical manifestations have a palpable mass. Laboratory findings are not diagnostic. Ultrasound or CT scan may suggest the diagnosis.

Treatment

Most long-term survivors are patients who underwent cholecystectomy for cholelithiasis and in whom the malignancy was an incidental finding. The management of these patients is controversial. There is some suggestion that T2 or more advanced tumors have a better prognosis if a radical second procedure, which includes lymphadenectomy and partial hepatic resection for lesions located adjacent to the liver, is performed. For lesions that are apparent at operation, removal of the hepatoduodenal nodes, resection of segment IV/V or extended right hepatectomy and, in some cases, pancreaticoduodenectomy has been reported to improve survival. By contrast, other reports have indicated that there has been no improvement associated with these procedures. Some groups have reported that adjuvant radiation therapy or chemotherapy improves survival.

Prognosis

Large cumulative series report 5-year survival rates of 5 percent. The overwhelming majority of survivors are in the group that had incidentally diagnosed tumors. T1 lesions have a 5-year survival rate of approximately 100 percent. T2 lesions have a survival rate of 40 percent when subjected to the more radical operations. In some series, no difference was noted when node-negative and node-positive patients were compared.

Bile Duct Carcinoma

Pathology

The autopsy incidence of bile duct carcinoma is about 0.3 percent. Unlike gallbladder carcinomas, bile duct tumors occur more frequently in men. There is no evidence that bile duct stones have a role, and the relationship between the tumors and sclerosing cholangitis remains ill-defined. Approximately two-thirds of the lesions are located in the proximal ducts, often at the confluence of the right and left main hepatic ducts (Klatskin tumors). The tumors are generally small but involve the whole thickness of the duct, growing in a scirrhous concentric manner and resulting in ductal obstruction. The proximal lesions often extend into the hepatic parenchyma. Rarely, the ductal tumors are polypoid tumors, which are associated with a more favorable prognosis, as is the case with carcinomas of the ampulla of Vater.

Ductal lesions are cholangiocarcinomas of the adenocarcinoma type. Most tumors are well differentiated and associated with a marked fibrous reaction. Perineural involvement is common. Intraoperative frozen-section diagnosis is often difficult. The liver and regional lymph nodes are the most frequent sites of metastasis. The incidence of metastasis at operation is 50 percent. In some cases multicentric ductal tumors have been reported.

Clinical Manifestations

Characteristically, patients present with the recent onset of jaundice, acholic stools, and dark urine. The jaundice is often preceded by pruritus. Almost all patients have had significant weight loss associated with loss of appetite. Half the patients have abdominal pain; cholangitis may result from the obstruction. The gallbladder is palpable in one-third of the patients who have distal lesions and is not felt with proximal tumors.

The laboratory findings are compatible with the diagnosis of obstructive jaundice with elevation of the bilirubin and alkaline phosphatase and mild increase of the transaminases. Increased level of carcinoembryonic antigen (CEA) can be detected in the bile. Ultrasound scanning demonstrates intrahepatic ductal dilatation and distention of the extrahepatic ducts proximal to the point of obstruction. CT scanning will also define the extent and location of ductal dilatation; it rarely demonstrates the tumor itself. Precise demonstration of the site of obstruction is achieved by *PTC* or *ERCP*. In the face of isolated intrahepatic ductal dilatation, the former is preferable, and when there is evidence of distention of the gallbladder or extrahepatic ducts, ERCP is more rewarding (Fig. [29-22](#)).

Treatment

Treatment is directed at resecting the tumor, if possible, or palliation by relieving the obstruction. Cure can be achieved only by surgical removal of the lesion, while palliation can be effected by operation, radiologic intervention, or endoscopic decompression. Curative resection generally entails removal of the common duct and the common hepatic duct up to and sometimes including the confluence of the right and left hepatic ducts, followed by anastomosis of the proximal dilated system to a Roux-en-Y limb of small intestine (Fig. [29-23](#)). The resectability of proximal tumors is about 20 percent, and the cure rate remains under 15 percent. If a proximal lesion extends into the liver parenchyma, varying amounts of the liver are removed en bloc, and proximal intrahepatic ducts are anastomosed to the intestine (Fig. [29-24](#)). Orthotopic liver transplants have been performed for intrahepatic tumors with some long-term survivors. The cure of distal bile duct tumors has been improved by radical lymphadenectomy and pancreaticoduodenectomy (Whipple procedure).

Surgical palliation is performed by anastomosing the dilated ductal system proximal to the point of obstruction to the limb of intestine. In more proximal lesions, this can be achieved by using the extrahepatic portion of the left main hepatic duct (Fig. [29-25](#)). Transection of the liver to the left of the falciform ligament and anastomosing the intestine to the dilated hepatic duct (Longmire procedure) rarely provides long-term relief of jaundice. Using *PTC* or *ERCP*, a stent can be passed through the tumor to provide drainage of the dilated ducts. These require frequent changes. Effort should be directed to providing drainage into the intestine rather than externally because external drainage of bile prevents an enterohepatic circulation and is accompanied by loss of appetite. There have been conflicting reports regarding the efficacy of adjuvant radiotherapy and chemotherapy for either cure or palliation.

OPERATIONS OF THE BILIARY TRACT

Perioperative Considerations

Prophylactic antibiotics are not indicated for patients undergoing elective cholecystectomy unless there are specific risk factors. These include jaundice, common duct stones, diabetes, and age greater than 65 years. Interventional procedures such as *PTC* or *ERCP*, especially in patients with biliary tract obstruction, should be covered with prophylactic antibiotic therapy. The antibiotic usually is selected with the assumption that the most likely involved organisms are *E. coli*, *Klebsiella* species, and enterococci. A second-generation cephalosporin is appropriate. The drug is administered before the operation or intervention, and two subsequent doses are given at 6-h intervals.

Preoperative decompression of the proximal distended ducts in patients with obstructive jaundice does not significantly improve the outcome and has been associated with an increased incidence of complications. Short-term drainage may be indicated as a bridge to an operation in a patient with cholangitis and sepsis. The preoperative placement of catheters transhepatically may facilitate dissection of proximal tumors, and they can be left in place as stents that traverse anastomoses.

Cholecystostomy

Cholecystostomy accomplishes decompression and drainage of the distended, hydropic, or purulent gallbladder. It is particularly applicable if the patient's general condition is such that it precludes prolonged anesthesia, since the operation may be performed under local anesthesia. It is also performed in cases in which marked inflammatory reaction obscures the anatomic relation of critical structures. Cholecystostomy may be a definitive procedure, particularly if a postoperative tube cholangiogram is normal.

Technique

(Fig. [29-26](#)). A circumferential purse-string suture is placed in the fundus of the gallbladder, and a small incision is made through the serosa within the suture. A trocar is inserted into the lumen of the gallbladder, which is then decompressed. After the gallbladder has been emptied, a stone forceps may be introduced to the junction of the ampulla and cystic duct, and obstructing calculi may be removed. A mushroom or Foley catheter is inserted into the lumen of the gallbladder, and a second purse-string suture is placed concentrically to the first one. The sutures are tied, inverting the serosa. Unless a small, oblique incision was used initially, the drainage tube should be brought out through a stab wound.

If the fundus of the gallbladder is necrotic, the gangrenous portion should be excised and the remainder of the gallbladder closed around the catheter, using purse-string sutures.

Open Cholecystectomy

A principal aim of open cholecystectomy is to avoid injury to the common duct close to its junction with the common bile duct to obviate a long cystic duct remnant. A more conservative approach toward elective cholecystectomy is indicated for cirrhotic patients. If an operation is performed, increased bleeding should be anticipated; extensive intrahepatic dissection should be avoided. Intraoperative infusion of vasopressin and an antifibrinolytic agent should be considered.

Technique

(Fig. 29-27). The gallbladder may be approached through an oblique right upper quadrant incision (Kocher or Courvoisier), through a vertical right paramedian incision, or through the upper midline. There are frequently adhesions between the gallbladder, particularly the ampulla, and the duodenum and colon. These should be lysed by sharp dissection. By applying traction laterally to the ampulla and retracting the duodenum medially, the veil of peritoneum running from ampulla to hepatoduodenal ligament may be accentuated and incised. The cystic duct is identified and a silk ligature passed around it. Traction is applied to the ligature to prevent passage of a stone down the cystic duct during dissection of the gallbladder. Dissection is continued craniad in this peritoneal fold, and the cystic artery is identified. The course of this artery to the gallbladder should be demonstrated to avoid ligating the right hepatic artery. The cystic artery should be doubly ligated and transected. If bleeding occurs from the cystic artery, it is best controlled by applying pressure on the hepatic artery within the hepatoduodenal ligament. The artery is compressed between the index finger, which is inserted into the foramen of Winslow, and the thumb anteriorly. The peritoneum overlying the gallbladder is then incised close to the liver, and dissection is begun from the fundus of the gallbladder down to an ultimate pedicle of cystic duct. During this dissection, blood vessels coursing from the liver may require ligation, and the gallbladder bed should be inspected for large draining ducts, which should also be ligated. Attention is then directed toward visualization of the junction of the cystic duct and the common duct. The cystic duct is transected and ligated 3 to 5 mm from the common bile duct. It is not necessary to close the bed of the gallbladder. A drain may be brought out from the hepatorenal pouch, which is the most dependent portion of the upper abdomen with the patient in the supine position, via a separate stab wound if there is any concern that blood will accumulate or if there is marked pericholecystic inflammation and edema. Several series have shown that in the absence of specific indications, drainage is not required.

This method is directed at facilitating demonstration of the junction between the cystic duct and the common bile duct. The gallbladder may also be removed in the so-called retrograde fashion, in which the cystic duct is ligated close to the junction with the common duct as the initial part of the procedure. Then, after the cystic duct and artery have been transected, dissection is begun from the cystic duct and continued outward toward the fundus (Fig. 29-28).

Laparoscopic Cholecystectomy

The application of minimally invasive surgical techniques to removal of the gallbladder has emerged as the preferred way of treating symptomatic gallstone disease. Although a subcostal incision is avoided, these operations should be viewed with the same respect for surgical principles as are the open procedures. Trocars are introduced after the instillation of a pneumoperitoneum, and the gallbladder and liver can be retracted so as to provide optimal visualization. It is essential that the ductal structures be carefully identified before division. Because of the nature of this procedure, bleeding is a particularly worrisome problem and should be guarded against. This procedure begins by retracting the gallbladder up over the edge of the liver so as to facilitate exposure of the triangle of Calot (Fig. 29-29). The cystic duct and artery are then identified, and ductal anatomy is confirmed. Operative cholangiography can be used to selectively define anatomy as well as to search for common bile duct stones. The cystic duct is then divided. The gallbladder is dissected from this area up toward the fundus. Before complete separation of the gallbladder from the liver bed, the gallbladder fossa should be carefully inspected for bleeding. After this has been managed, the gallbladder is carefully withdrawn through one of the ports and the pneumoperitoneum released. As with open cholecystectomy, bile duct injury and hemorrhage can and should be avoided.

Operations of the Extrahepatic Bile Duct

Exploration for Choledocholithiasis

(Fig. 29-30). Exploration for choledocholithiasis is indicated when ductal stones have been identified by palpation or cholangiography or when the cause of obstruction has not been defined. The procedure is often facilitated by performing a Kocher maneuver (freeing the lateral and posterior attachments of the second portion of the duodenum). Common duct dissection can be facilitated by traction on the cystic duct. After the anterior aspect of the duct has been visualized, aspiration of bile with a fine needle provides confirmation. After a fixation suture has been placed laterally and medially and traction applied, a vertical incision is made between these through the anterior wall. A choledochoscope can be introduced at this time to visualize the lumen and determine whether any stones are present.

Ductal stones can be removed by irrigation, balloon-tipped catheters, scoops, or forceps. These procedures should be applied initially to the distal common duct and subsequently proximally to each of the main hepatic ducts. After the stones have been removed, a No. 3 Bakes dilator is passed into the duodenum and the tip is visualized through the anterior wall. When the duct is clear of stones, a T tube is inserted into the duct. The limbs of the T tube should be short so that the distal limb does not pass through the ampulla, and the proximal limb does not obstruct either of the hepatic ducts. The incision in the duct is closed around the long limb of the tube, and saline is injected to demonstrate the absence of leaks. A completion cholangiogram confirms the absence of stones and the passage of dye into the duodenum. The latter can be facilitated by the injection of glucagon. The T tube should be brought out through a stab wound. A postoperative cholangiogram is performed about 1 week postoperatively, and if absence of stones and clear passage of opaque medium into the duodenum are demonstrated, the tube is removed.

The common duct can be explored and cleared of stones laparoscopically (see Chap. 44).

Transduodenal Sphincteroplasty

(Fig. 29-31). Division of the sphincter of Oddi is occasionally indicated for a stone impacted at the ampulla, a stricture, or a functional disorder. The procedure is also applicable for multiple or recurrent ductal stones. A generous Kocher maneuver should be performed initially, followed by a longitudinal anterior duodenotomy. The passage of a Bakes dilator or catheter down the duct facilitates identification of the sphincter, which should be incised at the 11-o'clock position to avoid damaging the pancreatic duct. A pie-shaped segment is removed from the sphincter and the duodenal and ductal mucosa are coapted with fine absorbable sutures. A T tube is inserted into the common duct, and the duodenotomy is closed either longitudinally or horizontally, with care being taken not to compromise the lumen.

Choledochoduodenostomy

(Fig. 29-32). This procedure is applicable to patients with multiple common duct stones to obviate the use of a T tube. The sine qua non for the performance of this procedure is a dilated common duct. A Kocher maneuver is performed to relieve any tension on the anastomosis. The distal common duct is incised longitudinally, as is the anterior portion of the duodenum, and a one-layer, large-diameter anastomosis is made.

Choledochojejunostomy (Roux-en-Y)

(see Fig. 29-23). Although an occasional transection of the common duct with a sharp instrument can be repaired by end-to-end anastomosis over a T tube, most ductal injuries and strictures are preferably repaired with choledochojejunostomy or, more often, a hepaticojejunostomy, using a 45-cm defunctionalized Roux-en-Y limb of jejunum to obviate reflux of intestinal contents into the biliary tree. A precise mucosa-to-mucosa anastomosis should be performed using the antimesenteric side of the jejunum with interrupted absorbable sutures. In most instances, a stent is not necessary.

CHAPTER 30 - Pancreas

Howard A. Reber

ANATOMY

The pancreas lies almost transversely in the retroperitoneum, behind the stomach, between the duodenum on the right and the spleen on the left. It is arbitrarily divided into a head with its uncinat process, a neck, a body, and a tail. The *head* of the pancreas lies at the level of the second lumbar vertebra near the midline. The posterior surface of the head rests next to the medial border of the right kidney, on the right renal vessels, and the inferior vena cava (Fig. 30-1). The *uncinate process* extends posterior and to the left of the head of the gland, behind the portal vein and the superior mesenteric vessels. The *neck* of the pancreas, which joins the head with the body of the gland, is anterior to the superior mesenteric vessels and portal vein.

The portal vein is formed by the confluence of the superior mesenteric and splenic veins. There are usually no tributaries between the anterior surface of the superior mesenteric and portal veins and the posterior surface of the neck. Thus, during resection of the head of the pancreas, the two can be separated safely by blunt dissection, and the neck may be transected.

The *body* of the pancreas lies at the level of the first lumbar vertebra and begins at the left border of the superior mesenteric vein. The posterior surface is in contact with the aorta, the left adrenal gland and kidney, the left renal vessels, and the splenic artery and vein, which run along its superior border. The *tail* of the pancreas lies at the level of the twelfth thoracic vertebra, and its tip usually reaches the hilus of the spleen.

Bile and Pancreatic Ducts

The common bile duct passes posterior to the head of the pancreas on its way to the duodenum and is partially or completely covered by the pancreas in over 70 percent of cases. The duct enters the duodenal wall and runs within it for about 1.5 cm. The main pancreatic duct (*Wirsung*) arises in the tail of the pancreas and enters the duodenal wall caudal to the bile duct. The two ducts usually lie side by side for several millimeters before they join as a common channel. The single pancreaticobiliary duct enters the duodenal lumen on the papilla of Vater, located on the posteromedial wall of the second portion of the duodenum, at the level of the second or third lumbar vertebra. The *ampulla of Vater* is a dilatation of the common pancreaticobiliary channel within the papilla and is distal to the junction of the two ducts. An ampulla is present in about 90 percent of cases, and it usually is quite short (5 mm or less). In 10 percent of people, the individual ducts empty separately into the duodenum, and there is no ampulla. When a common channel exists, it may be important in the pathogenesis of gallstone pancreatitis because a calculus could lodge in the ampulla and obstruct the ducts.

The accessory pancreatic duct (*Santorini*) usually drains the anterior and superior portions of the head of the pancreas. In 60 percent of cases, it enters the duodenum about 2 cm cranial and slightly anterior to the papilla of Vater, through the minor papilla. Because the accessory duct often communicates with the duct of Wirsung, drainage can occur through either the minor or major papilla. The minor papilla is always found distal to the point where the gastroduodenal artery crosses posterior to the duodenum. To avoid injury to the accessory pancreatic duct during gastrectomy, dissection of the duodenum should not progress past the artery.

Numerous variations of ductal anatomy occur, but only *pancreas divisum*, which occurs in up to 10 percent of normal people, occasionally may cause disease. Pancreas divisum occurs when the embryologic dorsal and ventral pancreatic ducts do not fuse, and the main pancreatic duct empties through the minor papilla (Fig. 30-2). In this case, only the duct draining the uncinat process empties through the papilla of Vater. In some people with pancreas divisum, pancreatitis may occur as a result of relative obstruction to the outflow of pancreatic juice through a minor papilla not normally required to handle such a large volume.

In adults, the main pancreatic duct is about 3 to 4 mm in diameter in the head of the pancreas, 2 to 3 mm in the body, and 1 to 2 mm in the tail. Some dilatation occurs normally with aging, and a diameter of 5 to 6 mm may be normal in patients age 70. Nevertheless, ductal dilatation is more commonly an indication of disease and implies ductal obstruction.

Blood Supply (Fig. 30-3)

The blood supply to the head of the gland comes from the superior pancreaticoduodenal *artery*, which arises from the gastroduodenal artery and divides into anterior and posterior branches. These form collaterals with branches of the inferior pancreaticoduodenal artery, which arise from the superior mesenteric artery. The dorsal pancreatic artery usually arises from the proximal 2 cm of the splenic artery and, after supplying some branches to the head, passes to the left to supply the body and tail of the gland. There it is called the transverse pancreatic artery. Numerous branches from the splenic artery anastomose with the transverse artery and also supply the body and tail. Variations of the arterial supply are common, although most are not important to the surgeon. In the most common significant variation (25 percent of cases), the right hepatic artery originates from the superior mesenteric instead of from the common hepatic artery. The right hepatic artery may then pass through the substance of the pancreas, usually the uncinat process, where it can be injured during pancreatic resection. It continues posterior to the portal vein and often along the right side of the common bile duct. Some surgeons perform preoperative arteriography before pancreatic resection to forewarn themselves of such anomalies.

The head of the pancreas is drained by *veins* that parallel the arteries. The superior pancreaticoduodenal, right gastroepiploic, and a colic vein join to form a major gastrocolic trunk on the anterior surface of the head. This trunk empties into the superior mesenteric vein just before it passes under the neck of the pancreas and may be a useful anatomic landmark to identify the vessel during pancreatic surgery. The trunk may be ligated without consequence when a pancreatectomy is performed. Another fairly constant unnamed vein drains the posterior portion of the head of the pancreas and empties into the anterior aspect or right side of the portal vein at the superior margin of the gland. Additional delicate veins also empty into the right side of the superior mesenteric and portal veins directly from the pancreas. These can only be seen during resection of the head of the gland and must be ligated carefully. Venous drainage of the body and tail of the pancreas is directly to the splenic vein and through the inferior pancreatic vein to the inferior or superior mesenteric veins.

Lymphatics

Lymphatic drainage of the pancreas is rich and, in general, follows venous drainage in all directions. The *superior* nodes, located along the superior border of the pancreas, collect lymph from the anterior and superior upper half of the gland. The *inferior* nodes, along the inferior margin of the head and body, drain the anterior and posterior lower half. *Anterior* nodes drain the anterior surface of the head of the pancreas. They are located beneath the pylorus, anteriorly in the groove between the pancreas and duodenum, and the root of the mesentery of the transverse colon. *Posterior* nodes drain the posterior surface of the head. They are found posteriorly in the groove between the pancreas and duodenum, along the common bile duct, the aorta as high as the origin of the celiac axis artery, and at the origin of the superior mesenteric artery. *Splenic* nodes drain the tail of the pancreas. Lymphatic drainage is important in regard to the spread of pancreatic cancer, which arises most commonly in the head of the gland. Most patients with cancer already have nodal metastases at the time of diagnosis, usually involving several of the groups mentioned, except for the splenic. Any curative procedure must eradicate the involved nodes as well as the primary tumor.

Nerves

The pancreas receives sympathetic fibers by way of the splanchnic nerves and parasympathetic innervation by way of the vagus nerves (celiac division of the posterior vagus trunk). In general, the nerves follow the blood vessels and pancreatic ducts as they travel to the pancreatic acini. The splanchnic nerves also carry visceral afferent pain fibers that pass through the celiac plexus and ganglia. It is not known whether afferent fibers of the vagus are involved in pancreatic pain. Because pancreatic cancer and chronic pancreatitis are often accompanied by significant pain, efforts to relieve it sometimes include destruction of the celiac ganglia, with variable success.

PHYSIOLOGY

Exocrine Function

The pancreas secretes 1 to 2 L/day of a clear, watery, alkaline (pH 8.0-8.3) liquid that contains more than 20 different digestive enzymes. This electrolyte-rich juice is isosmotic with plasma and is secreted chiefly by the centroacinar cells and those cells which make up the walls of the smaller pancreatic ducts in response to secretin. The principal cations of this juice are sodium and potassium, which are always present in concentrations similar to those found in plasma (the sum of the two is approximately 165 mmol/L). The concentrations of the principal anions (bicarbonate and chloride) vary. When the stimulus to secrete is minimal, the chloride concentration is high (e.g., 110 mmol/L) and that of bicarbonate low (e.g., 50 mmol/L). When the secretory stimulus is maximal, the bicarbonate concentration rises (to approximately 140 mmol/L), and the chloride concentration falls (to ~20 mmol/L). The secretion of bicarbonate at such high concentrations requires active transport. In part, the reciprocal relationship of the two anions is achieved by the passive exchange of intraductal bicarbonate for interstitial chloride. This exchange occurs as the juice flows through the larger pancreatic ducts on its way to the duodenum. At slower flow rates, there is more opportunity for exchange to take place, and more bicarbonate is lost. The alkaline pancreatic juice helps to neutralize gastric acid in the duodenum and provides the optimal pH for the activity of the pancreatic digestive enzymes.

The digestive enzymes are synthesized and stored in the pancreatic acinar cells and are released in response to *cholecystokinin (CCK)* and vagal cholinergic stimulation. Pancreatic enzymes are proteolytic (e.g., trypsin, chymotrypsin, carboxypeptidase, ribonuclease, deoxyribonuclease, and elastase), lipolytic (lipase, colipase, and phospholipase A₂), and amylolytic (amylase). Although lipase and amylase are secreted in their active forms, the proteolytic enzymes and phospholipase A₂ are secreted as inactive “zymogens.” Activation of trypsinogen to trypsin occurs when the zymogen is exposed to the duodenal enzyme enterokinase. Trypsin then converts the other zymogens to their active forms. In the intestine, the proteolytic enzymes digest proteins into peptides, lipase breaks fats into glycerol and fatty acids, phospholipase A₂ catalyzes the conversion of biliary lecithin to lysolecithin, and amylase converts starch to disaccharides and dextrins.

Enzyme synthesis occurs on polysomes attached to the rough endoplasmic reticulum, following which the newly formed enzymes migrate through various subcellular compartments and end up as zymogen granules, which are stored. Lysosomal enzymes, which degrade unneeded intracellular constituents, are also synthesized by a similar process. They are segregated from the digestive enzymes and stored separately in other subcellular structures called *lysosomes*. Secretory stimulation results in fusion of the zymogen granule membrane with the apical (luminal) membrane of the acinar cell, and the enzymes are discharged into the duct. There is experimental evidence that the lysosomal enzymes (e.g., cathepsin B) could activate trypsinogen inside the cell if the two ever came into contact. Thus segregation of the lysosomal enzymes from the inactive digestive enzymes may be important to prevent the cellular injury that might follow enzyme activation. Such abnormal intracellular enzyme activation seems to be the cause of pancreatitis in several experimental animal models, although it is unknown whether this can occur in human beings.

Regulation of Secretion

Pancreatic secretion is under complex neurohormonal control. Ductal fluid and bicarbonate are secreted chiefly in response to the hormone secretin, which is released from the mucosa of the duodenum and proximal small bowel in response to acid in the bowel lumen. Bicarbonate secretion is triggered when the pH of the duodenal lumen falls below 4.5.

Acinar enzyme secretion is stimulated both by vagal cholinergic discharge and by the hormone CCK. CCK is released from the proximal small bowel by fatty acids, oligopeptides, and some amino acids.

Pancreatic secretion has been divided artificially into cephalic, gastric, and intestinal phases. The *cephalic* phase begins with the sight, smell, and anticipation of food. Although mostly enzymes are secreted, some bicarbonate is also produced. Enzymes are released by vagal cholinergic pathways; *vasoactive intestinal polypeptide (VIP)* , which is structurally related to secretin, may cause the bicarbonate response. The *gastric* phase begins when food enters the stomach. Gastric distention, as well as the exposure of the stomach mucosa to nutrients (e.g., peptides), causes primarily an enzyme-rich pancreatic secretion. This effect is blocked by atropine or truncal vagotomy and probably involves a gastropancreatic vagovagal reflex. The *intestinal* phase begins when the chyme empties into the duodenum. This phase is important for the maintenance of enzyme output as gastric distention diminishes. Gastric acid is also responsible for pancreatic bicarbonate secretion. When the buffering effect of the food is lost, the duodenal pH begins to fall, and secretin is released. The mechanisms responsible for this phase are both neural and hormonal, involving both stimulatory (e.g., secretin, CCK, gastrin-releasing peptide [GRP], bombesin, neurotensin, VIP) and inhibitory (e.g., *pancreatic polypeptide [PP]* , calcitonin-gene-related peptide [CGRP], peptide YY [PYY], neuropeptide Y [NPY], somatostatin) effects on the pancreas. In addition to these inhibitory effects, there is also evidence for a negative feedback mechanism for pancreatic secretion. The presence of pancreatic proteases and bile within the duodenum appears to inhibit the release of CCK. Thus pancreaticobiliary diversion from the intestine is characterized by elevated plasma CCK levels and stimulation of pancreatic secretion. This may have some clinical relevance in patients with chronic pancreatitis who are sometimes treated with large amounts of oral pancreatic enzymes in an effort to inhibit pancreatic secretion.

The quantity of pancreatic enzymes that is secreted in response to a meal is almost 90 percent in excess of what is actually needed for normal digestion. Thus patients develop symptoms of malabsorption only when secretion falls to about 10 percent or less of normal. Pancreatic insufficiency can result from blockage of the main pancreatic duct, which prevents the enzymes from entering the intestine (e.g., pancreatic cancer), from destruction of the pancreatic secretory parenchyma (e.g., chronic pancreatitis), and from surgical procedures that remove the pancreas or result in poor mixing of the gastric chyme with the pancreatic secretions (e.g., partial gastrectomy with gastrojejunostomy). Pancreatic insufficiency affects fat absorption much more than protein or carbohydrate absorption because protein digestion is aided by gastric pepsin and small bowel brush border enzymes and carbohydrate digestion by salivary amylase. Moreover, fat malabsorption causes troublesome diarrhea, while malabsorption of protein and carbohydrate is generally asymptomatic. On a diet containing 100 g of fat a day, normal subjects excrete 5 to 7 g/day of fat in the feces (i.e., 5 to 7 percent fat malabsorption is normal). A total pancreatectomy causes 70 percent fat malabsorption; partial pancreatic resections may not cause any malabsorption, providing that the pancreatic remnant is normal. Vitamin malabsorption is rarely a problem, since water-soluble B vitamins are absorbed throughout the small intestine, and fat-soluble vitamins do not require pancreatic enzymes for absorption. Vitamin B₁₂malabsorption occurs in some patients but is rarely a significant problem. Therefore, vitamin B₁₂ replacement is unnecessary.

Because complete correction of malabsorption is not possible, the goal of treatment of pancreatic exocrine insufficiency is to eliminate the diarrhea that the steatorrhea provokes. At least 5 to 10 percent of the normal amount of enzymes must be delivered to the duodenum at the same time as the gastric chyme in order for this goal to be achieved. This represents about 30,000 units of lipase for each meal, which can be given either throughout the meal or as a single dose at the beginning. A number of different enzyme preparations are available; the least expensive and most effective one should be chosen. Because lipase is inactivated below pH 4.0 and gastroduodenal pH may fall below this level, enzyme therapy may be ineffective if gastric acidity is high.

Patients should be instructed to begin a diet consisting of 4 meals per day and a minimum of 3000 kcal/day. The diet should contain at least 400 g of carbohydrate, 100 to 150 g of protein, and moderate amounts of fat (25 g/meal). If the enzymes eliminate the diarrhea, the fat in the diet can be liberalized until symptoms recur and then maintained just below that level. If the enzymes do not eliminate the symptoms, fat should be restricted further to 50 to 75 g/day. If the diarrhea still persists, H₂ blockers should be added to decrease gastric acidity. If this is still not effective, the H₂ blockers should be stopped, and an enteric-coated enzyme preparation may be tried. In this form, these enzymes are coated with a protective polymer that resists acid and dissolves only above pH 5.0. Thus lipase is more likely to be delivered to the duodenum in its active form.

Endocrine Function

The islets of Langerhans constitute 1 to 2 percent of the pancreatic mass, but they receive about 20 percent of the total pancreatic blood flow. They are dispersed throughout the pancreatic parenchyma, but some of the hormone-secreting cells are concentrated in specific areas. The insulin- secreting cells are evenly distributed and are usually localized in the core of each islet, where they form 60 to 80 percent of the cells. They are surrounded peripherally by a mantle of other cells that are specialized to secrete glucagon (15 to 20 percent of the islet cells), somatostatin (5 to 10 percent), or pancreatic polypeptide (15 to 20 percent). These last cells are found chiefly in the islets of the head of the pancreas. The glucagon cells occur chiefly in the body and tail of the gland.

Insulin

Insulin is a 51-amino-acid peptide (MW 5734 Da) that consists of two polypeptide chains. It is synthesized by the beta cells by means of a precursor, proinsulin. Insulin lowers blood glucose concentration by enhancing glucose uptake by all the body cells, promoting glycogenesis and inhibiting gluconeogenesis. It also stimulates lipogenesis, inhibits lipolysis, and enhances protein synthesis. Although the factors that govern insulin secretion are multiple and complex, the most important is an elevation of the extracellular blood glucose concentration. Other substrates, including amino acids (e.g., arginine) and fatty acids, also stimulate insulin release. The primary sites of action of the hormone are the liver, muscle, and fat cells.

Glucagon

Glucagon is a single-chain 29-amino-acid peptide (MW 3483 Da) formed in the alpha cells of the islets. It increases blood glucose by causing hepatic glycogenolysis and gluconeogenesis. Thus the effects of glucagon counterbalance those of insulin. Glucagon also relaxes and dilates smooth muscle such as the stomach, duodenum, and sphincter of Oddi. The hormone is released by a low blood glucose concentration, amino acids, catecholamines (e.g., during stress), sympathetic nervous discharge, and CCK. Insulin and hyperglycemia suppress glucagon release.

Somatostatin

Somatostatin is a tetradecapeptide (MW 1637 Da) arising in the delta cells of the islets. Both oral and intravenous nutrients stimulate somatostatin secretion, and both neural and hormonal mechanisms may be involved. The hormone inhibits the release of insulin, and in turn, its own release is inhibited by insulin. It may act as an important local paracrine regulator of glucose homeostasis. Somatostatin has a wide spectrum of activities, most of which are inhibitory. These include suppression of the release of gastrin, secretin, VIP, PP, gastric acid, pepsin, pancreatic enzymes, and glucagon. Somatostatin also inhibits intestinal, biliary, and gastric motility.

Pancreatic Polypeptide

Pancreatic polypeptide (PP) is a 36-amino-acid peptide (MW 4200 Da) arising in the PP cells. Orally ingested protein, vagal cholinergic stimulation, and hypoglycemia are all potent stimulants for the release of PP. PP itself inhibits pancreatic exocrine secretion.

The endocrine pancreas influences the synthesis and secretion of pancreatic enzymes from the exocrine parenchyma. At least in part, this is the result of an *islet-acinar portal system* in which the blood that first perfuses the islets collects into a vascular network that surrounds the acini before draining out of the gland. Thus the acini are exposed to higher concentrations of the islet hormones than are the peripheral tissues of the body. This may be important clinically. For example, insulin activates amylase gene expression and amylase synthesis in acinar cells and regulates their sensitivity to CCK. This could explain why about 40 percent of patients with type I diabetes have some impairment in exocrine pancreatic function. Up to 70 percent of patients with chronic pancreatitis also develop diabetes.

CONGENITAL ANOMALIES

Annular Pancreas

Annular pancreas is formed by a thin band of normal pancreatic tissue that completely encircles the second portion of the duodenum and is continuous with the head of the pancreas anteriorly and posteriorly. It is probably the result of abnormal rotation and fusion of the ventral pancreatic primordium during the second month of fetal life. Forty percent of infants with annular pancreas have associated duodenal stenosis or atresia. Symptoms of duodenal obstruction (gastric distention and vomiting) occur in about one- third of cases in the first week of life and about one-half of cases in the first year. The rest are asymptomatic until adulthood, when abdominal pain, nausea, and vomiting may occur. Some cases, however, probably never cause problems and remain undiagnosed. There is no gender predilection in infancy, although adult patients are more often males. The diagnosis may be suspected when an upper gastrointestinal series shows obstruction of the second portion of the duodenum, but it can only be confirmed by direct inspection at surgery. In adults, duodenal narrowing from chronic ulcer disease also must be considered in the differential diagnosis. The treatment is duodenojejunostomy or gastrojejunostomy, either of which bypasses the obstruction. The obstructing pancreatic ring must not be simply divided because this may not relieve the obstruction, and pancreatic fistula can result.

Pancreatic Cysts

Congenital cysts of the pancreas are rare but are increasingly likely to be diagnosed at any age on abdominal CT scans for unrelated disease. If they are single, they may require surgery to distinguish them from a pseudocyst or a cystic neoplasm. Congenital cysts have an epithelial lining; pseudocysts do not. The diagnosis of benign polycystic disease of the pancreas may be possible from the CT image of multiple cysts of various sizes involving the entire pancreas, especially when cysts are also present in other organs (e.g., kidneys, liver, cerebellum, as in von Hippel-Lindau disease). In the absence of symptoms or serious concern that the cysts are neoplastic, surgery may be unnecessary.

Ectopic Pancreas

Ectopic pancreas usually occurs in the stomach or duodenum but has been found in Meckel's diverticulum, the colon, the appendix, and elsewhere. The tissue usually functions and contains islets in about one-third of cases. The condition is usually asymptomatic. However, if symptoms occur, they may simulate duodenal ulcer, appendicitis, intestinal obstruction, etc., depending on the site. Treatment is surgical, and the diagnosis may be suspected from the characteristic gross appearance. The lesions are submucosal, firm, yellowish nodules with a visible central umbilication.

PANCREATITIS

Acute pancreatitis is a nonbacterial inflammation of the pancreas caused by the activation, interstitial liberation, and the digestion of the gland by its own enzymes. It is characterized clinically by acute abdominal pain, elevated concentrations of pancreatic enzymes in blood, and an increase in the amount of pancreatic enzymes excreted in urine. There may be just a single episode of pancreatitis, or several episodes may recur. In the United States, the most common cause of acute pancreatitis is cholelithiasis.

During a mild attack, the morphologic changes are characterized by pancreatic and peripancreatic edema and fat necrosis, but pancreatic necrosis is absent. This is often referred to as *edematous pancreatitis*. The mild form may turn into a severe form (or the episode may be severe from the beginning). In its severe form, extensive pancreatic and

peripancreatic fat necrosis, pancreatic parenchymal necrosis, and hemorrhage into and around the pancreas are evident. This form of the disease is often referred to as *necrotizing pancreatitis*. During such an episode of acute inflammation, both the exocrine and endocrine functions of the gland are impaired for some weeks or even months. If the cause (e.g., cholelithiasis) and any complications (e.g., a pseudocyst) of the pancreatitis are eliminated, the pancreas usually returns to normal. Some scarring may persist after a severe attack, but both exocrine and endocrine functions are normal, and there is little, if any, histologic abnormality evident. Even multiple attacks of acute pancreatitis rarely lead to chronic pancreatitis.

Chronic pancreatitis is characterized clinically by recurrent, acute episodes of abdominal pain indistinguishable from those of acute pancreatitis. For several years or more, patients may be asymptomatic in between episodes that typically occur two or three times a year. In most cases the pain-free intervals shorten, and pain eventually may become constant. As the disease progresses, pancreatic function becomes impaired. The exocrine insufficiency is manifested as steatorrhea and malabsorption. The endocrine insufficiency causes diabetes, often requiring insulin for its management. An unusual form of chronic pancreatitis occurring in about 5 percent of cases is not associated with pain. The principal clinical manifestation of the disease in these patients is pancreatic functional insufficiency. In the United States, the most common cause of chronic pancreatitis is alcoholism. Morphologically, chronic pancreatitis is characterized by a permanent and usually progressive destruction of pancreatic parenchyma. The acinar cells are destroyed first, replaced by dense fibrous scar tissue. Eventually, the islet cells are also damaged by this sclerotic process. Often the main pancreatic duct is dilated, sometimes with focal areas of narrowing along its length. Intraductal protein plugs and/or calculi are common. Both acute and chronic inflammatory cells are present, as well as edema and focal necrosis. Cysts and pseudocysts occur frequently.

A distinct morphologic form of chronic pancreatitis is *obstructive chronic pancreatitis*. Here the ductal system is moderately dilated proximal to the obstruction, which is most often caused by a tumor or scar from a previous injury. In the obstructed part of the pancreas, there is uniform, diffuse atrophy and fibrosis of the acinar parenchyma. Calculi and intraductal protein plugs are unusual.

In chronic pancreatitis (unlike acute pancreatitis), the morphologic changes in the pancreas are irreversible and often progressive, even if the cause (e.g., alcoholism) is removed. This usually leads to permanent functional impairment as more and more acinar and islet cell mass is destroyed. The only exception is obstructive chronic pancreatitis. Here there does seem to be some improvement both morphologically and functionally when the obstruction is relieved.

The terms *recurrent acute* and *recurrent or relapsing chronic pancreatitis* are obsolescent. They referred to repetitive episodes of pancreatic inflammation in patients with either of the two forms of the disease.

Etiology

Gallstone pancreatitis accounts for about 40 percent of all cases of pancreatitis and about 90 percent of cases of acute pancreatitis in the United States. Eradication of the gallstone disease prevents further attacks of pancreatitis. The etiologic mechanism probably involves the transient obstruction of the pancreatic duct by a gallstone in the common bile duct at the ampulla of Vater. Gallstones are recoverable in the feces of over 90 percent of patients within 10 days of an attack, suggesting that the obstruction is brief and that most such stones pass into the duodenum. The usual age at onset is the middle to late forties, with women more commonly affected than men.

Alcoholic pancreatitis accounts for 40 percent of all cases of pancreatitis and about 75 percent of cases of chronic pancreatitis in the United States. In some cases, an episode of binge drinking may precipitate an attack typical of acute pancreatitis. This usually occurs in a patient who is a chronic alcoholic, in whom the pancreas has probably already been permanently damaged by alcohol even though other evidence of pancreatic disease is absent (e.g., pancreatic exocrine insufficiency, diabetes). In other cases, the presentation is less acute. Patients may present with chronic abdominal and/or back pain, often with steatorrhea and diabetes from pancreatic exocrine and endocrine insufficiency. Pancreatic calcifications are found in at least one-third of patients. Weight loss is common, since food often aggravates the pain and intake is voluntarily restricted. The patients may be addicted to the narcotics necessary for pain relief. The usual age at onset is the midthirties, with men more commonly affected than women.

Alcoholic pancreatitis generally is diagnosed after patients have consumed alcohol for at least 2 years and usually between 6 to 10 years. It probably makes no difference whether the ethanol is consumed as wine, beer, or spirits, but the daily consumption averages 100 to 150 g/day. There is evidence that the diet of alcoholic patients who develop pancreatitis is richer in fat and protein than the diets of other alcoholics who do not. It is estimated that about 10 to 15 percent of individuals who consume such large amounts of alcohol eventually develop pancreatitis; a similar number develop cirrhosis of the liver. The factors that govern individual susceptibility to each are unknown.

Early studies suggested that ethanol caused pancreatitis by inducing spasm of the sphincter of Oddi, thereby creating an obstruction to the outflow of pancreatic juice. Experimentally, secretion in the face of similar obstruction has caused acute pancreatitis, but this cannot be the full explanation. Ethanol is also a cellular metabolic poison, and it has deleterious effects on the synthesis and secretion of digestive enzymes by the pancreatic acinar cells. This causes an increase in the concentration of enzyme protein in pancreatic juice and the eventual precipitation of this protein in the pancreatic ducts. Calcium, normally soluble in pancreatic juice, may then precipitate within the matrix of these protein plugs. This creates multiple points of ductal obstruction randomly scattered throughout the pancreas. Further damage follows continued secretion in the face of this widespread obstruction. Ethanol also increases the permeability of the pancreatic ducts. This allows pancreatic enzymes, normally contained within the ducts, to leak out into the surrounding tissue. If the enzymes are active, damage to the pancreas results. There is recent evidence that acute ethanol ingestion markedly but transiently depresses pancreatic blood flow. Thus cellular damage could be provoked by ischemia. Table [30-1](#) lists the common causes of acute pancreatitis.

Hypercalcemic states, most commonly hyperparathyroidism, may cause acute and chronic pancreatitis. The mechanism is unclear, but hypercalcemia may favor the intraductal precipitation of calcium stones, which are seen in up to half these patients. Calcium also influences the activation of certain pancreatic enzymes and a variety of acinar cell synthetic and secretory events. Acute hypercalcemia increases the permeability of pancreatic ducts, perhaps allowing enzymes to leak from them and damage the tissue.

Hyperlipidemia, especially that associated with elevated chylomicrons and very low density lipoproteins, may be a cause of acute pancreatitis. The mechanism may involve the release by pancreatic lipase of large amounts of toxic fatty acids in the pancreatic capillary circulation. Vascular endothelial damage might cause sludging of red blood cells, stasis, and pancreatic ischemic injury and inflammation. Hyperlipidemia also can occur transiently during an attack of pancreatitis, usually in alcoholics. In such patients, it is not thought to play an etiologic role.

Hyperlipidemia as a cause of pancreatitis should be recognized for two reasons. First, because the elevated serum lipid level interferes with the chemical determination of amylase, the serum amylase level in these patients with acute pancreatitis is often reported as "normal." The appearance of a milky white (lactescent) serum in a patient with acute abdominal pain, however, should alert the clinician to the correct diagnosis. Because the lipid is not excreted in the urine, the finding of a high urinary amylase excretion may still be diagnostic in this setting. Second, dietary or pharmacologic control of the hyperlipidemia minimizes the chances of recurrent episodes of pancreatitis.

Hereditary pancreatitis is transmitted as a mendelian dominant trait. At least one form is due to a mutation in the gene for trypsinogen, which may interfere with the normal protective mechanism by which active trypsin is degraded. Trypsin could then digest the pancreas, producing pancreatitis. The condition is rare, although over 250 patients have been reported. Symptoms typical of acute pancreatitis appear in most patients between the ages of 12 and 14 years. Relentless progression of the process is usual, with recurrent attacks of acute inflammation. Eventually, many patients develop the typical manifestations of chronic pancreatitis, including calcifications (32 percent), diabetes (19 percent), and steatorrhea from exocrine insufficiency (15 percent). As in patients with chronic pancreatitis from other causes, an increased incidence of pancreatic cancer has been noted. In most of the reported cases where *endoscopic retrograde cholangiopancreatography (ERCP)* has been performed, the pancreatic ducts have been dilated.

Protein deficiency in children with severe protein-calorie malnutrition may cause kwashiorkor and a specific type of chronic pancreatitis. Treatment with adequate diet rapidly restores pancreatic function to normal, provided that parenchymal fibrosis is not too extensive. Pancreatic calcification is absent, and episodes of abdominal pain are infrequent. Another variety of chronic pancreatitis, possibly related to malnutrition, occurs only in certain tropical and subtropical countries (e.g., Nigeria). It begins in childhood and in most cases is associated with abdominal pain, pancreatic calcification, steatorrhea, and diabetes. The pancreatic ducts are usually dilated and obstructed. Adequate nutrition does not reverse the process.

Postoperative (iatrogenic) pancreatitis occurs after a variety of procedures in proximity to the pancreas, and the causes are usually obvious. They include direct injury to the gland (e.g., pancreatic biopsy, pancreatic resection) or obstruction of the pancreatic duct (e.g., the placement of a long-arm T-tube through the sphincter of Oddi into the duodenum or forceful dilation of the sphincter of Oddi to a diameter of more than 5 mm during common duct exploration). For this reason, these latter two procedures are no longer done. Pancreatitis also occasionally follows endoscopic sphincterotomy or surgical sphincteroplasty.

Sometimes the operation is distant from the pancreas, and there is no obvious explanation. For example, pancreatitis complicates up to 5 percent of cases of heart surgery that require cardiopulmonary bypass. It has been suggested that impaired pancreatic perfusion may damage the pancreas in this setting.

Pancreatitis can follow Billroth II gastrectomy if the afferent limb of the jejunum becomes obstructed. In this case, pancreatic juice and bile accumulate in the limb and may reflux into the pancreatic duct under pressure.

Drugs are an uncommon but important cause of acute pancreatitis. Those most commonly incriminated include steroids, azathioprine, 6- mercaptopurine, thiazide diuretics, furosemide, sulfonamides, tetracycline, and estrogens (which produce pancreatitis by inducing hypertriglyceridemia).

Duct obstruction of brief duration may cause acute pancreatitis, but when it is persistent over months or years, it is a recognized cause of chronic pancreatitis. Unlike other forms of chronic pancreatitis, some morphologic and functional recovery of the pancreas can occur if the obstruction is removed. Of course, when the process is advanced, significant recovery is not possible. Obstruction occurs in a variety of clinical settings.

Chronic pancreatitis has been reported in patients with severe *strictures* at the point where fusion of the ventral and dorsal pancreatic ducts occurs during fetal life. Strictures also occur in other areas of the main duct and are probably due to scarring after trauma or acute pancreatitis from any cause.

Pancreas divisum has been most commonly associated with recurrent episodes of acute pancreatitis in young adulthood, but chronic pancreatitis may occur when the outflow obstruction is severe and persistent over a period of years. In patients with acute pancreatitis and pancreas divisum, therapy directed toward relief of obstruction at the minor papilla may be effective. However, once chronic pancreatitis is established, surgical treatment should consist of pancreatic resection or drainage.

Chronic *inflammation of the papilla of Vater* with obstruction of the duct of Wirsung is rare. In most cases the inflammation is probably caused by the passage of common duct

stones through the papilla. In others there is no apparent explanation. There are probably some cases of chronic pancreatitis that are secondary to the outflow obstruction caused by this process. Nevertheless, the clinician must be extremely cautious about attributing chronic pancreatitis to this entity. In any case, as with pancreas divisum, treatment of chronic pancreatitis directed toward relief of the papillary obstruction is ineffective.

Miscellaneous additional causes of pancreatitis exist. They include acute pancreatitis that follows scorpion (*Tityus trinitatis*) venom poisoning, various infectious agents (mumps, group B Coxsackie viruses, herpes simplex, mononucleosis), and exposure to anticholinesterase insecticides.

Idiopathic pancreatitis still accounts for 15 to 20 percent of the total, suggesting that a number of other causes are still obscure. About one- third of patients with no obvious cause for their episodes of acute pancreatitis eventually will be found to have cholelithiasis. Thus, to avoid overlooking a treatable condition, an extensive search for the cause always must be made before the designation *idiopathic* is applied.

Pathogenesis

Acute pancreatitis is thought to result from enzymatic digestion of the gland by its own enzymes, although the mechanism(s) by which enzyme activation occurs in humans remains unknown. The pathogenesis of pancreatitis is best discussed within the framework of various theories that attempt to relate experimental observations to known clinical characteristics of the disease.

Obstruction-Secretion

Ligation of the pancreatic duct in animals results in edema of the pancreas that may resemble mild acute edematous pancreatitis in humans. It is self- limited, however, and generally resolves within a week; over several months the acinar tissue is replaced by fibrous scar. Partial duct obstruction, along with stimulation of pancreatic secretion, produces a more severe pancreatic inflammation. These observations may be relevant to biliary pancreatitis, when a gallstone obstructs the pancreatic duct during pancreatic secretion. Acute alcoholic pancreatitis also may have a similar mechanism. Alcohol in the stomach stimulates the secretion of gastric acid, which enters the duodenum and releases secretin. This, in turn, stimulates the pancreas to secrete. Alcohol also causes spasm of the sphincter of Oddi, which would obstruct the flow of pancreatic juice. This theory does not explain the mechanism by which the pancreatic enzymes become activated to begin the autodigestive process.

Common Channel Theory

In two patients who died from acute pancreatitis, Opie (1901) observed at autopsy that a gallstone was lodged in the ampulla of Vater, obstructing the bile and pancreatic ducts and creating a common channel between them. He suggested that bile reflux through the channel into the pancreatic duct was the cause of the pancreatitis. This hypothesis continues to be debated. It is known that infected bile that contains deconjugated bile salts and bile incubated with pancreatic juice that contains lysolecithin injure the lining of the pancreatic ducts. Their permeability is increased so that pancreatic enzymes can leak from them into the surrounding pancreatic parenchyma. This could initiate pancreatitis. On the other hand, fresh bile is apparently innocuous to the ducts. Moreover, in 90 percent of people the common channel may be too short to allow for bile reflux in the presence of an obstructing gallstone.

Duodenal Reflux

Reflux of duodenal contents through the papilla of Vater into the pancreatic duct causes pancreatitis in experimental animals. The rare case of pancreatitis that occurs after a Billroth II gastrectomy with obstruction of the afferent loop probably has a similar causation. This theory is attractive because it explains pancreatic enzyme activation, since duodenal enterokinase would gain access to the pancreatic duct. Nevertheless, normal mechanisms inherent in the duodenal wall and sphincter of Oddi efficiently prevent reflux, and there is no direct evidence that this mechanism accounts for pancreatitis in humans.

Increased Pancreatic Duct Permeability

Animal experiments have shown that a variety of conditions can increase the permeability of the pancreatic ducts so that pancreatic enzymes, normally contained within the ducts, can leak out. These include the acute ingestion of ethanol, direct exposure of the duct to deconjugated bile salts, pancreatic secretion against an obstruction, and acute hypercalcemia. If those enzymes have been activated, they cause acute pancreatitis. Nevertheless, there is no direct evidence that this occurs in human pancreatitis, and it is unknown how enzyme activation might occur.

Enzyme Autoactivation

In experimental animals, intrapancreatic autoactivation of trypsinogen occurs, and pancreatitis develops when pancreatic secretion is stimulated by supramaximal doses of cerulein or when animals are fed a choline- deficient diet supplemented with ethionine. These observations may be important because they offer a novel explanation for enzyme activation that does not require exposure to duodenal enterokinase. However, there is no evidence that enzyme autoactivation occurs in human pancreatitis, and there is no apparent connection between these experimental models and the human disease.

Presently we have only an incomplete understanding of the pathogenesis of pancreatitis. The diverse causes of the disease suggest that any of a number of inciting factors may result in injury to the gland and that the pancreas responds in a limited fashion. Biliary pancreatitis is associated with *acute* inflammation and almost certainly follows transient obstruction of the pancreatic duct by a gallstone. It is unknown whether bile reflux, elevated ductal pressures, or other factors are important. Alcoholic pancreatitis is associated with *chronic* inflammation, although acute inflammatory episodes do occur. The chronic changes are due to the toxic effects of ethanol on the acinar secretory cells and probably to widespread ductal obstruction from protein plugs.

Acute Pancreatitis

Clinical Manifestations

The typical attack of acute pancreatitis begins with severe and persistent epigastric or upper abdominal pain that often radiates through to the back. Frequently it follows the ingestion of a large meal and is associated with nausea and persistent vomiting and retching. The findings are the same regardless of the causation, even if the event represents an episode of acute pancreatic inflammation in a patient with chronic pancreatitis.

The pain is of variable intensity and may be less severe with edematous pancreatitis compared with the necrotizing form of the disease. Examination of the abdomen reveals tenderness most marked in the epigastrium but sometimes present throughout. The bowel sounds are decreased or absent. Usually there are no masses palpable; when one is present, it most often represents a swollen pancreas (phlegmon), pseudocyst, or abscess. With necrotizing pancreatitis, the abdomen may be distended with intraperitoneal fluid. The temperature is only mildly elevated (100 to 101°F) in uncomplicated cases. There may be evidence of a pleural effusion, especially on the left side.

When the disease is more severe, the patient also may exhibit signs of profound fluid losses from sequestration of edema fluid and/or blood in the peripancreatic retroperitoneal spaces or in the peritoneal cavity (ascites). Severe dehydration, tachycardia, and hypotension may be present. In about 1 percent of patients, a bluish color is evident around the umbilicus (Cullen's sign) or in the flanks (Grey Turner's sign). This represents blood that has dissected to those areas from the retroperitoneum near the pancreas in patients with necrotizing pancreatitis.

Although the clinical presentation often suggests the correct diagnosis, and the laboratory findings usually confirm it, it is important to stress that *acute pancreatitis is a diagnosis of exclusion*. Other acute upper abdominal conditions (e.g., perforated peptic ulcer, acute cholecystitis, gangrenous small bowel obstruction) must be considered in every patient. If doubt remains, a laparotomy may be indicated for diagnosis (<5 percent of patients), since the diseases with which acute pancreatitis is most likely to be confused are often lethal if not treated surgically.

Diagnostic Studies

The hematocrit may be elevated because of dehydration or low as a result of pancreatic or retroperitoneal blood loss in necrotizing pancreatitis. In the absence of suppurative complications, white blood cell counts over 12,000/mm³ are unusual. Liver function tests are usually normal, but mild elevations of the serum bilirubin concentration (<2 mg/dL) may be seen. This is probably due to partial obstruction of the intrapancreatic portion of the common bile duct by the swollen head of the pancreas. Ultrasound examination may reveal evidence of pancreatic and peripancreatic edema or fluid collections. CT scans may indicate similar changes. Nevertheless, these latter two studies are not commonly needed to diagnose pancreatitis. Their main value is in the diagnosis and management of complications of the disease.

The most widely used tests to diagnose acute pancreatitis depend on the release of various pancreatic enzymes from the inflamed gland. The serum *amylase* concentration rises to more than 2.5 times normal within 6 h of the onset of an acute episode and usually remains elevated for several days. Values above 1000 I.U./dL are characteristic (but not diagnostic) of biliary pancreatitis; lower values are typical for acute alcoholic pancreatitis. The level of the serum amylase concentration does not correlate with the severity of the episode of pancreatitis.

There are several reasons why a patient with acute pancreatitis may have a normal serum amylase concentration: (1) The urinary clearance of amylase increases shortly after the onset of pancreatic inflammation. Thus the serum concentration may fall to normal because more is excreted in the urine. For this reason, the urinary excretion of amylase is often measured as well. Excretion of more than 5000 I.U./24 h is abnormal. (2) In patients with hyperlipidemia and pancreatitis, the chemical determination of amylase is interfered with by the lipid. Serum amylase values are usually falsely normal in this setting. Urinary amylase measurement is still accurate and is usually elevated, however. (3) In patients with chronic pancreatitis who have suffered significant destruction of pancreatic parenchyma, there may be insufficient amylase released to raise the serum concentration above normal, even with an episode of acute inflammation. Pancreatic fibrosis also may limit the permeability of the gland and its capillaries, so absorption of amylase into the blood is restricted.

It is important to recognize that the serum amylase concentration and the urinary amylase excretion both may be increased in patients without pancreatitis. Examples are patients with perforated duodenal ulcer, gangrenous cholecystitis, small bowel obstruction, and other acute intraabdominal inflammatory conditions. This probably occurs because the pancreatic amylase leaks directly into the peritoneal cavity (e.g., perforated viscus) or translocates through the inflamed and permeable bowel wall and is absorbed into the blood.

The usual laboratory assay measures amylase isoenzymes from both pancreatic (p-type amylase) and salivary or other (s-type amylase) sources. Thus serum amylase elevations in some patients without pancreatic disease may be due to excessive s-type amylase alone. Examples are salivary or ovarian tumors, chronic sialadenitis, and liver disease. Macroamylasemia is another condition in which the serum amylase concentration is elevated but the pancreas is normal. In this abnormality, the amylase molecules (usually s-type) exist in the serum as large macromolecular aggregates whose effective size and molecular mass are much greater than the normal amylase molecule's (~55,000 Da). These macromolecules are too large for glomerular filtration and excretion by the kidney, so their serum concentration increases. Urinary excretion of amylase is low. The identification of both macroamylasemia and s-type amylase can be made by electrophoretic analysis of the serum. This should be done when the serum amylase concentration is high and the clinical picture is inconsistent with the diagnosis of pancreatitis.

Other pancreatic enzymes also have been measured in an effort to improve the diagnostic accuracy of serum amylase determinations. The greatest experience has been with serum *lipase*, which appears to be more reliable than amylase to diagnose acute pancreatitis. This is probably because the pancreas is the main source of lipase in the blood. Nevertheless, the test is still not used widely because the older method for lipase determination was cumbersome and time-consuming. A new technique that is rapid and simple may increase its utility. Radioimmunoassay kits are now available for the rapid determination of serum *trypsin* and *elastase* concentrations, and these also appear to be sensitive markers of pancreatic inflammation. To date, they have been used mostly in research protocols.

Radiologic studies are not used commonly to diagnose acute pancreatitis, but certain nonspecific abnormalities are often present. The most frequent finding on a plain abdominal film is the dilatation of an isolated loop of intestine (duodenum, jejunum, or transverse colon) adjacent to the pancreas (*sentinel loop*). A gas-filled ascending and right transverse colon that stops abruptly in the middle or left transverse colon (*colon cutoff sign*) is due to colonic spasm near the inflamed pancreas. An upper gastrointestinal series may show a widened duodenal loop or a swollen ampulla of Vater because of edema in the head of the pancreas. Calcification in the pancreas itself signifies the presence of chronic pancreatitis but does not prove the presence of acute inflammation. Chest films may reveal pleural effusions, more common on the left side.

In patients with biliary pancreatitis, a plain abdominal film may show radiopaque gallstones in the region of the gallbladder. However, the best way to confirm the presence of gallstones when biliary pancreatitis is suspected is with *ultrasound* (US) examination. Ultrasound also may reveal an edematous, swollen pancreas, peripancreatic fluid collections, or pseudocysts. Serial US examinations may be useful to follow the clinical course of patients with protracted or complicated pancreatitis or pseudocysts. In about 20 percent of cases of acute pancreatitis, US examination of the pancreas is technically unsatisfactory because of the presence of overlying bowel gas.

A *CT scan* of the pancreas should be obtained in all patients with acute pancreatitis whose illness has not begun to resolve within 2 or 3 days or whenever complications are suspected. Possible findings include a normal pancreas, pancreatic edema, a mass of inflamed peripancreatic tissue and pancreas (phlegmon), pancreatic and/or peripancreatic fluid collections (acute pseudocysts), or abscess. Extension of the inflammation from the area of the pancreas to other tissue planes (retrocolic, perinephric) may be evident and implies a more serious prognosis. The adequacy of pancreatic perfusion also can be estimated if the CT is done first without and then with intravenous contrast material, which must be injected rapidly as a bolus. A viable pancreas "enhances" as the contrast material flows through it; lack of enhancement suggests necrosis of that part of the pancreas (Fig. [30-4](#)). This technique represents a major advance in the diagnosis and management of complicated acute pancreatitis, since patients with significant pancreatic necrosis (>50 percent of the pancreas) are more likely to develop pancreatic infection and to require surgical intervention. If infection is suspected, a percutaneous ("skinny") needle can be introduced into collections of fluid, especially near poorly perfused pancreatic tissue, using CT or US as a guide. The aspirated material should be sent for Gram stain and bacterial and fungal culture. Proof of infection is an indication for laparotomy and surgical drainage.

Prognostic Signs

Early identification of patients who are at increased risk for the development of serious complications of pancreatitis allows them to be managed more aggressively, which may decrease the mortality rate. Three different approaches have been used: (1) Specific biochemical markers have been sought that discriminate between edematous and necrotizing pancreatitis, since the latter is known to have a higher rate of complications. For example, in necrotizing pancreatitis, the serum level of a γ -macroglobulin (which binds trypsin) falls, and the levels of a α -protease inhibitor and complement (C3 and C4) increase. So far the best discrimination between edematous and necrotizing pancreatitis has been achieved with serum C-reactive protein, a nonspecific acute-phase reactant that is elevated in the latter. C-reactive protein is still not widely used outside the research setting, however. (2) Multiple biochemical and/or physiologic measurements have been made during the first several days after hospital admission, which, taken together, have prognostic value. Ranson developed a series of different criteria for the severity of acute pancreatitis (Table [30-2](#)). Modifications of these criteria exist, but Ranson's original ones are still used most widely. The APACHE II scoring system also has been applied recently to patients with acute pancreatitis and appears to have prognostic significance as well. (3) Contrast-enhanced CT scan provides the most objective information about the extent of the inflammatory process, the degree of pancreatic necrosis, and the presence of infection, all of which affect the treatment and the prognosis. Because it is an invasive and expensive test, however, it is not done on all patients who are admitted with the disease. It should be done on patients who appear to be at higher risk based on any of the preceding prognostic criteria (e.g., >3 Ranson signs), those whose illness is not resolving within 2 or 3 days of admission, or for any other reason if a complication is suspected.

Treatment

Medical Treatment

The treatment of uncomplicated acute pancreatitis is medical and is directed primarily toward the restoration of fluid and electrolyte balance and the avoidance of secretory stimulation of the pancreas. *Nasogastric suction* should be instituted in most patients, except those with mild disease unassociated with significant vomiting or pain. All oral intake should be withheld until the ileus has resolved and pain is absent. The enzyme abnormalities usually have returned to normal by that time. For unclear reasons, the serum enzymes sometimes remain elevated even though the patient is asymptomatic. The resumption of oral intake is usually tolerated in these circumstances. Occasionally, symptoms will recur when oral intake is resumed. When this occurs, another period of fasting is indicated.

Fluid requirements may be considerable, since large volumes can be sequestered in the retroperitoneum adjacent to the pancreas. The amount of crystalloid and colloid (albumin, blood) given should be sufficient to maintain an adequate hematocrit, circulating blood volume, and urine output. It should be stressed that the most important aspect of early resuscitation is adequate and aggressive fluid replacement. Renal failure from inadequate replacement is a frequent finding in patients who die from this disease. Moreover, the pancreatitis itself may progress from the impaired pancreatic perfusion that can accompany the shock state. Electrolyte derangements may be present if vomiting has been significant and dehydration is severe. A hypokalemic, hypochloremic, metabolic alkalosis is most common. Hypocalcemia may occur in patients with severe pancreatitis. It must be treated urgently with parental calcium because it predisposes to cardiac arrhythmias. The prognosis appears to be related to the degree of hypocalcemia and the ease with which it is corrected. Hypomagnesemia is also common, particularly in alcoholic patients, and the magnesium should be replaced. About 30 percent of patients with acute pancreatitis develop arterial hypoxemia ($P_{aO_2} < 70$ mmHg) and require supplemental O_2 by mask. Because the onset of this is often insidious and may precede any changes on the chest film, it is prudent to determine arterial blood gases every 12 h for the first several days after admission to the hospital in most patients and longer in those who appear to have more serious disease. An occasional patient may develop *adult respiratory distress syndrome (ARDS)* and require endotracheal intubation and mechanical ventilation. Table [30-3](#) lists the changes in cardiovascular function in acute pancreatitis, and Table [30-4](#) lists the changes in respiratory function.

A number of drugs have been shown to exert no beneficial effect in patients with acute pancreatitis. These include antibiotics (which should be used only to treat specific suppurative complications), anticholinergics, gastric acid antisecretory agents, glucagon, somatostatin, and inhibitors of proteolytic enzymes (e.g., Trasylol). Parenteral nutrition has no specific beneficial effect on the course of pancreatitis. It should be used, as in any other patient, when oral intake must be withheld for prolonged periods and enteral nutrition is not possible. Elemental diets introduced by tube into the small intestine do not avoid pancreatic stimulation.

Peritoneal lavage has been used in patients with severe acute pancreatitis and intraperitoneal fluid to remove toxins and various metabolites from the peritoneal cavity and minimize their systemic absorption. Although controlled trials failed to show that this decreased mortality rates, there was some evidence that the incidence of cardiopulmonary complications was lessened. For this reason, and because there are many anecdotal reports where patients rapidly improved during lavage therapy, it is still done. The usual indication is severe pancreatitis that fails to show significant clinical improvement after several days of intensive therapy by more conventional means. The technique requires the insertion of a peritoneal lavage catheter and the rapid infusion and withdrawal of lactated Ringer's solution (1 to 2L/h) for 2 to 3 days or longer. If a response is seen, it is usually during the first 6 to 8 h. If no improvement occurs, surgery may be required.

Biliary pancreatitis is caused by a gallstone that obstructs the pancreatic and bile ducts. In the majority of cases, the gallstone dislodges spontaneously and usually passes into the intestine. When this happens, the patient's clinical course begins to improve, and the episode is generally short-lived. If the stone remains impacted, the attack of pancreatitis may become severe and refractory to the usual treatment. Impaction should be suspected when a patient with pancreatitis is known to have gallstones, when the serum bilirubin concentration is elevated more than 4 mg/dL, when the alkaline phosphatase level is elevated, and when the clinical course does not improve within 24 to 36h. If a skilled endoscopist is available, ERCP with *endoscopic sphincterotomy* to remove the stone may abort the attack. Otherwise, surgical removal of the impacted stone is indicated.

Surgical Treatment

Surgery is contraindicated in uncomplicated acute pancreatitis. Surgery is occasionally performed in patients with abdominal pain in whom the diagnosis is unclear, and the patient is found to have acute pancreatitis. If the pancreatitis is mild to moderate in severity and gallstones are present, a cholecystectomy should be done, and an operative cholangiogram should be obtained. Common duct stones should be removed. The pancreas should not be disturbed. For severe pancreatitis, the biliary tree should be drained if stones are present (cholecystostomy), but cholecystectomy probably should not be done. The common duct should be decompressed with a T-tube if stones are present, and if a stone is impacted at the ampulla of Vater, it should be removed. It is unclear whether drains should be placed to the area of the pancreas; many surgeons would not do this, thinking that the foreign body might predispose to infection. If necrotic pancreas or peripancreatic tissue is found, it should be debrided and drained widely.

In most patients with biliary pancreatitis, the diagnosis is obvious without the need for operation, and the pancreatitis resolves within 2 or 3 days. In these patients, cholecystectomy should be performed during the same hospitalization, usually 4 to 6 days after the original admission. The older practice of discharging the patient and delaying cholecystectomy for 6 weeks was associated with a 60 to 80 percent incidence of recurrence of pancreatitis. On the other hand, patients with severe episodes of biliary pancreatitis should be discharged once they have recovered, and cholecystectomy should be deferred for at least 6 weeks. By this time, the inflammation has subsided and the operation can be done without increased risk.

Complications

Severe episodes of acute pancreatitis may be associated with both systemic and local complications. *Systemic complications* include respiratory insufficiency with ARDS, renal failure, and depressed myocardial function. To some extent, this multiple organ failure may be due to secondary pancreatic infection and the systemic effects of sepsis, as seen in other disorders. Bacterial translocation and absorption of endotoxin from adjacent inflamed colon may be important. There is also evidence that systemic absorption of pancreatic proteases, phospholipase A_2 , and inflammatory cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor, and other noxious agents released from the inflamed pancreas may contribute. This is the rationale for peritoneal lavage: to remove the putative toxins. Inadequate fluid resuscitation accounts for some cases of renal failure. The treatment of multiple organ failure in this setting is no different from that in any other. Resistance to maximal treatment may justify surgical intervention to debride and drain the pancreas, although pancreatic infection is the usual indication.

Local complications include the development of pancreatic or peripancreatic infection and pseudocyst formation. Pseudocysts will be discussed in a separate section. Septic complications are best divided into infection of pancreatic necrosis and pancreatic abscess. *Infected pancreatic necrosis* occurs in at least 40 percent of patients with severe acute pancreatitis and necrosis of more than 50 percent of the pancreas (demonstrated by CT scan). Infection is difficult to recognize clinically. Even with sterile necrosis, patients may appear septic, with high fever, leukocytosis, and abdominal tenderness. Sterile necrosis in a stable patient should be managed expectantly, without surgical intervention. If gas

bubbles (presumed to originate from bacterial fermentation) are seen on the CT image, infection is certain, and surgery should be undertaken (Fig. 30-5). Nevertheless, percutaneous aspiration with Gram stain and culture of the involved material is usually required to prove the presence of infection. Infected pancreatic necrosis is most often diagnosed during the second week of an episode of pancreatitis. The organisms are usually a mixed flora including *Escherichia coli*, *Bacteroides*, *Staphylococcus*, *Candida albicans*, etc., so broad-spectrum antibiotics should be used. Antibiotics, however, are only adjunctive. Surgical drainage is necessary for definitive management. Percutaneous drainage is almost always inadequate, since the material is thick and contains particulate debris that rapidly clogs the narrow lumen of these tubes. At operation, the infected necrotic material should be debrided widely and the involved areas drained to the outside with large sump drains or packed open. Postoperatively, peritoneal lavage may be useful to mechanically remove additional devitalized tissue. Reoperation to drain recurrent or persistent infection is required in at least *one-fifth* of these patients. Associated complications such as fistulas from the bowel or pancreas or bleeding from the retroperitoneal structures are common. The overall mortality rate varies from 10 to 35 percent. Table 30-5 lists the indications for surgery in severe acute pancreatitis.

The decision to operate on a patient with severe acute pancreatitis is often difficult and requires mature clinical judgment. Those indications which are widely accepted include (1) for differential diagnosis when the surgeon is concerned that the symptoms are due to a disease other than pancreatitis for which operation is mandatory, (2) in persistent and severe biliary pancreatitis when an obstructing gallstone that cannot be removed endoscopically is lodged at the ampulla of Vater, (3) in the presence of infected pancreatic necrosis, and (4) to drain a pancreatic abscess if percutaneous drainage is not adequate. Other indications that are less well defined are (1) the presence of sterile pancreatic necrosis involving more than half the pancreas and (2) when the pancreatitis persists or the patient's condition deteriorates despite maximal medical therapy. Some less common indications for operation in these patients (e.g., peritonitis, hemorrhage, biliary obstruction, duodenal obstruction, etc.) have been omitted because the need for operation is generally more *apparent*.

Pancreatic abscesses are localized collections of pus in or near the pancreas and are confined by a capsule. They are usually diagnosed later than infected necrosis, about 3 to 4 weeks after the onset of the attack. Although systemic evidence of toxicity is often less, the patients may appear quite septic. CT scans reveal a fluid collection that may be indistinguishable from a pseudocyst. As with infected necrosis, gas bubbles in the fluid prove infection, but aspiration of the fluid with Gram stain and culture is usually required for the diagnosis. If the fluid is thin in consistency and there is little particulate matter in it, percutaneous drainage may be adequate treatment. Open surgical drainage is indicated if the material is thick, if rapid improvement does not occur after percutaneous drainage, or if there is CT evidence of considerable surrounding tissue necrosis in addition to the abscess. The mortality rate is about 20 percent.

Prognosis

The mortality rate for all patients with acute pancreatitis is approximately 10 percent. Necrotizing pancreatitis associated with infection has a mortality rate of about 35 percent, although there is some evidence that earlier diagnosis of infection and aggressive surgical intervention may lower this figure.

Chronic Pancreatitis

Clinical Manifestations

In 95 percent of patients with chronic pancreatitis, the principal symptom is *abdominal pain*. It is usually located in the epigastrium and is described as cramping, boring, or aching. In more than half the cases, it is also felt in the back. During an episode of acute inflammation, the pain is similar to that felt by patients suffering attacks of acute pancreatitis. In between such episodes, patients have recurrent pain that may last from a few days to several weeks, separated initially by several months or more. Typically the pain-free intervals become shorter and the painful attacks last longer so that pain eventually occurs every day. When the disease is so far advanced that most of the exocrine function is lost, about one-third of patients experience spontaneous pain relief. Another 10 to 20 percent have temporary remissions of pain that last 1 to 3 years. Some pain relief is typically obtained when the patients sit with the knees flexed and a pillow pressed to the abdomen. Most require analgesic drugs and many become addicted to narcotics. Assessment of the severity of pain is often difficult because many of these patients are addicted to alcohol and/or narcotics and have unstable personalities. Consequently, secondary gain may lead to an exaggeration of symptoms. The mechanism of the pain is uncertain, although it may be related to elevated duct and pancreatic tissue pressures and impaired parenchymal blood flow, a kind of compartment syndrome. Table 30-6 lists the potential causes of pain in chronic pancreatitis.

Variable *weight loss* occurs in 75 percent of patients with chronic pancreatitis because food usually aggravates the pain, and thus intake is voluntarily restricted. Significant weight loss from malabsorption is less common. Nevertheless, patients may complain of bulky, offensive, fatty or oily stools.

About two-thirds of patients with chronic pancreatitis have abnormal glucose tolerance, and half of these have *diabetes mellitus*. In these patients some degree of malabsorption is also present, since exocrine and endocrine insufficiency usually develop concurrently. The diabetes is usually easily controlled with insulin, but hypoglycemia may be a problem in alcoholics with irregular eating habits.

As a rule, most patients with chronic pancreatitis have failed to adapt to the stresses of society and have inadequate personalities. The additional stresses created by the disease often result in depression and anxiety. These personality traits are important in evaluating these patients, as well as in choosing specific types of therapy.

In most patients with chronic pancreatitis there are few physical findings. There may be some epigastric tenderness, some evidence of weight loss, and occasionally jaundice. If a mass is palpable, it is most likely a pancreatic pseudocyst.

Diagnostic Studies

These are not especially helpful in the diagnosis of chronic pancreatitis. About two-thirds of patients with alcoholic pancreatitis have abnormal liver function. Mild elevations of serum concentrations of bilirubin (2 to 4 mg/dL), alkaline phosphatase, and serum glutamic-oxaloacetic transaminase (SGOT) and mild depression of serum albumin concentration may occur. Pancreatic exocrine function is impaired in almost all patients, but there is a wide range of normal values for bicarbonate and enzyme secretion and volume flow in response to secretory hormones. Thus mild abnormalities may not be apparent. Pancreatic function tests are rarely indicated in patients with overt pancreatic disease (chronic pancreatitis or pancreatic cancer). Although these tests would confirm the presence of pancreatic insufficiency, they (1) rarely influence therapeutic decisions and (2) cannot distinguish between pancreatitis and cancer. They are of greater value in patients with vague complaints in whom the presence of pancreatic disease is suspected but for which no direct evidence exists. In these patients, these tests are 90 percent sensitive in detecting functional abnormalities. Thus a normal test along with one or two other studies that are also normal (e.g., ERCP or CT scan) reliably rules out pancreatic disease.

In 30 to 50 percent of patients with chronic pancreatitis, plain x-rays of the abdomen reveal pancreatic calcifications (Fig. 30-6). When calcifications are present, the diagnosis of chronic pancreatitis is certain even if there is no clinical evidence. With early chronic pancreatitis, and even in some patients with advanced disease, ductal abnormalities demonstrated by ERCP may be minimal. In the majority of patients with advanced disease, the main duct may be dilated up to 1 cm or more in diameter with intermittent points of obstruction (Fig. 30-7). Strictures, cysts, and ductal calculi may be seen. The common bile duct is also opacified by this technique, and distortion of its anatomy is evident. Chronic pancreatitis characteristically produces angulation of the distal common duct with a smooth, tapered narrowing of its intrapancreatic portion (Fig. 30-8). Generally, all patients with chronic pancreatitis who are being considered for operation should undergo ERCP examination. The study provides critical information about ductal anatomy. Patients with dilated ducts are candidates for drainage procedures; those who do not have ductal dilatation may require pancreatic resection (Fig. 30-9). Occasionally, it is impossible to obtain a preoperative ERCP. In these cases, a pancreatogram can be done at operation by puncturing the duct directly through the anterior surface of the gland.

CT scans also provide useful information. When the duct is grossly dilated, it usually can be seen running the length of the gland (Fig. 30-10). Pseudocysts and cystic communications with the ductal system are evident. Biliary dilatation and the level of bile duct obstruction are defined. CT scans provide the most precise information about the size and configuration of the pancreas, information that is useful in decisions regarding possible pancreatic resection.

Differential Diagnosis

The diagnosis of chronic pancreatitis is usually straightforward. Most patients are chronic alcoholics with recurring episodes of abdominal pain, diabetes, weight loss, pancreatic calcifications, and some evidence of malabsorption. Occasionally, the distinction between chronic pancreatitis and pancreatic cancer may be difficult. This may occur when there is no previous history of pancreatitis, when the patient presents with jaundice and pain is not a prominent part of the picture, or when weight loss is significant. In such circumstances, surgery may be necessary to make the diagnosis.

Complications

The principal complications of chronic pancreatitis are pseudocyst formation, diabetes mellitus, and malnutrition. *Jaundice* is seen sometime during the course of the disease in up to one-third of patients. This is most often the result of transient obstruction of the intrapancreatic portion of the common bile duct during an episode of acute pancreatic inflammation. It subsides when the acute process resolves. As many as 10 percent of patients develop persistent *common duct obstruction* from fibrous constriction of the duct in the head of the gland. The obstruction is almost never complete, which is different from the obstruction caused by pancreatic cancer. *Duodenal or colonic obstruction* occurs in less than 1 percent of patients with chronic pancreatitis and is caused by the inflammation in the adjacent pancreas with subsequent scarring. Gastrojejunostomy is effective in the former case, resection of the involved segment of colon in the latter.

Medical Treatment

The medical treatment of an episode of acute pancreatic inflammation is the same as the treatment of any bout of acute pancreatitis. In patients with *diabetes* from chronic pancreatitis, ketoacidosis is rare, even if blood glucose levels are quite high. Even small amounts of insulin may induce a profound hypoglycemia. This is probably due to concurrent glucagon deficiency. Thus the patient must be instructed thoroughly on the dangers of hypoglycemia, its symptoms, and management. Mild elevations in blood sugar do not require treatment, but fasting elevations in excess of 250 mg/dL should be managed with insulin. Frequently, only 20 to 30 units a day is required. Rigid control of blood sugar is not advisable. Oral agents are almost never successful.

The medical management of *pain* in patients with chronic pancreatitis should include the cessation of all alcohol intake. As many as 50 percent of patients experience some pain relief when they stop drinking. Pancreatic secretion itself may exacerbate the pain. For this reason, patients have been treated with somatostatin analogues, which effectively suppress secretory activity. Efficacy is as yet unproven, but even if the pain is relieved, long-term administration of these drugs is impractical because they can only be given parenterally, they are expensive, and they have significant side effects (e.g., gallstones).

The analgesic management of these patients should begin with small doses of oral medications such as codeine derivatives, either alone or combined with acetaminophen. If more potent narcotic analgesics are required, especially for prolonged periods, serious consideration must be given to surgical pain relief. All too often these patients are denied surgical treatment until after they have become addicted to narcotics and are severely disturbed psychologically as a result of living with constant pain.

Surgical Treatment

The most common indication for surgery is persistent severe pain, although a variety of other complications may require operative intervention (Table 30-7). The indications for surgery for pain relief are impossible to state in precise terms. When the pain interferes substantially with the quality of life, surgery should be considered. Pertinent considerations include obvious effects on health and well-being such as weight loss and nutritional status, need for frequent hospitalization, inability to maintain employment, psychiatric manifestations (usually depression), deterioration of family life, and narcotic addiction.

All patients who are being evaluated for possible surgical intervention should undergo an abdominal CT scan and an ERCP, in addition to the standard preoperative assessment for a major abdominal procedure. Psychiatric evaluation is also appropriate in many patients. Information from these studies helps with decisions about the type of surgical procedure that may be indicated.

There are two categories of operations for the relief of pain in patients with chronic pancreatitis. The first are drainage operations, which attempt to drain more adequately a dilated ductal system that is presumed to be obstructed. The second are the pancreatic resection operations, which remove diseased pancreatic tissue, usually in situations where the pancreatic ducts are normal or narrowed in size. Sphincterotomy or sphincteroplasty of the sphincter of Oddi has no place as the primary treatment of pain in patients with this disease.

Drainage Procedures

When the diameter of the main pancreatic duct in the head and body of the pancreas increases to 7mm or more, a lateral pancreaticojejunostomy (the Puestow procedure) is technically feasible (Fig. 30-11). The duct is opened throughout the length of the pancreas and anastomosed side to side to a Roux-en-Y limb of jejunum. Immediate pain relief is likely in 80 to 90 percent, but pain recurs unpredictably in 25 to 50 percent of patients after 5 years. In some patients, recurrence of pain may be due to stenosis of the pancreaticojejunal anastomosis. This can be proved by ERCP. Reconstruction of the anastomosis may then be beneficial. In the majority of cases, there is no apparent cause for the recurrence of pain, and pancreatic resection must be considered. If the Puestow operation is done in a pancreas with a normal-sized duct, both short- and long-term results are unsatisfactory, perhaps because the anastomosis strictures close in most cases.

The operative mortality of longitudinal pancreaticojejunostomy is about 4 percent, and the morbidity is minimal. Because almost no pancreas is resected, the procedure rarely results in diabetes. Nevertheless, a number of patients eventually will require insulin, since destruction of the pancreas probably continues. Although pancreatic enzymes can now empty freely through the pancreaticojejunostomy, there is rarely any clinical improvement in the degree of malabsorption. However, patients may gain weight because eating no longer produces pain, and therefore, they eat more.

Pancreatic Resections

Pancreatic resection should be considered for pain relief when the pancreatic duct is narrow or normal in diameter, when a previous pancreaticojejunostomy has failed, or when the pathologic changes in the pancreas particularly involve one part of the gland and the rest is less diseased. The standard Whipple pancreaticoduodenectomy (the operation usually done for pancreatic cancer) may be indicated when most of the disease involves the head of the pancreas (Fig. 30-12). A modification of this operation is the pancreaticoduodenectomy with preservation of the stomach and pylorus (Fig. 30-13). The theoretical advantage of this procedure is that it preserves gastric function and avoids some of the nutritional disturbances that may follow the standard pancreaticoduodenectomy. Ninety-five percent distal pancreatectomy entails removal of the spleen and all the pancreas except for a thin rim of tissue that lies within the C loop of the duodenum. Because the spleen is sacrificed and all the patients require insulin after this operation, it is not done frequently. Today, total pancreatectomy is performed rarely because of the uniform requirement for insulin and the significant alterations in digestive and absorptive functions that follow. A new operation, in which the head of the pancreas is resected but the entire duodenum is preserved, may be preferred to the Whipple procedure in those patients in whom the head of the pancreas is the major focus of disease. The theoretical advantages of this procedure include the preservation of gastroduodenal and biliary continuity and function and a low likelihood of the development of diabetes, since most of the pancreas is preserved.

The mortality rate of the various pancreatic resection operations is less than 5 percent. The significant drawback associated with major pancreatic resections is the creation of the diabetic state, which is often difficult to control. For this reason, such procedures should not be done in unreliable alcoholic patients who may be addicted to narcotics. Pain is relieved in 80 to 90 percent of patients in the first several years after these operations, and even after 5 years, about 80 percent continue to be pain-free. Tables 30-8 through 30-10 list late results, mortality rates, and long-term pain relief of pancreaticoduodenectomy for chronic pancreatitis in various hands.

Nonsurgical destruction of the celiac ganglia may have a place in the management of patients with severe pain from chronic pancreatitis. In those in whom the surgeon and gastroenterologist wish to avoid or delay pancreatic resection, percutaneous injection of the ganglia with absolute ethanol may provide some relief for a period of time. Consultation with an anesthesiologist interested in pain management may be helpful. Although permanent pain relief is unusual with this technique, a limited period of improvement may be useful for patient and physician alike, resulting in a better rapport and a better understanding of the patient's commitment to a treatment program. In a few cases, spontaneous improvement in the pain may even occur.

Pancreatic Transplantation

In an effort to avoid diabetes, autografts of the body and tail of the pancreas have been done in a small number of patients who were subjected to total or near-total pancreatectomy. Success has been limited, and more experience is required before this approach can be recommended widely.

Prognosis

In patients with alcoholic chronic pancreatitis, life expectancy is reduced by 10 to 15 years, and the mean age at death is approximately 50 years. The principal causes of death include upper respiratory malignancies (most patients are heavy cigarette smokers), malnutrition, complications of diabetes, and suicide. Abuse of ethanol and/or drugs is often contributory.

PSEUDOCYSTS

Pancreatic pseudocysts are localized collections of fluid with high concentrations of pancreatic enzymes. They occur usually as a complication of pancreatitis, although some occur after trauma. Pseudocysts are located either within the pancreatic parenchyma or in one of the potential spaces that separate the gland from the adjacent abdominal viscera. Most of the time they are found in the lesser peritoneal sac behind the stomach, but they also may occur at great distances from the pancreas (e.g., neck, mediastinum, pelvis). They are called pseudocysts because, unlike congenital cysts or cystic neoplasms, they lack a true epithelial lining.

The pathogenesis of pseudocysts depends on the clinical setting in which they develop. During an attack of acute pancreatitis, fluid extravasates from the pancreas, where it becomes walled off by surrounding structures and fails to reabsorb as the inflammation resolves. In patients with chronic pancreatitis, ductal strictures or stones may obstruct the pancreatic duct or its branches and produce localized ductal dilatations. These areas coalesce and lose their epithelial lining as they enlarge to form a pseudocyst. Some pseudocysts follow trauma and are the result of either pancreatitis or ductal disruption with direct leakage of fluid from the gland. Occasionally, pseudocysts form after the pancreas is injured during splenectomy.

Ethanol abuse and biliary tract disease account for most of the cases, with men outnumbering women 2:1 in most series. The average age at diagnosis is 45 years. About one-third of pseudocysts are located in the head and two-thirds in the body or tail of the gland. Multiple cysts occur in 20 percent of patients.

Clinical Manifestations

Pseudocysts should be suspected when a patient with acute pancreatitis fails to recover after 5 to 7 days of treatment or, after some improvement, begins to deteriorate again. In patients with chronic pancreatitis, there is often no acute episode to herald the appearance of the cyst. Instead, the patient may complain of abdominal pain or symptoms that reflect compression of an adjacent viscus by the cyst. Nausea, vomiting, and weight loss may reflect duodenal or gastric outlet obstruction from a pseudocyst. Jaundice may be present if the cyst compresses the common bile duct.

Diagnostic Studies

Ultrasound (US) and CT scanning are the most useful tests to diagnose pseudocysts. However, CT scans are more sensitive and specific than US and have the additional advantages of superior resolution and more precise localization (Fig. 30-14). Moreover, bowel gas, obesity, and displacement of intraabdominal structures from prior surgery may impair US images. The main disadvantages of CT are the relatively high cost compared with US and exposure to ionizing radiation. CT scan should be used for the initial evaluation of patients suspected of having pseudocysts; US should be reserved for follow-up examinations.

ERCP also has been used before surgery to provide anatomic information about pseudocysts, but it should not be done routinely. ERCP is indicated in jaundiced patients to differentiate between common bile duct compression by the cyst and a stricture of the intrapancreatic portion of the common duct caused by a fibrotic pancreas. In the former case, cyst drainage alone would relieve the jaundice, whereas in the latter instance, a biliary bypass procedure to relieve the biliary obstruction also would be required. Because it may introduce bacteria into a previously sterile cyst, ERCP should be performed only when cyst drainage is to be done within 24 h.

Complications

The most feared complications of pseudocyst are hemorrhage, rupture, and infection. Hemorrhage occurs in approximately 6 percent of patients, rupture into the gastrointestinal tract or peritoneal cavity in 7 percent, and infection in 14 percent. Other complications include obstruction of the gastrointestinal tract (duodenum or stomach) in 3 percent and common bile duct obstruction in 6 percent.

Hemorrhage, from erosion of pseudocysts into major blood vessels (e.g., splenic or gastroduodenal arteries), may be massive. Arteriography is the initial diagnostic procedure of choice if the patient is stable. It offers the opportunity for selective embolization to plug the bleeding vessel. This may be definitive or, by temporarily stopping the hemorrhage, allow resuscitation of a critically ill patient and permit surgery to proceed on an urgent rather than emergency basis. Frequently, blood loss may be so rapid that it precludes diagnostic procedures and requires emergency operation. Both the cyst and the bleeding vessel should be excised, if possible. Even with aggressive surgical management, the mortality rate is at least 30 percent.

If the pseudocyst ruptures freely into the peritoneal cavity, the patient may develop symptoms and signs of acute peritonitis. Treatment of free rupture requires urgent operation with irrigation of the peritoneal cavity and usually external drainage of the cyst. Free rupture of a pseudocyst is a serious complication; the mortality rate is approximately 15 percent. Rupture into the gastrointestinal tract may produce vomiting or diarrhea but is usually not a surgical emergency.

Pseudocyst infection may occur in the early weeks after cyst formation as a complication of an episode of severe acute pancreatitis. Pseudocyst infection must be distinguished

from infected pancreatic necrosis. Less commonly, superinfection of a mature cyst is heralded by fever and leukocytosis in a patient who has not been acutely ill. In either case, infection can be proved by percutaneous drainage of the cyst under US or CT guidance, with Gram stain and culture of the fluid. Infected pseudocysts may resolve permanently with percutaneous drainage for a week or so. However, if percutaneous drainage does not produce prompt clinical improvement, surgery is required.

Treatment

Pseudocysts that develop in patients with chronic pancreatitis are unlikely to resolve spontaneously and may be viewed as mature from the time of discovery. About 40 percent of acute pseudocysts (those which develop during an episode of acute pancreatitis) will disappear spontaneously as the pancreatitis resolves, however. If mature pseudocysts are asymptomatic and are less than 5 cm in diameter, they probably require no treatment, since serious complications generally occur in cysts that are larger. These patients should be followed and the cysts reevaluated at 3- to 6-month intervals with US. The onset of symptoms, growth in the size of the cyst, or development of a complication demands intervention.

Surgery

The three types of surgical procedures used to treat pseudocysts are resection, external drainage, and internal drainage. Elective surgery should be delayed until the pseudocyst is mature, i.e., until the wall is firm enough to hold sutures. This requires 4 to 6 weeks for cysts that arise during acute pancreatitis. For cysts that arise during chronic pancreatitis, no wait is necessary. At operation, the interior of the cyst should be inspected for evidence of tumor, and a biopsy of the cyst wall should be obtained to exclude a cystic neoplasm (e.g., cystadenocarcinoma). *Resection* is the preferred method of treatment but is usually possible only for cysts in the tail of the gland, when the head and body are normal or minimally changed (e.g., traumatic pseudocysts). *External drainage* is preferred when the cyst wall is not sufficiently thickened to allow anastomosis to the gut lumen. A large-bore tube is sewn into the cyst lumen, and the other end is brought out through the abdominal wall. Pancreatic fistulas complicate about 20 percent of external drainage operations and usually close within a few months. Fistulas and recurrent cysts are more common when the cyst communicates with the pancreatic duct. *Internal drainage*, in which the cyst is anastomosed to a Roux-en-Y limb of jejunum (cystojejunostomy), to the posterior wall of the stomach (cystogastrostomy), or to the duodenum (cystoduodenostomy), is the most frequently used operation for pseudocysts. Dependent drainage by cystogastrostomy is preferred for collections adjacent to the stomach, whereas cystojejunostomy can be done for cysts in any location. Obliteration of the cyst cavity usually follows internal drainage within a few weeks. Patients recover rapidly and are usually eating within a week. Infected pseudocysts adherent to the stomach can be drained by cystogastrostomy. Otherwise, drainage should be external because the suture line of a Roux-en-Y cystojejunostomy may not heal in an infected surgical field.

Mature pseudocysts also may be treated nonsurgically, but these techniques are still being evaluated. External drainage may be established with a narrow-lumen catheter placed percutaneously via US or CT guidance. Successful obliteration is claimed in as many as 80 percent of cases; if the cyst persists, surgery should be performed. Nonsurgical management is contraindicated in patients with cyst rupture or hemorrhage or when adjacent vascular structures preclude a percutaneous approach. In addition, if there is ever concern that the "pseudocyst" may actually represent a cystic neoplasm, surgery is required. This should be considered if there is no history of pancreatitis, septations are seen within the cyst on CT scan, or cyst calcifications are present. If any of these features are present, suspicion that the cyst represents a neoplasm should be high. Strong consideration should be given to surgical intervention rather than nonoperative management (e.g., percutaneous drainage). Table [30-11](#) lists the characteristics of cystic neoplasms of the pancreas.

Prognosis

Pancreatic pseudocysts recur at a rate of approximately 10 percent, although most of these probably are new cysts that arise from recurrent episodes of pancreatitis. After external drainage, the rate is approximately 20 percent. Even when pseudocysts do not recur, many patients experience chronic pain, a manifestation of underlying chronic pancreatitis.

Pancreatic Ascites

Ascites may occur when pancreatic secretions collect within the abdomen following disruption of the pancreatic duct or when a pseudocyst continuously leaks into the abdomen. A leak into the retroperitoneum may track some distance from its source, and the fluid collection may appear in the mediastinum, pleural space (pancreatic pleural effusion), or groin. Most patients are male alcoholics with chronic pancreatitis, although ascites also may occur following pancreatic trauma. Symptoms of a distinct episode of acute pancreatitis rarely precede pancreatic ascites. Patients usually present with increasing abdominal girth, weight loss, and muscle wasting. Although the presentation can be confused with cirrhosis, abdominal paracentesis is diagnostic. The combination of high protein content (>3 g/100 mL) and amylase concentration in the ascitic fluid greater than the serum amylase concentration is pathognomonic. The initial therapy should consist of parenteral nutrition, especially if malnutrition is severe. A somatostatin analogue to suppress pancreatic secretions also may be useful. In some cases, the ascites resolves with this treatment, which should continue for 10 to 14 days. If the ascites persists, operation is indicated and should be preceded by endoscopic retrograde pancreatography to show the site of the ductal disruption. If it is located in the distal pancreas, distal pancreatectomy may be appropriate. If the leak is located in the head or body of the gland, internal drainage using a Roux- en-Y limb of jejunum is preferable. The success rate is approximately 85 percent, but in patients who are severely debilitated, postoperative morbidity is considerable.

TUMORS OF THE PANCREAS

Ductal Adenocarcinoma

In the United States, cancer of the exocrine pancreas is the fourth leading cause of cancer death in men and the fifth in women. Each year, about 28,000 cases will be diagnosed, and almost as many patients will die of advanced disease. Ductal adenocarcinoma of the pancreas accounts for approximately 90 percent of exocrine tumors, and it is a characteristically aggressive lesion. At the time of diagnosis, the tumor is confined to the pancreas in fewer than 10 percent of patients, 40 percent have locally advanced disease, and over 50 percent have distant spread. More than 95 percent of patients eventually die of their disease, and even after resection for attempted cure, the median length of survival is only 18 to 20 months.

Clinical Manifestations

Pancreatic cancer occurs in the head of the pancreas in 75 percent of cases and in the body and tail of the gland in the rest. This distinction is important because lesions of the head, close to the bile duct, may produce obstructive jaundice when they are still small and curable. Indeed, biliary obstruction, in the absence of other symptoms, is associated with a better prognosis. Painless jaundice alone (13 percent) is uncommon, however. About 75 percent of patients with carcinoma of the head of the pancreas present with *obstructive jaundice, weight loss* (average 20 pounds), and deep-seated *abdominal pain*. The jaundice is usually unrelenting but fluctuates in about 10 percent of patients. Cholangitis is uncommon (10 percent). Jaundice may be accompanied by pruritus. When back pain occurs (25 percent), it is associated with a worse prognosis, and it implies retroperitoneal invasion by the tumor. The sudden onset of diabetes mellitus is noted in about 20 percent of patients. Body and tail tumors almost always produce symptoms late and are usually far advanced at the time of diagnosis. Very few are resectable, and the prognosis is particularly grim.

Physical examination and routine laboratory tests are primarily of value in supporting the diagnosis of obstructive jaundice and in detecting very advanced disease. Hepatomegaly, present in 65 percent of patients, is a nonspecific finding. Although it can indicate liver metastases, the liver also may enlarge as a result of bile duct obstruction alone. A palpable abdominal mass (10 percent) and ascites (5 percent) suggest advanced disease. *Courvoisier's sign*, a distended and palpable gallbladder in the jaundiced patient, suggests malignant obstruction. It is present in only 25 percent of patients.

Diagnostic Studies

The total bilirubin level tends to be greater with malignant obstruction compared with benign causes such as choledocholithiasis (e.g., mean levels of 15 versus 5 mg/dL). Serum amylase elevations are uncommon (5 percent) in patients with pancreatic cancer.

A number of screening tests for pancreatic cancer have been investigated. Ideally, such a test would be inexpensive, abnormal early in the course of the disease when it was still curable (high sensitivity), and normal in other conditions (high specificity). Of the many *serum markers* that have been evaluated (CEA, POA, GT-II, CA 19-9, DU-PAN-2), the results with CA 19-9 have been the most encouraging. However, even CA 19-9, a monoclonal antibody to the Lewis blood group antigen, has a sensitivity of only 80 percent. The smallest lesions and presumably those most amenable to cure are least likely to be detected. Gastric, colorectal, and other carcinomas also may be associated with elevations in CA 19-9, so the specificity is only about 90 percent.

The diagnostic approach to pancreatic cancer varies depending on whether the patient presents with obstructive jaundice or other symptoms. In those with jaundice, the clinician's attention is directed rapidly toward an assessment of the biliary tree. An abdominal CT scan, perhaps preceded by a US examination, is generally performed early in the evaluation. ERCP also may be done. The presumptive diagnosis usually can be arrived at within several days. In patients without jaundice, where the complaints are weight loss, pain, or other nonspecific problems, a number of other studies may precede a CT scan and/or ERCP examination. Nevertheless, in both groups, CT and ERCP have become the mainstay for diagnosis of this disease.

Ultrasound

US is relatively inexpensive and has a sensitivity of 70 percent and a specificity of 95 percent for the diagnosis of pancreatic cancer. However, the examination is unsatisfactory because of body habitus or overlying bowel gas in 20 percent of patients. When it demonstrates dilated intrahepatic and extrahepatic biliary radicles, it confirms the presence of extrahepatic biliary obstruction. US also helps to identify gallstones as a cause of obstruction.

Computed Tomography

Spiral CT has a sensitivity of 85 percent and a specificity of 95 percent for the diagnosis of pancreatic cancer. Lesions larger than 2 cm are usually detectable (Fig. [30-15](#)). More reliable than US, CT visualizes the entire pancreas and also provides some information about resectability (e.g., liver metastases and major vascular involvement may be detected). Nodal enlargement may reflect metastases, but nodes smaller than 1 to 2 cm may be missed altogether, and inflammatory changes in nodes cannot be distinguished from neoplastic ones. About 20 percent of metastatic liver lesions are overlooked.

Endoscopic Retrograde Cholangiopancreatography

ERCP has a sensitivity of 95 percent but a specificity of only 85 percent. This is due to the difficulty in distinguishing between cancer and chronic pancreatitis. The study can be performed successfully in over 90 percent of patients and detects some tumors that are not visualized by CT.

The characteristic finding that suggests the diagnosis of pancreatic cancer is a constriction of both the pancreatic and bile ducts in the head of the gland. This is the so-called double-duct sign (Fig. [30-16](#)). However, ERCP is superfluous in some patients. If the patient has a typical history for pancreatic cancer and a mass in the head of the pancreas is seen on CT scan that is consistent with the diagnosis, ERCP is not needed. During ERCP, cytologic study of cells obtained directly from the pancreatic duct may reveal cancer in up to 80 percent of cases. It also may be possible to determine the origin of a periampullary tumor (pancreatic versus duodenal, ampullary, or bile duct) with this technique. Therapeutic

ERCP also permits endoscopic stent placement. Although this is not indicated for preoperative biliary decompression, it provides effective palliation of the jaundice for certain patients who may not need an operation.

Fine-Needle Aspiration

Preoperative *fine-needle aspiration (FNA)* for cytologic examination can be obtained percutaneously under CT or US guidance. The technique has a sensitivity of about 85 percent and a specificity of almost 100 percent. *However, the clinician must remember that a negative FNA never reliably eliminates the possibility that cancer is present.* FNA is justified when the knowledge that the diagnosis is pancreatic cancer will unquestionably alter the patient's management. For example, a patient with cancer of the body of the pancreas and retroperitoneal extension of tumor seen on CT scan is not likely to benefit from operation. Proof of the diagnosis by FNA would avert the need for operative biopsy and permit the use of other palliative measures (radiotherapy, chemotherapy, celiac ganglion injection, etc.) (Fig. [30-17](#)). The routine use of FNA for patients with a mass in the head of the pancreas and obstructive jaundice is unnecessary.

Laparoscopy

Laparoscopy has been used to stage patients with pancreatic cancer. At least 20 percent of patients with no evidence of metastases from the preceding tests have small lesions evident on the liver surface, omentum, or peritoneum that can be seen laparoscopically. Such documentation of unresectability could be helpful in the patient with a body or tail lesion who would not benefit from surgery. It has no value in the patient who requires surgical bypass for relief of jaundice and gastric outlet obstruction.

Magnetic Resonance Imaging

MRI appears to offer no advantage over CT scan.

Upper Gastrointestinal Series

An upper gastrointestinal (UGI) series may show displacement of the stomach and widening of the duodenal C loop, but these are relatively late changes and are usually detectable on CT examination. A UGI series may be of some value to assess gastric outlet obstruction but is not performed routinely in the absence of specific indications.

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (PTC) permits visualization of the proximal biliary tree in patients with ductal obstruction who cannot be studied from below with ERCP. Although PTC is the preferred method for proximal bile duct tumors (e.g., Klatskin tumors), ERCP provides more diagnostic information and is better for periampullary lesions.

Angiography

This study is not performed for diagnosis but may provide information about resectability of the cancer. Rarely, complete occlusion of the celiac, hepatic, and/or superior mesenteric arteries or the portal vein suggests that the lesion is unresectable. More commonly, distortion of the vessels is seen, which is more difficult to interpret. The sensitivity and specificity of angiography to determine resectability are each 70 percent. Preoperative recognition of such vascular anomalies as a right hepatic artery arising from the superior mesenteric artery (25 percent of patients) can facilitate their preservation at surgery. Nevertheless, such anomalies also can be determined at the time of operation. Since modern spiral CT provides similar information, most surgeons do not routinely perform angiography.

Summary

An *algorithm* for the *management* of the patient with suspected cancer is presented in Fig. [30-18](#). Spiral CT scan provides the best overall initial assessment and may be the only test required. If the history and clinical picture suggest pancreatic cancer and CT reveals a mass in the head of the pancreas without evidence of unresectability, laparotomy may be undertaken without additional studies. Exploration provides the best means of confirming resectability; and even if resection is not possible, most patients will benefit from biliary and gastric bypass. If the CT suggests hepatic or peritoneal metastases or vascular invasion that precludes resection, percutaneous FNA may be appropriate if a positive biopsy will avoid an operation. If the biopsy is negative, laparoscopy should be the next step. In some patients with a general medical condition that makes operation too risky, no further evaluation may be necessary. Age alone is not a contraindication to major pancreatic resection. Endoscopically placed biliary stents effectively relieve biliary obstruction and are an alternative to surgical biliary bypass in patients who do not undergo operation.

If the mass involves the body and tail of the gland, usually there is evidence of metastatic disease or local spread. Since these patients seldom benefit from palliative operations, percutaneous FNA is often indicated to provide a tissue diagnosis before initiating adjuvant therapy. Occasionally, these tumors appear resectable or the biopsy is negative or equivocal. In these cases, laparoscopy for further assessment may be reasonable. The patient should undergo laparotomy under the same anesthetic if the attempted biopsy is unsuccessful or the lesion appears resectable.

If the patient with suspected pancreatic cancer has a normal or nondiagnostic CT, ERCP is indicated. If both the CT and ERCP are normal, pancreatic cancer is an extremely unlikely cause of the symptoms that are being evaluated.

Differential Diagnosis

The other periampullary neoplasms (carcinoma of the ampulla of Vater, distal common bile duct, or duodenum) also may present with abdominal pain, weight loss, and obstructive jaundice. While the preoperative studies may suggest the correct diagnosis, sometimes this is possible only at operation. Occasionally it is not apparent even at that time, and the pathologist may have to determine the true origin of the neoplasm. This element of diagnostic uncertainty is acceptable because the treatment (pancreaticoduodenectomy) is the same for each of these lesions. Chronic pancreatitis also can be confused with pancreatic cancer, and it may be impossible to distinguish between the two even at operation. Nevertheless, pancreaticoduodenectomy is an acceptable treatment for this as well.

Treatment

Pancreatic resection for pancreatic cancer is appropriate only if all evidence of gross tumor can be removed with a standard resection, i.e., if cure is considered possible. Resection for palliation is not commonly done. In the absence of evidence of distant metastases (e.g., to the liver, peritoneal surfaces, distant lymph nodes), resectability usually depends on whether the tumor has grown to involve adjacent major vascular structures. These structures are the superior mesenteric and portal veins and the superior mesenteric and hepatic arteries. The vena cava also may be involved. Because the pancreas is so close to the portal vein and superior mesenteric vessels, and because of the propensity of pancreatic cancer to spread early to adjacent structures, only about 20 percent of tumors of the head are resectable at the time of exploration. Fewer than 5 percent of tumors of the body and tail can be removed.

In some patients, the diagnosis has already been determined preoperatively by FNA or other technique. If this is not the case, most surgeons will try to establish a tissue diagnosis at an early stage of the operation. When the cancer has extended to the surface of the gland, a simple “shave” biopsy of the lesion is safe and reliable. If the lesion is located deep within the pancreas, a needle biopsy or FNA is preferred. For cancers in the head of the pancreas, the needle is often inserted into the gland through the duodenum so that if a pancreatic fistula develops, it will drain into the bowel rather than leak into the peritoneal cavity. Although these techniques are accurate and reasonably safe, they are often inconclusive with the small deep-seated lesions that are most likely to be cured by resection. This occurs because the tumor is surrounded by a zone of chronic inflammation and may be missed altogether when the needle is inserted. Thus most experienced pancreatic surgeons are willing to perform a pancreaticoduodenectomy on the basis of clinical inferences, drawn preoperatively and at operation, that suggest the diagnosis of cancer. Biopsy proof is not required.

Pancreaticoduodenectomy (Whipple Resection)

This is the most commonly performed operation for carcinoma of the pancreatic head (see Fig. [30-12](#)). It includes resection of the distal stomach, gallbladder, common bile duct, head of the pancreas, duodenum, proximal jejunum, and regional lymphatics. Truncal vagotomy used to be done to reduce the risk of marginal ulceration, but it is done infrequently today. Instead, many patients are managed with acid antisecretory agents. Restoration of gastrointestinal continuity requires pancreaticojejunostomy, choledochojejunostomy, and gastrojejunostomy. The operative mortality rate in expert hands is less than 5 percent. When death occurs, it is most often due to complications such as postoperative pancreatic or biliary fistula, hemorrhage, and infection.

Pylorus Preservation

About a third of all pancreatic surgeons in the United States now perform a modification of the Whipple procedure in which the stomach and pylorus are preserved (see Fig. [30-13](#)). This operation is preferred by some because it is believed that it avoids the undesirable nutritional sequelae (i.e., weight loss, dumping syndrome, diarrhea) that may follow the standard Whipple procedure. Although the lymphatic dissection is less radical than with the standard operation, there is no evidence as yet that it is associated with a lower survival rate.

In the United States, the 5-year survival rate in all patients who have undergone pancreatic resection for pancreatic cancer is approximately 10 percent. In those patients without lymph node involvement, the 5-year survival rate is about 35 percent.

Total Pancreatectomy

A number of more extensive procedures have been proposed to improve the cure rates associated with the Whipple operation. To date, none has proved more effective. One of the proposed procedures is *total pancreatectomy*. The rationale for this procedure included the observation that in 30 to 40 percent of pancreatic cancer patients, the tumor was multicentric and would not be removed completely by a Whipple resection. However, most series of total pancreatectomy showed no evidence of increased survival, and recent studies have suggested that concerns regarding multifocal disease were unwarranted. However, it may still be appropriate when tumor is present at the planned site of transection of the pancreas or when the gland is too soft to permit a satisfactory anastomosis to the jejunum.

Extended Whipple Resections

These operations involve wider soft tissue and lymph node dissections than the standard Whipple and include resections of the superior mesenteric vessels and portal vein when they are involved with tumor. Some retrospective data have suggested a better outcome with this aggressive approach. Nevertheless, these operations are best done within the framework of an experimental protocol, since the morbidity is greater and increased efficacy has not been proven.

Palliative Operations

Surgical palliation in patients with cancer of the head of the pancreas is directed toward relief of obstructive jaundice, gastric outlet obstruction, and pain. Patients with body and tail lesions are less likely to have jaundice or duodenal obstruction, but pain is often significant. Nonoperative techniques for pain relief are preferred.

At some time in the course of the disease, obstructive jaundice develops in about 70 percent of patients with pancreatic cancer. Cholecystojejunostomy and choledochojejunostomy are both safe and are the procedures of choice to relieve the biliary obstruction (Fig. 30-19). If the gallbladder is chosen for the anastomosis, the surgeon must be certain that the cystic duct is patent and enters the common bile duct away from the tumor. An intraoperative cholangiogram may be necessary to confirm this. Roux-en-Y jejunostomy theoretically is better than simple loop reconstruction because it prevents reflux of intestinal contents into the biliary tree and secondary cholangitis. Since most of these patients die within 7 or 8 months, this is rarely a concern, and the simpler loop reconstruction is usually done. Jaundice is relieved in 85 to 90 percent of patients. When it is not, it is usually because of irreversible hepatic parenchymal damage from high bilirubin levels and long-standing obstruction.

For patients in poor general medical condition or in whom the tumor is known to be unresectable, nonoperative palliation of obstructive jaundice is preferred. Percutaneous or endoscopically placed plastic biliary stents are each effective, but the latter are better accepted by patients. The major problem with either technique is stent occlusion, associated with recurrent jaundice and sepsis. This requires stent replacement every 3 to 4 months in up to two-thirds of patients. Metal stents have a larger diameter and may last longer.

About one-third of patients with cancer of the head of the pancreas eventually develop gastric outlet obstruction, which is treated effectively by a gastrojejunostomy (Fig. 30-20). If obstruction is not present at the time of initial exploration and biliary bypass, there is some debate about whether gastrojejunostomy should be done prophylactically. Because it is difficult to predict which patients will obstruct later in the course of their disease, and it does not appear to increase the operative morbidity or mortality rates, many surgeons do perform gastrojejunostomy in patients who are expected to survive more than a few months.

Pain is a symptom in up to 80 percent of patients with pancreatic cancer, and its severity and persistence correlate well with the stage of the disease. This problem is managed best by chemical destruction of the celiac nerves, achieved by percutaneous injection of 50% ethanol into the region of the ganglia under CT guidance. This also can be done at operation. Adequate pain relief is possible in up to 80 percent of patients, although it often recurs. Celiac injection can be repeated if needed.

Adjuvant Therapy

Neither radiation nor chemotherapy given singly is effective. Radiotherapy combined with 5-fluorouracil given as a radiosensitizer has been shown to increase survival in both patients with resectable and those with unresectable disease.

Prognosis

Most patients with pancreatic cancer die within 1 year of the time that the diagnosis is made (Table 30-12). In patients with carcinoma of the head of the pancreas who have undergone resection, prognosis is related to whether lymph node metastases have already occurred. In patients with positive nodes, the 5-year survival rate is less than 10 percent; in those patients without nodal involvement, the 5-year survival rate is approximately 35 percent.

Carcinoma of the Ampulla of Vater

About 10 percent of periampullary cancers arise from the ampulla of Vater. These tumors produce symptoms that are similar to those seen in pancreatic cancer, although weight loss and pain are less prominent. Obstructive jaundice occurs early and is present in almost all patients because of the location of the lesion near the bile duct. Jaundice may fluctuate because as pieces of the tumor slough into the duodenal lumen, the degree of obstruction of the bile duct varies. The stools often contain occult blood from the ulcerating neoplasm. The lesion is visible by endoscopy if it extends into the duodenal lumen, and a tissue diagnosis can be obtained easily by biopsy. If the neoplasm resides entirely within the ampulla, the diagnosis of ampullary neoplasm may not be possible. It may be suspected if the ERCP or CT scan suggests that the obstruction is at the most distal point in the bile duct. Sometimes it may not be possible to distinguish an ampullary tumor from one that arises from the head of the pancreas, even at the time of operation. Because these tumors grow more slowly and tend to remain localized longer than pancreatic cancers, many more are resectable for cure. The treatment consists of pancreaticoduodenectomy, and the 5-year survival rate is 35 to 40 percent. Occasionally, in patients who are not candidates for the Whipple resection, local excision of the tumor through a duodenotomy may be indicated.

Cystic Neoplasms

Approximately 90 percent of primary malignant neoplasms of the nonendocrine pancreas are carcinomas of duct cell origin. Several types of cystic neoplasms also occur that may be confused with pseudocysts.

Papillary-cystic neoplasm of the pancreas is a rare lesion that occurs almost exclusively in women under 25 years of age. It is often large and may present as a hemorrhagic cystic tumor in the body or tail of the gland. Although it can be locally invasive, metastases are unusual, and resection is generally curative. *Serous (microcystic) cystadenomas* are the most common benign neoplasm of the exocrine pancreas, and they occur with equal distribution throughout the gland. Histologically, they appear as numerous, small cysts lined by flattened cuboidal epithelial cells. The cell cytoplasm contains glycogen but no mucin. The cystic spaces are filled with a serous material. The tumor has been likened to the cut surface of the lung, with multiple epithelium-lined cystic spaces analogous to alveoli. *Mucinous cystadenomas* are premalignant lesions that often evolve into *cystadenocarcinomas*, which are frankly malignant tumors. These are most common in the body or tail of the pancreas and are often quite large (e.g., 10 to 20 cm) when diagnosed. Most patients are women (8:1). The cellular lining consists of mucin-producing columnar epithelial cells. They take the form of papillary projections into the lumen of the cyst, giving it an irregular appearance.

Manifestations

The most common symptom of any of these tumors is vague abdominal discomfort. Obstructive jaundice occurs in fewer than 10 percent of patients. Anorexia, weight loss, and weakness may occur, particularly with cystadenocarcinoma. Radiographic studies may reveal calcification within the cyst (at least 10 percent of patients), which is an uncommon finding with pseudocysts. Barium studies of the stomach and duodenum may reveal displacement by the tumor mass. Angiography characteristically reveals hypervascularity, and arteriovenous shunting is frequently observed. The hypervascularity differentiates these cystic tumors from pseudocysts and the usual type of ductal adenocarcinoma, both of which are hypovascular. US and CT demonstrate multicystic tumors, sometimes with solid components.

Treatment

Surgery is usually indicated because of the concern that a cyst may be malignant and to manage symptoms that may be present. At operation, the diagnosis of malignancy may be difficult. Benign serous cystadenomas typically have a honeycombed appearance on cut section. They may contain hundreds of small cystic spaces that vary in diameter from a few millimeters to a centimeter. These lesions apparently have no malignant potential, but they should be excised if it can be done safely. They should *not* be drained internally. Both the benign and malignant neoplasms may be unilocular or multilocular. The most characteristic feature of the malignant cystadenocarcinoma is the viscid mucinous fluid it contains. This fluid has the gross appearance of raw egg white and can be strung like egg white for 6 to 12 in. between the instrument and the tumor. Examination of a frozen section is helpful but is not reliable in distinguishing benign from malignant stages unless it shows frank carcinoma or papillary projections, which are almost synonymous with malignancy. Whether or not overt malignancy is present, these macrocystic lesions should be excised, since there is a high likelihood that they will become malignant. During the resection of neoplastic cysts, efforts should be made to remove the tumor intact (rupture may disseminate cells). In order to be certain of the diagnosis in patients with presumed pseudocysts, a frozen-section diagnosis should always be obtained on a portion of the cyst wall before proceeding with internal drainage.

Prognosis

Cystadenocarcinomas have a better prognosis than the usual adenocarcinomas of the pancreas. Although precise statistics are unavailable because of the rarity of the lesions, resection of apparently localized tumors probably cures about two-thirds of patients.

Islet Cell Neoplasms

Insulinoma

Insulinoma arises from the beta cells and is the most common islet cell neoplasm. It produces insulin, and the symptoms are all related to hypoglycemia. The tumors may occur at any age and are found equally distributed throughout the pancreas. About 80 percent are solitary and benign, and about 40 percent are less than 1 cm in diameter. Fifteen percent are malignant, and metastases are usually evident at the time of diagnosis. Fewer than 5 percent of insulinomas are associated with the multiple endocrine adenopathies (MEA) syndrome; these are usually multiple and are distributed throughout the pancreas.

Clinical Manifestations

Symptoms related to cerebral glucose deprivation include bizarre behavior, memory lapse, and unconsciousness. Some patients have been mistakenly diagnosed with psychiatric or neurologic illness. Symptoms related to sympathetic discharge include palpitations, nervousness, sweating, and tachycardia. Many patients gain significant weight because symptoms are produced by fasting; consequently, they eat excessively to avoid this. The classic diagnostic criteria (*Whipple's triad*) are usually present. These include (1) hypoglycemic symptoms produced by fasting, (2) blood glucose concentration below 50 mg/dL during symptomatic episodes, and (3) relief of the symptoms during intravenous administration of glucose.

Diagnostic Studies

The most useful diagnostic test, and the one indicated in most patients, is the demonstration of fasting hypoglycemia in the face of inappropriately high levels of insulin in the serum. The patient is fasted, and blood samples are obtained every 6 h for blood glucose and insulin measurements. The fast is continued until hypoglycemia or symptoms appear or for a maximum of 72 h. By 48 h, over 95 percent of the tumors have been diagnosed. If hypoglycemia has not developed after 70 h, the patient should be exercised for the final 2 h. Although the insulin levels are not always elevated in patients with insulinoma, they will be high relative to the blood glucose concentration. A ratio of plasma insulin to glucose greater than 0.3 is diagnostic. Proinsulin, which constitutes more than 25 percent of total insulin in about 85 percent of patients with islet cell tumors, also should be measured. Very high proinsulin levels (>50 percent) suggest that the insulinoma is malignant.

Provocative tests using a variety of drugs that stimulate the release of insulin (e.g., tolbutamide, leucine, arginine) have been used in some patients, but they are diagnostic in only 50 percent of patients and are rarely indicated. A calcium infusion provocative test also may be of value.

Differential Diagnosis

Fasting hypoglycemia occurs with some nonpancreatic tumors as well, and the clinical picture may be identical with that seen with insulinoma. Plasma insulin levels are normal, however. In most cases, the nonpancreatic tumors are large and are readily detected with various diagnostic studies. The majority are of mesenchymal origin (e.g., hemangiopericytoma, fibrosarcoma) and are located in the abdomen or thorax, although hepatoma, adrenocortical carcinoma, and a number of other lesions also can produce hypoglycemia. The principal mechanisms by which these tumors produce hypoglycemia are (1) secretion by the tumor of somatomedins (insulin-like peptides that mediate the effects of growth hormone), which can be measured by specific radioimmunoassay, and (2) inhibition of gluconeogenesis or glycogenolysis. Surreptitious self- administration of

insulin is also seen, most often by individuals who have access to insulin in their job. Insulin antibodies are usually detectable in the serum if these individuals have been taking injections for at least 2 months. Circulating C-peptide levels are normal in these patients but usually are elevated in patients with insulinoma.

Treatment

Surgery should be undertaken promptly, since the tumor may be malignant and, with repeated attacks of hypoglycemia, permanent cerebral damage may occur.

Surgical Therapy

Because 10 to 20 percent of the tumors are not easily identified at operation, preoperative localization studies are helpful. CT scans are usually obtained, but the majority of lesions are not seen because of their small size. Selective angiography demonstrates the tumor in about 50 percent of patients. Percutaneous transhepatic venous catheterization allows sampling of blood draining from the pancreas at multiple sites along the splenic and portal veins. Insulin is measured in the samples, and the point where the insulin concentration rises sharply indicates the location of the tumor. If patients are receiving diazoxide, it should be discontinued for at least a week prior to operation because of the reported association with hypotension on induction of anesthesia.

At operation, the entire pancreas must be fully mobilized and carefully palpated to find the tumor. Intraoperative US also should be done. If the tumor is found, it should be enucleated if it is superficial. If it is deeply situated, it should be removed as part of a partial pancreatectomy. Tumors in the head of the gland can nearly always be enucleated, so a pancreaticoduodenectomy is not often indicated. If the tumor cannot be found, and the results of venous sampling studies suggest its location, that portion of the pancreas should be resected. Under these circumstances, a Whipple resection may be appropriate if these studies indicate that the tumor is in the head of the gland. If no such localizing information is available, it is common practice to remove the distal half of the pancreas and have a pathologist slice the specimen into thin sections to look for the tumor. If it is found, the operation is concluded. If not, more is removed until an 80 percent distal pancreatectomy has been done. Since the tumors are evenly distributed, this confers an 80 percent probability of cure.

For islet cell hyperplasia, nesidioblastosis, or multiple benign adenomas, distal subtotal pancreatectomy is indicated to sufficiently decrease insulin levels so that medical management can be more effective. For malignant insulinomas, both resection of the primary tumor and debulking of metastases are warranted if technically feasible and safe.

Medical Therapy

Frequent feedings supplemented with a slowly absorbed form of carbohydrate such as cornstarch may be helpful, but usually patients require treatment with diazoxide, which suppresses the release of insulin. Fewer than two-thirds of patients are controlled successfully with this agent, and many develop significant adverse reactions that include hirsutism and salt and water retention. For incurable islet cell tumors, streptozocin appears to increase survival, with 60 percent of patients living an additional 2 years. Toxicity of the drug is considerable, however, so streptozocin is not used routinely as an adjuvant to surgical therapy.

Gastrinoma (Zollinger-Ellison Syndrome)

The principal manifestations of the Zollinger-Ellison syndrome are due to gastric acid hypersecretion caused by excessive gastrin production by the tumor. Although the normal pancreas does not contain gastrin-producing cells, most gastrinomas arise in the pancreas. The others are found chiefly in the duodenum. In the pancreas, about 60 percent of gastrinomas are non-beta islet cell carcinomas, 25 percent are solitary adenomas, and 10 percent are microadenomas or hyperplasia. About 5 percent of gastrinomas occur in the first or second part of the duodenum. One- quarter of gastrinomas are associated with the *multiple endocrine neoplasia type I (MEN I)* syndrome, in which case the tumors are usually multiple and benign. Those without MEN I (sporadic gastrinomas) are more often single and malignant. The diagnosis of malignancy requires the histologic demonstration of blood vessel invasion or the finding of metastatic disease, since the cellular characteristics of benign and malignant lesions are similar. Even when malignancy is present, the tumors are often slow-growing and compatible with a long survival, however. Thus the principal threat to life is the severe peptic ulcer diathesis that the hypergastrinemia provokes, and this is the main focus of therapy.

Clinical Manifestations

Symptoms of gastrinoma are chiefly those of gastric acid hypersecretion: severe, refractory peptic ulcer disease and, often, diarrhea. The diarrhea results from fat malabsorption, since the excessive quantities of gastric acid destroy pancreatic lipase. In addition, the acid damages the small bowel mucosa, and the intestine is overwhelmed with large volumes of gastric and pancreatic secretions. About 5 percent of patients present with diarrhea alone. The diagnosis should be suspected when (1) patients present with ulcer disease that is refractory to the usual forms of acid antisecretory therapy (antacids and H₂-receptor antagonists), (2) patients present with multiple ulcers or ulcers in unusual locations (e.g., third-fourth portion of duodenum, proximal jejunum), and (3) ulcers recur after surgical procedures that would normally cure the ulcer diathesis.

Diagnostic Studies

The diagnosis of gastrinoma requires the demonstration of fasting hypergastrinemia (>200 pg/mL of blood) in the face of gastric acid hypersecretion (basal acid output >15 mEq/h with an intact stomach or >5 mEq/h after ulcer surgery). Most patients with gastrinoma have serum gastrin values that exceed 500 pg/mL, and some are as high as 10,000pg/mL. When the serum gastrin level is in the range 200 to 500pg/mL, however, a secretin provocative test is usually done to confirm the diagnosis. Following 2 units/kg secretin (bolus, I.V.), a rise in the serum gastrin level of 200 pg/mL within 15min or a doubling of the fasting gastrin level is diagnostic. An upper gastrointestinal series will reveal the ulcers, and in the stomach, prominent rugal folds and excessive luminal secretions are often seen. The duodenum and small bowel may be hyperactive, with edema in the bowel wall and accelerated transit time. A CT scan should be done in all patients, and it often shows the tumor. If not, angiography with portal venous sampling to find “hot spots” of gastrin may be helpful.

Differential Diagnosis

The differential diagnosis of gastrinoma includes gastric outlet obstruction, retained antrum after a Billroth II gastrectomy, and antral G cell hyperplasia, all of which are characterized by hypergastrinemia and acid hypersecretion. In these conditions, the secretin test is negative.

Treatment

Medical Treatment

The medical treatment of gastrinoma is directed at control of the acid hypersecretion. Although H₂-blocking agents (cimetidine, ranitidine) may be effective, because of its long duration of action, omeprazole (a proton pump blocker) is the drug of choice. The dose should be adjusted to keep the H⁺ output less than 5 mEq during the hour preceding the next dose. Over 90 percent of patients are adequately controlled in this fashion. In patients with malignant gastrinoma, a combination of streptozocin and fluorouracil, with or without doxorubicin, may be effective.

Surgical Treatment

All patients with sporadic gastrinoma should undergo surgical exploration, unless there is evidence of extensive metastatic disease. Because patients with gastrinoma and MEN I syndrome have multiple small pancreatic tumors that cannot all be resected, surgery is generally not indicated (Fig. 30-21).

At operation, if the tumor is found in the pancreas, it should be enucleated if possible. If not, a distal pancreatectomy may be required. Pancreaticoduodenectomy is rarely indicated. Ninety percent of the tumors are found in the triangle defined by the junction of the cystic and common bile ducts, the junction of the second and third portions of the duodenum, and the junction of the neck and the body of the pancreas (“gastrinoma triangle”). US may be useful to detect small lesions deep within the substance of the gland. Intraoperative endoscopy to transilluminate the duodenal wall may help to find duodenal tumors that otherwise would escape attention. These tumors are often very small. Resection of lymph nodes that contain gastrinoma appears to have cured some patients of the syndrome, with serum gastrin concentrations returning to normal. In about a third of patients, the tumor is never identified at operation.

Total gastrectomy should be done in patients whose ulcer disease is refractory to medical therapy and who are unable to undergo resection of the tumor because of multiple hepatic metastases or the MEN I syndrome.

VIPoma (Verner-Morrison Syndrome; WDHA Syndrome: Watery Diarrhea, Hypokalemia, and Achlorhydria; Pancreatic Cholera)

Eighty to ninety percent of cases of WDHA syndrome are caused by an islet cell tumor of the pancreas that secretes VIP. The rest are associated with tumors in extrapancreatic sites such as the retroperitoneal sympathetic chain and the adrenal medulla.

Clinical Manifestations

The syndrome is characterized by a profuse watery diarrhea that contains large quantities of potassium, resulting hypokalemia (often 2 to 3 mEq/L), and profound weakness. Some gastric acid secretion is present in about half the patients; in the rest it is absent. Stool volume can be as great as 10 L/day but averages about 5 L/day during acute episodes. It contains over 300 mEq potassium (20 to 25 times normal) and resembles dilute tea. The diarrhea is “secretory” in nature; it persists during fasting and does not respond to antidiarrheal agents. Severe metabolic acidosis is common from loss of bicarbonate in the stool. Many patients are hypercalcemic, perhaps because the tumor also secretes a parathormone-like substance. Abnormal glucose tolerance may be the result of hypokalemia and altered sensitivity to insulin. Flushing is a prominent feature in about 15 percent of patients, usually in association with a bout of diarrhea. Up to 50 percent of the pancreatic tumors are malignant, and 75 percent of those have already metastasized by the time of diagnosis.

Diagnostic Studies

Patients with severe diarrhea must be studied carefully before attributing the cause to VIPoma. Chronic laxative abuse is the most common explanation. The specific diagnosis requires the demonstration of elevated fasting plasma VIP concentration by radioimmunoassay; plasma VIP levels are normal in other diarrheal states. Plasma PP and prostaglandin levels also should be measured, since some people with the syndrome have had elevations in the level of these substances, while VIP levels were normal. CT scan and then angiography should be used to localize the tumor. Transhepatic portal and splenic venous sampling also may be helpful.

Treatment

The immediate goal of management is the correction of dehydration and electrolyte abnormalities, especially hypokalemia. Once the diagnosis is suspected, a trial of somatostatin is indicated. This should control the diarrhea during the preoperative preparation and performance of the diagnostic studies. At operation, the tumor should be resected, and if metastases are present, they should be debulked. Plasma VIP concentrations should return to normal if all the tumor has been removed. If no pancreatic tumor is identified, the adrenal glands and sympathetic chains should be explored. If no tumor is found anywhere, a distal 80 percent pancreatectomy should be performed. In some patients with diffuse islet cell hyperplasia, symptoms have improved with this strategy.

In patients with inoperable or metastatic malignant tumors in whom complete resection is not possible, streptozocin alone or in combination with 5-fluorouracil may be effective. Almost all tumors respond initially, and a few long-term remissions have been noted. Renal function must be monitored carefully when streptozocin is used; selective arterial administration of the drug is preferred when renal function is impaired. In patients for whom no definitive therapy is possible, symptomatic relief has been reported with several agents, including high-dose steroids, trifluoperazine, and somatostatin. The tumors appear to be radioresistant.

Patients with benign tumors are cured by surgical excision. The average survival rate for patients with malignant tumors is approximately 1 year.

Glucagonoma

These tumors arise from a2cells in the islets. They produce a distinctive syndrome consisting of a migratory necrolytic dermatitis usually involving the legs and perineum, weight loss, stomatitis, hypoaminoacidemia, anemia, and mild diabetes mellitus. Visual scotomata may occur. An increased tendency to venous thrombosis and pulmonary emboli also has been reported. The condition is more common in women, and the age range is 20 to 70 years. The diagnosis is confirmed by demonstrating elevated plasma glucagon levels. The tumor should be localized with CT scans and arteriography, if necessary. About 25 percent of glucagonomas are benign. The majority are malignant and have metastasized by the time of diagnosis, however. The most common sites are the liver, lymph nodes, adrenal gland, or vertebrae. A few cases of the syndrome have been due to islet cell hyperplasia.

Treatment

Surgical excision of the primary tumor and debulking of metastases are indicated. Oral zinc supplements may improve the dermatitis. Somatostatin has been reported to return serum glucagon and amino acid levels to normal, clear the rash, and promote weight gain. Streptozocin and dacarbazine are the most effective chemotherapeutic agents.

Somatostatinoma

Somatostatin-producing tumors of the islet cells are characterized by mild diabetes mellitus, malabsorption and diarrhea, and dilatation of the gallbladder, often with cholelithiasis. Weight loss also may be prominent. Most of the tumors are located in the head of the pancreas and are malignant, with metastases to the liver at the time of exploration. CT scan usually shows a mass in the pancreas, with evidence of spread to the liver. The plasma levels of somatostatin are elevated, confirming the diagnosis.

The clinical manifestations are the result of the physiologic actions of the peptide. Inhibition of insulin release produces the diabetic state. Because glucagon release is also suppressed, the diabetes is easy to control. Cholelithiasis results from inhibition of gallbladder motility. Decreased biliary and pancreatic secretions probably cause the malabsorption.

Surgery may be indicated if the disease appears to be localized. More often, chemotherapy with streptozocin, dacarbazine, doxorubicin, etc. is the only treatment possible.

Miscellaneous Neoplasms

Because the pancreatic islets are part of the APUD (amine precursor uptake and decarboxylation) system, they retain the potential to produce a variety of neoplasms with multiple secretory products. For example, MEN I syndrome (Werner's syndrome) is a syndrome complex associated with tumors or hyperplasia in two or more of the endocrine glands. It involves the pancreas (81 percent), parathyroid (87 percent), pituitary (65 percent), and less frequently, the adrenal cortex (38 percent) and thyroid glands (19 percent). When the pancreas is involved, it usually becomes evident clinically later than does the parathyroid disorder (hyperparathyroidism is diagnosed in most patients before 40 years of age). In the pancreas, gastrinomas are most common, followed by insulinomas. Less often, the pancreatic tumors may secrete VIP, glucagon, pancreatic polypeptide, calcitonin, or 5-hydroxytryptophan (carcinoid-islet cell tumor). MEN I syndrome is present in about 25 percent of patients with gastrinoma and about 4 percent of all patients with insulinoma. Whatever the predominant cell type, the tumors are usually multicentric.

TRAUMA

Because of its protected retroperitoneal position, pancreatic injury only occurs with deep penetrating wounds or blunt trauma of significant force. Injury to the pancreas must be considered, however, in all patients who sustain injury to the upper abdomen. The diagnostic approach varies with the mechanism of injury. With penetrating trauma, almost all patients are operated on, and the diagnosis of pancreatic injury is made at the time of exploration. The diagnosis of blunt injury requires a high degree of clinical suspicion, since there may be few symptoms during the initial phases of management. In the first several days, the majority of patients will eventually develop epigastric and/or back pain, nausea, vomiting, ileus, and tenderness to abdominal palpation. Although the serum amylase concentration may be normal early, it eventually becomes elevated in 80 percent of patients. An elevated amylase level by itself is generally not an indication for surgical exploration, however. The decision to operate should be supported by evidence from physical examination or CT scan. CT may show fluid in the area of the pancreas or pancreatic ductal or parenchymal disruption. Because significant pancreatic injury may be missed by CT, it should be used primarily in patients in whom there is suspicion of injury, and operation is planned only if test results are positive. Diagnostic peritoneal lavage may be valuable, since many patients with pancreatic injury also have associated visceral injury that will result in a positive lavage.

Minor contusions and lacerations of the pancreas without evidence of ductal injury require only the control of hemorrhage and external drainage. Deeper lacerations or crush injuries with ductal injury and/or devitalization of the gland are best managed by distal resection of the injured gland and external drainage. Injuries to the head of the gland with significant damage to the duodenum and adjacent structures occasionally require a pancreaticoduodenectomy. However, even the majority of injuries to this area can be managed more conservatively.

Pancreatic trauma is associated with significant morbidity (e.g., pancreatic fistula in 10 percent and infection) and a mortality rate of about 20 percent. Most deaths are due to massive hemorrhage from erosion of adjacent vessels.

CHAPTER 31 - Spleen

Seymour I. Schwartz

ANATOMY

The spleen arises by mesenchymal differentiation along the left side of the dorsal mesogastrium in the 8-mm embryo. The weight of the spleen in the healthy adult ranges between 75 and 100 g, decreasing somewhat with age. The organ is located in the left upper quadrant, having a superior relationship to the undersurface of the left leaf of the diaphragm and protected anteriorly, laterally, and posteriorly by the lower portion of the rib cage. Its position is maintained by several suspensory ligaments, the major ones being the splenophrenic, splenorenal, splenocolic, and gastrosplenic ligaments. The gastrosplenic ligament normally contains the short gastric vessels, while the remaining ligaments are generally avascular, except in patients with portal hypertension, when collateral veins become apparent. Arterial blood enters the spleen via the splenic artery, a branch of the celiac artery. The major venous drainage courses through the splenic vein, which joins the superior mesenteric vein to form the portal vein.

Accessory spleens have been reported in 14 to 30 percent of patients, with a higher incidence occurring in patients operated on for hematologic disorders. These accessory organs, which receive their vascular supply from the splenic artery, are present, in decreasing order of frequency, in the hilus of the spleen, the gastrosplenic and splenocolic ligaments, the gastrocolic ligament, the splenorenal ligament, and the greater omentum (Fig. [31-1](#)). They also may occur in the pelvis of the female, and functioning splenic tissue has been removed from the scrotum in juxtaposition to the left testicle.

The spleen consists of a capsule that is normally 1 to 2 mm thick and trabeculae that enclose the pulp. The pulp itself has conventionally been divided into three zones: white, marginal, and red. Peripheral to the white pulp is the marginal zone, which contains end arteries arising from the central artery and from the penicillary arteries. The marginal zone contains lymphocytes, macrophages, and some red cells that have exited the terminal arteries. The marginal zone contains the marginal sinus, which filters material from the white pulp. Locally produced immunoglobulins enter this sinus and course to the peripheral circulation. Peripheral to the marginal zone is the red pulp, which consists of cords and sinuses that contain cellular elements of blood in transit.

Blood brought to the spleen via the splenic arteries courses through branches, the trabecular arteries, that leave the trabeculae and enter the white pulp as central arteries (Fig. [31-2](#)). These central arteries give off at right angles numerous arterioles, some of which terminate in the white pulp. The perpendicularity contributes to a skimming effect by which plasma exits while most red cells pass to the red pulp. Other branches cross the white pulp and end in the marginal zone or in the red pulp itself. The branch of the central artery that terminates in the red pulp, known as the "artery of the pulp," breaks up into many branches. Within the red pulp, the blood is collected in splenic sinuses. These large, thin-walled venous spaces drain into the pulp veins, which in turn drain into the trabecular veins and then into the main splenic veins to enter the portal circulation. Thus splenic pulp pressure reflects pressure throughout the portal venous system. The tissue between the splenic sinuses is a reticular, connective tissue meshwork that appears as cords on histologic section, and hence is designated the "splenic cords." At points of passage from cords to sinuses, deformability and flexibility are demanded of the red blood cells so that they can squeeze through. Although these fenestrations are of small diameter (0.5 to 5.0 mm), they are traversed by normal red cells, which easily adjust to these dimensions. Under normal conditions, 10 percent of red cells pass from terminal arterioles through arteriovenous connections; 90 percent of cells course from terminal arterioles into pulp cords and into splenic sinuses after traversing the cordal-sinus wall apertures. The total splenic blood flow averages 300 mL/min.

PHYSIOLOGY AND PATHOPHYSIOLOGY

(Fig. [31-3](#))

Galen is credited with the phrase "The spleen is an organ full of mystery." During the fifth to eighth month of fetal life, the spleen contributes actively to the production of both red cells and white cells that enter the circulation. This function does not continue in the normal adult. The role of the spleen in the immunologic processes of the body is discussed in Chap. [31-3](#). The splenic function that is the focus of surgical attention is related to the organ's reticuloendothelial tissue, which contributes to the removal of cellular elements from the circulating blood. Normally, cells pass through the spleen rapidly, but in the presence of splenomegaly and other disease states, the flow patterns become circuitous, contain more obstacles, and result in pooling of cells within the cords.

Abnormal and aged erythrocytes, abnormal granulocytes, normal and abnormal platelets, and cellular debris may be cleared by the spleen, which apparently is capable of discriminating between these and normal cellular components. In the normal adult, the spleen is the most important site of selective erythrocyte sequestration, and during its 120-day life cycle, the red cell spends an estimated minimum of 2 days within the spleen.

The action of the spleen that results in the pathologic reduction of circulating cellular elements of blood has been attributed to two possible mechanisms: (1) excessive splenic destruction of cellular elements, and (2) splenic production of an antibody that results in the destruction of cells within the circulating blood. Overactivity of splenic function leading to accelerated removal of any or all of the circulating cellular elements of the blood with resultant anemia, leukopenia, or thrombocytopenia, alone or in combination, is referred to as *hypersplenism*.

The normal adult spleen contains about 25 mL of red blood cells, but relatively few of these are removed during a single passage through the organ. The spleen is capable of removing nuclear remnants (Howell-Jolly bodies) from circulating erythrocytes. The postsplenectomy blood smear is characterized by the presence of circulating erythrocytes with Howell-Jolly bodies and Pappenheimer bodies (siderotic granules that stain with Wright's stain) as a result of the loss of the pitting function of the spleen.

During the course of a day, approximately 20 mL of aged red blood cells are removed. Aging changes the biophysical properties of the red cell, making splenic entrapment of red cells that have circulated for 105 to 120 days more likely. Delay in splenic transit of aged or abnormal cells can lead to further cell injury because of the relatively hypoxic, acidotic, and substrate- (glucose-) deprived environment that is present in congested splenic red pulp cords. These environmental conditions lead to further physical and chemical deterioration of the erythrocyte, making it more susceptible to phagocytosis by splenic macrophages and reticuloendothelial cells or to intrasinusoidal disintegration. The central event in cytolysis may be the fall in cellular *adenosine triphosphate (ATP)* to very low levels and the loss of vital cellular functions dependent on ATP, such as sodium and calcium efflux, priming of glycolysis, and maintenance of membrane integrity. To what extent repeated passages through the spleen contribute to normal red cell aging is not certain, but evidence that the red cell loses surface area with aging, combined with the ability of the spleen to remove bits of red cell with surgical precision, raises this possibility. On the other hand, a normal red cell life span in splenectomized subjects suggests that red cell aging occurs independently of splenic presence and at approximately the normal rate. A variety of erythrocytes altered by intrinsic factors (membrane, hemoglobin, or enzymic abnormalities) or extrinsic factors (antibody and nonantibody injury) may be prematurely removed by the spleen. Severely damaged cells may be removed by the reticuloendothelial system at a variety of sites. Minimally altered erythrocytes may require the specific rigors of the splenic circulation for premature destruction and therefore may have normal or near-normal survival after splenic removal.

The neutrophil is removed from the circulation with a half-life of about 6 h. Although the role of the spleen in the destruction of neutrophils under normal conditions is not well quantified, in some hypersplenic states the spleen's role is augmented, with resulting neutropenia. This augmented removal can occur because of splenic enlargement and sequestration of granulocytes or because of enhanced splenic removal of altered granulocytes, as seen in immune neutropenias.

The platelet (thrombocyte), under normal circumstances, survives about 10 days in the circulation. One-third of the total platelet pool is normally sequestered in the spleen, but the role of the spleen in the final removal of normal platelets has not been precisely defined. With splenomegaly, a larger proportion of platelets is sequestered in the spleen (up to 80 percent), and this and accelerated platelet destruction in the spleen account for thrombocytopenia. Increased sequestration and destruction of platelets occur in the absence of splenomegaly in patients with *idiopathic thrombocytopenic purpura (ITP)* as a consequence of immunologic alteration of the platelets. In thrombotic thrombocytopenic purpura (TTP), platelets are sequestered in the spleen because of encroachment of the vascular lumen by increased subendothelial collagen.

Splenectomy results in an increase in platelets, which at times reach levels greater than 1,000,000/mm³. Postsplenectomy thrombocytosis is usually transient but may persist. This is particularly notable in congenital hemolytic states that do not respond well to splenectomy. In these circumstances, continued hemolysis in the absence of the splenic removal mechanism can lead to persistent, extreme thrombocytosis and intravenous thrombosis.

DIAGNOSTIC CONSIDERATIONS

Evaluation of Size

Normally the spleen is not palpable on abdominal examination, but the organ may be felt in about 2 percent of healthy adults. In healthy subjects, no significant dullness is elicited by percussion over the spleen either anteriorly or laterally. As the organ enlarges, dullness may be detected at the level of the ninth intercostal space in the left anterior axillary line, especially on expiration. Thereafter, it becomes first percussible and then palpable below the left costal margin. With increasing splenomegaly, notching may be palpable on the anteromedial surface, distinguishing the spleen from other abdominal masses.

Routine radiologic examination of the abdomen usually provides an accurate estimate of the size of the spleen. Although splenomegaly may be suggested by medial or caudad displacement of the stomach bubble, frequently accompanied by caudad displacement of air in the splenic flexure of the colon, the organ's outline can often be clearly demarcated in the left upper quadrant, corroborating enlargement. Computed tomography (CT) and magnetic resonance imaging (MRI) depict the spleen and define abnormalities in size, shape, and parenchymal pathology, i.e., cyst, abscess (Fig. [31-4](#)), or tumor. Radioisotopic scanning with ^{99m}Tc-sulfur colloid also defines the organ; vascular shunts that allow blood to bypass splenic phagocytes interfere with the procedure.

Evaluation of Function

The functional abnormality of hypersplenism may be manifested by a reduction in the number of red cells, neutrophils, or platelets in the peripheral blood. An increase in the rate of red cell destruction will always result in a compensatory rise in the rate of production unless disease of the marrow coexists. The hallmark of increased red cell turnover (hemolysis) is reticulocytosis in the absence of blood loss. Other tests such as measurement of the plasma bilirubin, haptoglobin, and hemoglobin levels are less sensitive and are dependent on the rate and sites of hemolysis as well as on liver function, and are therefore only of adjunctive value.

Reduced red blood cell survival in patients with hemolytic anemia may be more precisely demonstrated by measuring the disappearance of blood radioactivity after the patient's erythrocytes are labeled with Na₂⁵¹CrO₄. With this technique, the normal half-life of the red cells is about 30 days (i.e., 50 percent of the cells remain in the circulation at that time). A half-life of 15 days or less indicates significantly increased hemolysis. The spleen's role in a hemolytic anemia may be assessed by determining the relative uptakes of ⁵¹Cr-tagged erythrocytes by the spleen and the liver. A spleen-liver ratio greater than 2:1 indicates significant preferential splenic sequestration and anticipates a beneficial effect of splenectomy.

Radioisotopic labeling also has been used to evaluate the survival of neutrophils and platelets. There is no clinically practical method of assessing the decreased longevity of

neutrophils or of measuring the role of the spleen in the destruction of these cells. Platelet destruction in the spleen is such a common mechanism in thrombocytopenia that radioisotopic studies are not often done if the bone marrow aspirate indicates an abundance of megakaryocytes, suggesting adequate platelet production.

Rupture of the Spleen

(see Chap. 6)

HEMATOLOGIC DISORDERS FOR WHICH SPLENECTOMY IS THERAPEUTIC

In 1887 Sir Spencer Wells operated on a patient with the preoperative diagnosis of a uterine fibroid, but instead he noted a “wandering spleen,” which he removed. The patient later proved to have hereditary spherocytosis; thus the first surgical cure of a hematologic disorder was inadvertent and became manifest postoperatively when the patient's anemia and chronic jaundice disappeared. Micheli is generally given credit for introducing the concept of splenectomy as treatment for hemolytic anemia in an article published in 1911. Kaznelson, as a medical student in Prague, proposed to Schloffer, a professor of surgery, splenectomy to treat idiopathic thrombocytopenic purpura in a 36-year-old woman. The case, and the successful elevation of the platelet count to above-normal levels, was reported four weeks after the procedure in 1916.

Hemolytic Anemias

Hemolytic anemias include a broad spectrum of disorders in which there is accelerated destruction of mature red blood cells. The congenital anemias are due to an intrinsic abnormality of the erythrocytes, and the acquired anemias are related to an extracorpuscular factor acting on an intrinsically normal cell. In both types of disorder, the reduced red blood cell survival may be demonstrated by measuring the disappearance of the patient's radioactive erythrocytes (labeled with ⁵¹Cr), and the spleen's role may be evaluated by determining the relative uptakes of this radioactivity by the spleen and liver.

Hereditary Spherocytosis

Hereditary spherocytosis is transmitted as an autosomal dominant trait and is the most common of the symptomatic familial hemolytic anemias. Ovalocytosis and stomatocytosis usually exist as harmless traits, but occasionally, when these forms constitute 50 to 90 percent of the red cell population, clinical manifestations indistinguishable from those noted with hereditary spherocytosis may occur. The fundamental abnormality stems from a defective erythrocyte membrane that causes the cell to be smaller than normal, unusually thick, and almost spherical. These cells also demonstrate increased osmotic fragility, i.e., lysis occurs at a higher concentration of sodium chloride than normal. The role of the spleen in this disorder is related to the inability of the spherocytic cells to pass through the splenic pulp. The cells that escape from the spleen are more susceptible to trapping and disintegration during each successive passage, until cell loss ensues. The precise pathogenesis of the cell injury may be related to a decreased availability of red cell *ATP in the environment of the spleen, combined with a cell membrane that has been shown in in vitro studies to be more susceptible to reduction in ATP levels.*

The salient clinical features of the disease are anemia, reticulocytosis, jaundice, and splenomegaly. It is unusual for the anemia to be extremely severe, and the jaundice usually parallels the severity of the anemia. Periodic and sudden increases in the intensity of the anemia and jaundice may occur, and rare fatal crises have been reported. Cholelithiasis with gallstones of the pigmented variety has been reported in 30 to 60 percent of patients but is rare in children under the age of ten. Leg ulcers are uncommon specific manifestations.

Diagnosis is generally established by peripheral blood smear analysis, which demonstrates that more than 60 percent of the red blood cells are spherocyte-shaped with a mean diameter less than normal and a thickness greater than normal. Increased osmotic fragility of the red blood cells provides diagnostic confirmation, but this test is rarely performed.

Splenectomy is the sole therapy for hereditary spherocytosis and ovalocytosis. It is generally recommended that the operation be delayed until the fourth year of life. Intractable leg ulcers associated with hereditary spherocytosis mandate early splenectomy because they heal only after the spleen has been removed. The results of splenectomy as a method of correcting anemia and preventing hemolysis have been uniformly good. Although the inherent membrane abnormality persists and the spherocytosis and increased osmotic fragility of the cells are not altered, in vivo hemolysis virtually ceases, and following removal of the spleen, the erythrocytes achieve a normal life span and the jaundice, if present, disappears. It is appropriate to perform an oral cholecystogram or ultrasonogram prior to splenectomy, and the gallbladder should always be examined at the time of operation. If gallstones are present, the gallbladder should be removed during the operation.

Thalassemia

Thalassemia (Mediterranean anemia) is transmitted as a dominant trait and primarily derives from a defect in hemoglobin synthesis. The development of intracellular precipitates (Heinz bodies) contributes to premature red cell destruction. The disease is classified as alpha, beta, and gamma types, determined by the specific defect in synthesis rate of the peptide chain. In the United States, most thalassemia patients are of southern European origin and suffer from beta thalassemia, i.e., a quantitative reduction in the rate of beta chain synthesis, resulting in a decrease in hemoglobin A (Hb-A). Thalassemia occurs in two major degrees of severity: homozygous thalassemia (thalassemia major), a severe disorder in which the affected child receives a gene for thalassemia from each parent, and heterozygous thalassemia (thalassemia minor), a mild disorder in which the affected child receives a gene from only one parent. Gradations of thalassemia range from heterozygous thalassemia (minor), often not detected until examination of the blood for an unrelated problem, to homozygous thalassemia, a severe, chronic anemia, with icterus, splenomegaly, and death early in life. In thalassemia minor, Hb-A₂ is always increased, and slight increases in Hb-F occur in 50 percent of patients. In both types of thalassemia, the hemoglobin-deficient cells are small, thin, and misshapen. The cells appear washed out and have a characteristic resistance to osmotic lysis.

The clinical manifestations of thalassemia major usually occur in the first year of life and consist of pallor, retarded body growth, and enlargement of the head. Intractable leg ulcers may be noted, intercurrent infections are common, and gallstones are reported in about one-fourth of patients. The manifestations of thalassemia minor may vary. Most patients with thalassemia minor lead normal lives, but some patients have a more severe expression of their disease (referred to as thalassemia intermedia) and generally present with signs and symptoms attributable to mild anemia, chronic mild jaundice, and moderate splenomegaly.

The diagnosis of thalassemia major is established by the peripheral blood smear, which reveals hypochromic, microcytic anemia with markedly distorted red cells of various sizes and shapes. Nucleated red cells, or “target cells,” are invariably present, and the reticulocyte count is elevated, as is the white cell count. The characteristic feature of the disease is the persistence of Hb-F and reduction of Hb-A levels, demonstrated by the alkali denaturation study. It is important that both parents have evidence of thalassemia minor.

Treatment is indicated only for symptomatic patients. Transfusions are usually required at regular intervals, but as most patients accommodate to low hemoglobin levels, the transfusions should be directed at maintaining the hemoglobin level at 10 g/dL. Although splenectomy does not influence the basic hematologic disorder, it may reduce both the hemolytic process and the transfusion requirements. Marked splenomegaly and/or symptomatic repeated splenic infarction also constitute indications for splenectomy. A postoperative complication rate of 43 percent following splenectomy in thalassemia is contrasted with 3 percent in patients undergoing splenectomy for other reasons; overall, however, the benefit- to-risk ratio favors splenectomy when indications are present.

Hereditary Hemolytic Anemia with Enzyme Deficiency

Included in this category are (1) enzyme deficiencies in anaerobic glycolytic pathways, the prototype of which is pyruvate-kinase (PK) deficiency, and (2) enzyme deficiencies in the hexose monophosphate shunt, the prototype of which is glucose-6-phosphate (G-6-PD) deficiency. These deficiencies render the cells susceptible to increased hemolysis. Splenic enlargement occurs more frequently with PK deficiency, and the spleen is rarely enlarged in patients with G-6-PD deficiency. Specific enzyme assays are employed to define the deficiency.

The majority of patients maintain hemoglobins greater than 8 g/dL, are asymptomatic, and do not require therapy. With significant anemia, blood transfusions are indicated, and the transfused cells survive normally. ⁵¹Cr- tagged red cell studies are not predictive of results with a high enough degree of accuracy to be useful. In severe cases of PK deficiency, splenectomy may be worthwhile. In patients with this disorder postoperative thrombocytosis with consequent hepatic, portal, or inferior vena caval thrombosis may occur if the hemolytic rate is unabated. Splenectomy is not indicated for patients with G-6-PD deficiency.

Hereditary High Red Cell Phosphatidylcholine Anemia (HPCA)

When patients with HPCA have undergone splenectomy, the anemia worsens and the hemolysis is unchanged.

Sickle Cell Disease

Sickle cell anemia is a hereditary hemolytic anemia seen predominantly in blacks and characterized by the presence of sickle- and crescent-shaped erythrocytes. In this hereditary hemoglobinopathy, the normal Hb-A is replaced by the abnormal form of hemoglobin, sickle hemoglobin (Hb-S). Hb-F is usually mildly increased. Combinations of Hb-S with other hemoglobin variants also occur as a result of an abnormal trait inherited from each parent, e.g., Hb-S/Hb-C or Hb-S/thalassemia.

Under conditions of reduced oxygen tension, Hb-S molecules undergo crystallization within the red cell, which elongates and distorts the cell. The sickling phenomenon occurs more readily with higher percentages of Hb-S, with a reduced pH, and under conditions of circulatory stasis that tend to exaggerate hemoglobin deoxygenation. The sickle cells themselves contribute to increased blood viscosity and circulatory stasis, thus establishing a vicious cycle. The primary consequence of this stagnation is thrombosis, which leads to ischemia, necrosis, and organ fibrosis.

The role of the spleen in this disorder is not clear. Early in the course of the disease, splenomegaly occurs, but following varying intervals in most patients, the spleen undergoes infarction and marked contraction with eventual autosplenectomy.

Although the sickle cell trait occurs in approximately 9 percent of the black population, the majority are asymptomatic. However, sickle cell anemia has been observed in 0.3 to 1.3 percent of blacks, who often show remarkable adaptation to the state of chronic anemia and jaundice. This adaptive state may be interrupted at intervals by acute symptoms or crises that are related to vascular occlusion. Depending on the vessels involved, the patient may have bone or joint pain, hematuria, priapism, neurologic manifestations, or ulcers over the malleoli. Abdominal pain and cramps due to visceral stasis are frequent, simulating an acute surgical abdomen. Thrombosis of the splenic vessels may result in the unusual complication of splenic abscess, manifested by splenomegaly, splenic pain, and fever. Many patients with sickle cell anemia die in the first decade of life, but a few survive to the fifth decade. Death may be the result of intercurrent infections or cardiac or renal failure.

The diagnosis is established by the presence of anemia, characteristic sickle cells on peripheral blood smear analysis, hemoglobin electrophoresis showing 80 percent or more Hb-S, and the presence of the trait in both parents. Leukocytosis is often noted, and the platelet count is frequently elevated. There may be modest elevation of the serum bilirubin, and cholelithiasis is a frequent accompaniment.

For most patients only palliative treatment is possible. Sodium cyanate will prevent sickling of Hb-S. Transfusions may be required to maintain adequate hemoglobin levels. Adequate hydration and partial exchange transfusion may help during a crisis. Splenectomy may benefit patients with marked hypersplenism or splenic abscesses. In the circumstance of splenic abscess, incision and drainage of the abscess cavity within the parenchyma of the spleen may be necessary, since removal of the organ is hindered by marked inflammatory and adhesive processes. Splenectomy may be of benefit in a very few patients in whom acute splenic sequestration of red cells can be demonstrated, although the operation does not affect the sickling process. A report on forty-six children who underwent splenectomy for hypersplenism and fourteen patients operated on for acute splenic sequestration with a median follow-up of 6 years noted that two patients died of overwhelming sepsis; neither received prophylaxis, and neither pneumococcal septicemia nor meningitis was confirmed.

Idiopathic Autoimmune Hemolytic Anemia

This is a disorder in which the life span of a presumably normal erythrocyte is shortened when exposed to an endogenous hemolytic mechanism. The causation has not been defined, but an autoimmune process appears to be fundamental. In such patients, antibodies reacting with the patient's normal red cells have been defined, and there is evidence that the spleen may serve as a source of antibody. Both "warm" and "cold" antibodies have been described. Some "warm" antibodies have Rh specificity. Most of these antibodies are hemagglutinins rather than hemolysins. It is believed that the reticuloendothelial system traps and destroys the immunologically altered cells. Sequestration occurs primarily in the spleen. By binding the Fc portion of the IgG molecule to the corresponding macrophage surface Fc receptor, the spherocytes become more rigid and more sensitive to destruction in the splenic circulation.

Although autoimmune hemolytic anemia may be encountered at any age, it occurs more frequently after the age of fifty and twice as often in females. Mild jaundice is often present. The spleen is palpably enlarged in half the cases, and gallstones have been demonstrated in a quarter of the cases. The extent of anemia varies, and hemoglobinuria and tubular necrosis have been reported in severe cases. In this circumstance, the prognosis is serious, as the mortality rate is 40 to 50 percent.

The diagnosis of hemolysis is made by demonstrating anemia and reticulocytosis accompanied by the products of red cell destruction in the blood, urine, and stool. The bone marrow is hypercellular with a predominance of erythroid precursors. A distinguishing feature of the disease is the demonstration by direct Coombs' test of an autoantibody on the patient's red cells.

In some patients the disorder tends to run an acute, self-limited course, and no treatment is necessary. If the anemia becomes severe, corticosteroids or blood transfusions may be required. In the "warm" antibody immune hemolytic anemias, splenectomy should be considered (1) if steroids have been ineffective, (2) if excessive doses of steroids are required to maintain remission, (3) if toxic manifestations of steroids become apparent, and (4) if steroids are contraindicated for other reasons. Excessive splenic sequestration of ⁵¹Cr-tagged red cells offers a guide for the selection of patients who may respond to splenectomy. A favorable response is to be anticipated in about 80 percent of selected splenectomized patients. Patients without prominent spleen-liver sequestration ratios may respond to splenectomy. Late relapses may occur in splenectomized patients.

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (immune thrombocytopenic purpura) (ITP) is an acquired disorder caused by the destruction of platelets exposed to circulating IgG antiplatelet factors. The spleen is the source of these factors. It is also the major site for sequestering sensitized platelets. The term ITP should be reserved for a hemorrhagic disorder characterized by a subnormal platelet count in the presence of bone marrow containing normal or increased megakaryocytes and in the absence of any systemic disease or history of ingestion of drugs capable of inducing thrombocytopenia.

Female patients outnumber males at a ratio of 3:1. The most common presenting signs are petechiae and/or ecchymoses. ITP occurs in some patients who are HIV positive or who have acquired immunodeficiency syndrome (AIDS). In the majority of patients these signs are accompanied by one or several other symptoms, including, in order of frequency, bleeding gums, vaginal bleeding, gastrointestinal bleeding, and hematuria. In some patients the clinical manifestations take an almost cyclic course with exacerbations occurring at the time of menses. The incidence of central nervous system bleeding ranges between 1 and 2 percent and usually occurs early in the course of the disease. The spleen is rarely palpable, and its enlargement should evoke suspicion of the presence of another disease causing thrombocytopenia.

The characteristic laboratory findings include a platelet count generally reduced to 50,000/mm³ or less and in some patients approaching zero. Associated with reduced platelet count, the bleeding time may be prolonged, but the clotting time remains normal. There is usually no significant anemia or leukopenia. When ITP is accompanied by an autoimmune hemolytic anemia it is known as Evans's syndrome. Platelet survival time following the transfusion of ⁵¹Cr-labeled normal platelets is short, but this test is not necessary for establishing the diagnosis of ITP. Bone marrow examination reveals either a normal or an elevated megakaryocyte count with or without a relative increase in small forms. Qualitative changes in the megakaryocytes are characterized by degranulation of the cytoplasm, rounding of cytoplasmic edges, the disappearance of the usual pseudopodia containing granule-free platelets, and a varying degree of vacuolization of the cytoplasm.

Acute ITP has an excellent prognosis in children under the age of sixteen; approximately 80 percent of these patients will make a complete and permanent recovery without specific therapy. Much of the discussion regarding therapy for ITP centers on the relative values and disadvantages of steroid therapy and splenectomy. In most series, the results achieved by splenectomy are significantly more impressive than are the responses to steroids (Fig. 31-5). Between 75 and 85 percent of the total number of patients subjected to splenectomy respond permanently and require no further steroid therapy. The same rates are reported for patients with systemic lupus erythematosus and AIDS. No reliable predictive factors for satisfactory response to splenectomy have been uncovered. Opinions differ regarding a correlation between an initial response to steroid therapy and the efficacy of splenectomy. In most patients the platelet count rises to over 100,000/mm³ in 7 days. Rarely, return to normal levels may take months. Even in patients in whom the platelet count does not return to normal levels, recurrent petechiae or bleeding episodes are rare. A long-term follow-up of splenectomized patients does not support the contention that disseminated lupus erythematosus develops after this procedure.

The generally accepted protocol for managing patients with diagnosed ITP includes an initial 6-week to 2-month period of steroid therapy. Infusions of high doses of intravenous g-globulin and plasmapheresis have been used with limited permanent success. If the patient does not respond with elevation of the platelet count, splenectomy is performed. If the patient does respond, the steroid therapy is tapered off, and if thrombocytopenia recurs, splenectomy is carried out. The same criteria pertain to patients with AIDS or HIV positivity. Any manifestation suggestive of intracranial bleeding demands emergency splenectomy. In one series, five of six patients with ITP and life-threatening intracranial bleeding were saved by splenectomy.

For patients with platelet counts approaching zero, platelet packs should be available for the operative procedure but should not be administered preoperatively. Platelet transfusion is reserved for patients who continue bleeding after removal of the spleen. Occasional patients in whom signs of the disease recurred months or years following splenectomy have achieved permanent cure following removal of an accessory spleen, the presence of which may be defined by technetium scan.

Systemic Lupus Erythematosus (SLE)

Refractory cytopenias associated with SLE may respond to splenectomy. The platelet count returns to normal in about two-thirds of patients, the hematocrit level increases 20 percent or more, and the white cell count returns to normal in almost all patients with SLE following splenectomy.

Thrombotic Thrombocytopenic Purpura

Although thrombotic thrombocytopenic purpura (TTP) is a disease of arterioles and capillaries, there are significant accompanying hematologic changes for which the response to splenectomy may be striking. The causation has not been precisely defined, but immune mechanisms have been suggested. Approximately 5 percent of reported cases occurred during pregnancy. TTP in pregnancy must be distinguished from an idiopathic thrombocytopenia that may develop in the third trimester because this state is reversed by termination of the pregnancy. Histologically there is widespread occlusion of multiple arterioles and capillaries by hyaline membranes, with minimal inflammatory change and limited infarction.

The pentad of clinical features of virtually all cases of TTP consists of fever, purpura, hemolytic anemia, neurologic manifestations, and signs of renal disease. The pertinent laboratory findings include anemia with reticulocytosis, thrombocytopenia, and leukocytosis, sometimes accompanied by an elevated serum bilirubin level, proteinuria, hematuria, casts, or azotemia. The peripheral blood smear reveals pleomorphic, normochromic red cells that are fragmented and distorted. The degree of thrombocytopenia varies during the course of the illness, but a profound decrease in platelet count often develops within hours of onset. The bone marrow usually reveals erythroid and myeloid hyperplasia with a normal or increased number of megakaryocytes.

In the majority of cases, the disease has a rapid onset, fulminant course, and fatal outcome usually due to intracerebral hemorrhage or renal failure. Repeated plasmapheresis usually reverses the process, but in occasional cases in which no response is effected, splenectomy coupled with high-dosage steroids has resulted in cure.

Secondary Hypersplenism

Pancytopenia, thrombocytopenia, and leukopenia or anemia may occur whenever there is splenomegaly or splenic congestion. Splenomegaly with engorgement of the vascular spaces accompanies portal hypertension, resulting in accelerated destruction of the circulating cells within the spleen. The clinical manifestations of thrombocytopenia, i.e., petechiae and spontaneous bleeding, are extremely uncommon in patients with portal hypertension. As no correlation exists between the degree of anemia, leukopenia, or thrombocytopenia and the long-term survival of patients with cirrhosis, hypersplenism per se is not an indication for splenectomy in a patient with portal hypertension. Percutaneous transfemoral embolization of the splenic arterial circulation has been performed in some of these patients. Although splenic hyperfunction was controlled, the development of painful infarction of the spleen and septic splenitis suggests that such an approach has limited value. The more common surgical situation entails the patient with bleeding esophagogastric varices accompanied by significant secondary thrombocytopenia. In the experience of Child and Turcotte with more than 300 shunts, it was necessary to perform only one splenectomy for persistent, clinically significant hypersplenism. Thrombocytopenia is generally improved by a portacaval shunt, and in the few instances in which the platelet count does not return to normal, complications are rarely attributable to thrombocytopenia. Splenectomy alone should not be performed in a patient with portal hypertension and secondary hypersplenism as there is no long-term effect on the elevated portal pressure. In the rare circumstance that splenectomy is required for a severe degree of hypersplenism in such a patient, it should be combined with a splenorenal shunt to decompress the portal circulation.

Myeloproliferative Disorders

Myeloid metaplasia is a panproliferative process manifested by increased connective tissue proliferation of the bone marrow, liver, spleen, and lymph nodes and simultaneous proliferation of hemopoietic elements in the liver, spleen, and long bones. The disease is closely related to polycythemia vera, myelogenous leukemia, and idiopathic thrombocytosis. The causation remains unclear. The spleen may be markedly enlarged, and portal hypertension has been described in some patients, due either to hepatic fibrosis of sufficient degree to be obstructive to the portal circulation or to increased forward blood flow through the splenoportal system in the absence of hepatic involvement.

Clinical manifestations generally become apparent in middle-aged and older adults. The presenting symptoms usually are related to anemia and increasing splenomegaly. Symptoms related to the spleen include the intermittent pain of splenic infarction, generalized abdominal discomfort, and a feeling of fullness after meals. Other symptoms include

spontaneous bleeding, secondary infection, bone pain, pruritus, hypermetabolism, and complications associated with hyperuricemia. The most common physical findings are pallor and splenomegaly. Hepatomegaly is present in about three-quarters of the patients.

The laboratory hallmark of myeloid metaplasia is in the peripheral blood smear. The red cells are characterized by fragmentation and immature forms and poikilocytosis with numerous teardrop and elongated shapes. Characteristically, the patients have anemia of the normochromic type. The white blood cell count is under 50,000 mm⁻³ in the majority of the patients but may reach extremely high levels. Immature myeloid cells are found in the peripheral smear. The platelet counts are normal in about one-quarter of the patients, thrombocytopenia is present in about one-third, and marked thrombocytopenia is present in 5 percent. Thrombocytosis with a platelet count over 1,000,000 mm⁻³ is observed in one-quarter of the patients. The platelets are frequently enlarged and bizarre in appearance. The leukocyte alkaline phosphatase is usually high, and hyperuricemia is frequently present. Radiographs of the bone demonstrate increased density in approximately 50 percent of the patients, particularly in the pelvic region. Marrow biopsy sections show varying degrees of bone marrow replacement by fibrous tissue interposed with small foci of megakaryocytes, erythropoiesis, and myeloid cells.

Treatment is generally directed at the anemia and splenomegaly. It usually consists of transfusions, hormones, chemotherapy, and radiotherapy. Male hormone preparations may be of value in patients with anemia due to marrow failure. Alkylating agents may be effective in reducing splenic size and transfusion requirements as well as for patients whose predominant clinical problem is hypermetabolism. Busulfan is the most commonly used alkylating agent, but cyclophosphamide may also be used in thrombocytopenic subjects since it is less likely to suppress platelet production. Since patients with myelofibrosis are very sensitive to chemotherapy, such agents must be used very cautiously.

Although splenectomy does not alter the general course of the disorder, the procedure is indicated for control of anemia and thrombocytopenia, and for symptoms attributable to splenomegaly. Prolonged partial thromboplastin time, abnormal prothrombin consumption, prothrombin time, and bleeding time are usually normalized by splenectomy. Thrombocytopenia associated with sufficiently reduced megakaryocytes to contraindicate chemotherapy is also a frequent indication for splenectomy, as is the large spleen that causes digestive difficulties or is symptomatic because of multiple infarctions despite chemotherapy and/or local irradiation. In patients with esophagogastric varices portal pressures should be determined before and after splenectomy. In most instances splenectomy alone will effect significant reduction in pressure, causing varices to decrease in size or disappear and obviating the need for a concomitant splenorenal or portacaval shunt.

The old concept that splenectomy resulted in the removal of a significant hemopoietic element has been disproved. Mortality and morbidity rates for patients with myeloid metaplasia undergoing splenectomy are higher than those reported for other hematologic disorders. Splenectomy in patients with myeloid metaplasia is associated with an operative mortality of 13 percent, a morbidity rate of nearly 45 percent, and a late morbidity rate of 16 percent. Postoperative thrombocytosis and/or thrombosis of the splenic vein extending into the portal and mesenteric vein occurs more commonly in these patients. The complication is characterized by intractable ascites, hepatic failure, and renal failure that is often not noted until a week after the operation. The incidence of this complication can be reduced by correction of a thrombocytotic state, if present, preoperatively using alkylating agents and by the use of drugs to prevent platelet aggregation and clotting during the perioperative period.

Hodgkin's Disease, Lymphomas, and Leukemias

Chemotherapy and/or radiation therapy is the standard approach to treatment of these disorders.

In Hodgkin's disease, non-Hodgkin's lymphoma, and chronic lymphocytic leukemia (CLL), splenectomy has improved cytopenia in over 75 percent of cases. In these patients, palliative splenectomy should be performed before the platelet count is excessively low or there are marked clinical abnormalities. Splenectomy may allow patients to begin or maintain chemotherapy. Palliative splenectomy may be indicated for symptomatic splenomegaly.

Hairy cell leukemia, or reticuloendotheliosis, is characterized by malignant cells with filamentous cytoplasmic projections. Patients without symptomatic splenomegaly and few “hairy” cells in the circulating blood do well without any treatment. Patients who live 4 years after the diagnosis has been established have a favorable long-term prognosis and do not require splenectomy. When hairy cell leukemia is accompanied by problems caused by neutropenia, thrombocytopenia, and anemia, splenectomy is effective therapy. A complete response occurs in two-thirds to three-quarters of patients, and a partial response is effected in another 20 percent. The 5- year survival rate has been reported as 61 to 76 percent. The response to splenectomy is unrelated to the weight of the spleen. Survival is not related to the hematologic response to splenectomy. Failures are managed with steroids and chemotherapeutic agents.

Staging of Hodgkin's Disease and Non-Hodgkin's Lymphoma

The diagnosis of Hodgkin's disease is generally established by histologic evaluation of a clinically suspect area of lymphadenopathy or splenomegaly. Demonstration of the typical, large, multinuclear cell, the Sternberg-Reed cell, is regarded as essential for the diagnosis. These cells, however, do not form the bulk of the tumor. Four major histologic types have been defined: lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion. Survival with Hodgkin's disease is related in part to the histologic type and also to the distribution of disease and the presence or absence of specific symptoms. Stage I disease is defined as limited to one anatomic region; Stage II disease is limited to two or more contiguous or noncontiguous regions on the same side of the diaphragm; Stage III disease refers to disease on both sides of the diaphragm with involvement limited to lymph nodes, spleen, and Waldeyer's ring; and Stage IV refers to involvement of the bone marrow, lung, liver, skin, gastrointestinal tract, and any organ or tissue other than the lymph nodes or Waldeyer's ring.

The indications for surgical staging of Hodgkin's disease have decreased significantly in recent years because of greater reliance on CT scans and the more liberal use of chemotherapy, which negates the need to determine the presence of infradiaphragmatic involvement. Currently the indications for surgical staging focus on Stage I patients in whom the disease is apparently limited to one anatomic region, and on Stage II patients in whom the disease is detected in two regions above the diaphragm and the pathology demonstrates nodular sclerosis.

The staging procedure begins with obtaining a wedge biopsy specimen of the liver before retractors are applied and cause confusing white blood cell migration. Splenectomy is then carried out, followed by removal of representative retroperitoneal, mesenteric, and hepatoduodenal nodes. An iliac marrow biopsy procedure is usually included. Surgical staging was found to upgrade the clinical stage in 27 to 36 percent of cases and to decrease it in 7 to 15 percent, for a total alteration of 42 percent. Current consensus is that surgical staging is not indicated for patients with non- Hodgkin's lymphoma. In these patients the combination of CT scans, marrow biopsy, and laparoscopically directed nodal and liver biopsies offers a reasonable alternative to diagnostic celiotomy.

Miscellaneous Diseases

Felty's Syndrome

The triad of rheumatoid arthritis, splenomegaly, and neutropenia is referred to as Felty's syndrome. Mild anemia and/or thrombocytopenia has been noted in some cases, and gastric achlorhydria is common. An antibody specifically directed against neutrophil nuclei is nearly always demonstrable by fluorescent stains. Corticosteroids and splenectomy have been used to reverse the neutropenia in order to reduce susceptibility to infection. The response to steroids is usually not long-lasting, but the hematologic effects of splenectomy generally are excellent. Splenectomy in these patients should be reserved for neutropenic patients who have serious or recurrent infections, patients who require transfusions for anemia, patients with profound thrombocytopenia, and patients with intractable leg ulcers. There is a sharp rise in the total number of leukocytes in the first 24 h, reaching a peak at about the third postoperative day. Although relative neutropenia may persist, the neutrophilic response to infection in the postsplenectomy state becomes normal. The clinical course of the arthritis is rarely altered.

Sarcoidosis

This disease affects young adults. There are few constitutional symptoms, and fever is unusual, although night sweats have been noted. Cough and shortness of breath may attend mediastinal or pulmonary involvement. Skin lesions appear in about 50 percent of patients, and generalized lymphadenopathy is frequent. Involvement of the liver and spleen may produce hepatomegaly and splenomegaly in about 25 percent of patients. About 20 percent of the patients with splenomegaly develop manifestations of hypersplenism, particularly thrombocytopenic purpura. Hemolytic anemia, neutropenia, pancytopenia, and spontaneous splenic rupture have all been observed.

There is no specific treatment, and spontaneous recovery can be anticipated in the majority of cases. Splenectomy should be considered for patients with splenomegaly when there are complications of hypersplenism, since the operation has been almost uniformly followed by correction of the hematologic abnormality.

Gaucher's Disease

This is a familial disorder characterized by abnormal storage or retention of glycolipid cerebroside in reticuloendothelial cells. Proliferation and enlargement of these cells produce enlargement of the spleen, liver, and lymph nodes. The disease is generally discovered in childhood but may become evident either early in infancy or late in adult life.

The sole clinical manifestation may be awareness of a progressively enlarging abdominal mass, primarily due to splenomegaly and, to a lesser extent, to hepatomegaly. Yellowish-brown pigmentation of the head and extremities occurs in 45 to 75 percent of cases. Bone pain and pathologic fracture may develop in long-standing cases. Many patients develop the hematologic manifestations of hypersplenism as a result of excessive sequestration of formed blood elements. Moderate to severe thrombocytopenia and normocytic anemia are almost always present, and often there is mild leukopenia. In the patients with hypersplenism, splenectomy almost uniformly has been beneficial in correcting the hematologic disorder, but there is no evidence that the operation influences the course of the basic disease. Partial splenectomy has been performed in children for symptomatic splenomegaly and hypersplenism to obviate development of overwhelming postsplenectomy infection (OPSI); 400 to 3800 g of tissue has been removed without complication. There has been no OPSI and no postoperative increase in accumulation of beta- glucocerebroside in the liver or bones. All children had an improved growth rate and hematologic picture.

Erythropoietic Porphyria

This is a congenital disorder of erythrocyte pyrrole metabolism that is transmitted as a recessive trait and characterized by the excessive deposition of porphyrins in the tissues. In the skin this results in pronounced photosensitization and severe bullous dermatitis. Premature red cell destruction within the spleen contributes to severe anemia. When the disease is complicated by hemolysis or splenomegaly, splenectomy is followed by marked improvement in the anemia and decreased concentrations of porphyrins in the red cells, bone marrow, and urine.

Systemic Mast Cell Disease (SMCD)

This disorder is manifested by urticaria pigmentosa and mast cell infiltration of the skin, bone marrow, or gastrointestinal tract. In patients with aggressive disease, including lymphadenopathic mastocytosis and eosinophilia and severe thrombocytopenia, splenectomy may be beneficial, extending survival and improving the ability to tolerate chemotherapy.

OTHER LESIONS

Ectopic Spleen

This unusual condition, also known as wandering spleen, is ascribed to lengthening of the splenic ligaments, which results in extreme mobility of the organ so that the spleen of normal size may be palpable in the lower abdomen or in the pelvis. In some cases, acute torsion of the pedicle occurs, necessitating surgical intervention. Adult women are more frequently affected but males predominate in the thirty-five recorded pediatric cases. Elective splenopexy, wrapping the spleen in Dexon mesh and tacking it to the diaphragm and retroperitoneum in its normal position, is indicated to preserve the organ and prevent acute torsion.

Cysts and Tumors

Cysts of the spleen are unusual. Parasitic cysts are usually due to echinococcal involvement, while the nonparasitic cysts may be categorized as dermoid, epidermoid, epithelial, and pseudocysts. Pseudocysts occur after occult rupture of the spleen caused by trauma. Symptomatic parasitic cysts of the spleen are best managed by splenectomy. Large symptomatic nonparasitic cysts may be widely unroofed to assure permanent cure. This can be performed laparoscopically. Asymptomatic pseudocysts do not require operation but should be followed ultrasonographically to rule out significant expansion.

Primary malignant tumors of the spleen are usually sarcomatous. Primary splenic non-Hodgkin's lymphoma is a rarity which has an excellent prognosis following splenectomy. Autopsy series have refuted the concept that metastases to the spleen are rare. Exploration for undiagnosed splenomegaly rarely reveals unsuspected metastatic deposit in the absence of known generalized metastases but may establish the diagnosis of a hematologic malignancy.

Abscesses

Splenic abscess is an uncommon cause of abdominal sepsis. Primary splenic abscesses occur much more often in the tropics, where they are frequently related to thrombosis of the splenic vessels with infarction in patients with sickle cell anemia. Pyogenic splenic abscesses have been reported with increasing frequency in intravenous drug abusers. Clinical manifestations include fever, chills, splenomegaly, and left upper quadrant tenderness. Diagnosis may be established by ultrasound or CT scan (Fig. 31-6). Removal of the spleen is the operation of choice, but some patients have been treated with splenotomy and drainage when there were gross adhesions or the condition of the patient did not permit splenectomy. Splenic fungal abscesses have developed in immunosuppressed patients and in patients taking steroids or chemotherapeutic agents. Many of these patients have been on systemic antibiotics, and intestinal colonization with *Candida* developed. In some cases the abscesses resolved with treatment with antifungal drugs, but more often success has been achieved when the drugs were combined with splenectomy.

SPLENECTOMY

When elective splenectomy is performed for hematologic disorders, specific considerations arise. Patients with malignant lymphoma and leukemia may develop cryoglobulinemia, and therefore the blood should be administered at room temperature. For patients with thalassemia and, more particularly, acquired hemolytic anemia, typing and crossmatching may be difficult, and sufficient time should be allotted during the preoperative period to accumulate the blood that may be required during the operation. For patients with marked immune thrombocytopenia (ITP), platelet packs are not administered preoperatively, since the platelets are rapidly destroyed by the spleen and thus are not very effective. A nasogastric tube is inserted after endotracheal intubation to decompress the stomach and to facilitate handling of the short gastric veins.

Technique

Although the midline incision is preferred for exposure of a ruptured spleen, either a left subcostal incision or a midline incision may be used for elective resection. The spleen is mobilized initially by dividing the ligamentous attachments, which are usually avascular but may contain large vessels in patients with secondary hypersplenism and myeloid metaplasia (Fig. 31-7 A). The short gastric vessels are then doubly ligated and transected (Fig. 31-7 B), with care being taken not to traumatize the stomach itself. If compromise of blood supply to the fundic portion of the greater curvature of the stomach is a concern, enfolding of this area should be performed to prevent the development of a gastric fistula. Finally, dissection of the splenic hilus with individual ligation and division of the splenic artery and vein is performed (Fig. 31-7 C). During the course of hilar dissection, care should be taken to avoid injury to the tail of the pancreas in order to avoid pseudocyst formation. The technique of initial ligation of the splenic artery by exposure through the gastrosplenic omentum has been used in cases of hypersplenism and splenomegaly. Preoperative occlusion of the splenic artery using steel coils placed selectively in the splenic artery under radiographic control has achieved the same end.

Whenever splenectomy is performed for a hematologic disorder, a careful search should be made for accessory spleens. The splenic bed is not drained routinely, but drains are used in patients with myeloid metaplasia if there is a question of continued oozing from distended collateral veins.

Partial Splenectomy

This procedure is particularly applicable in children with Type I Gaucher's disease to minimize the risk of postsplenectomy sepsis. After transection of the ligamentous attachment to permit complete mobilization of the organ, the hilar vessels to the segment to be removed are ligated and divided. The demarcation of the devascularized segment defines the line for transection; at least 30 percent of the spleen should be preserved (Fig. 31-7 D). Bleeding from the raw surface is controlled by cauterization, argon coagulation, or fibrin glue. The omentum can be used to cover the remaining raw surface.

Postoperative Course and Complications

Following splenectomy, characteristic changes in blood composition occur. Howell-Jolly bodies are present in almost all patients, and siderocytes are common. Generally, leukocytosis and increased platelet counts are observed. In patients with marked thrombocytopenia, the platelet count often returns to normal within 2 days, but peak levels may not be reached for 2 weeks. The white blood cell count usually is elevated the first day and may remain persistently elevated for several months. The most frequent complication is that of left lower lobe atelectasis. Other complications include subphrenic hematoma and abscess, injury to the pancreas causing fistula, or pancreatitis. Excessively elevated platelet counts, particularly in patients with myeloid metaplasia, and increased platelet adhesiveness have been reported. Although these factors have been implicated in the greater incidence of thrombophlebitis following splenectomy, many series can show no good correlation between these complications and the platelet counts. In patients with hereditary hemolytic anemia and associated red cell enzyme deficiency, postoperative thrombocytosis may lead to hepatic, portal, or caval thrombosis, particularly if the hemolytic rate is unabated by splenectomy.

There has been increasing concern regarding infection and sepsis in splenectomized patients. In a large review Singer reported that deaths from sepsis in splenectomized patients were 200 times as frequent as in the population at large. Fulminant postsplenectomy infection is very rare following removal of a traumatized spleen, but the incidence of pneumonia, septicemia, and meningitis was reported to be 166 times greater in patients who had undergone splenectomy for trauma than is expected for the normal population. No neutrophil defect or impairment of serum opsonin or chemotactic activity could be demonstrated after splenectomy for trauma. When the risk of infection in childhood Hodgkin's disease was assessed in 181 consecutive, previously untreated patients, the episode did not correlate with splenectomy alone, but appeared to be related more to the treatment with chemotherapy and radiotherapy. In a series of 221 patients with hematologic disease, late postsplenectomy pulmonary infection was seen in eight patients; all but one were receiving immunosuppressive therapy or had advanced malignant disease.

Splenectomy results in a variety of immunologic defects, including a poor response to intravenous immunization with particulate antigens, a deficiency in phagocytosis-promoting peptide, decreased serum IgM, and decreased properdin. The organisms most frequently isolated from septic splenectomized children are those of diplococcus pneumonia and *Haemophilus influenzae*. It is therefore reasonable to delay splenectomy for hematologic disorders in very young children, especially those under the age of 2 years, to attempt to preserve the traumatized spleen in the pediatric patient and to maintain patients with at-risk diseases on long- term oral antibiotic therapy.

All patients undergoing splenectomy should receive, as prophylaxis, pneumococcus vaccine and a vaccine against *H. influenzae*, if available. Vaccination is best performed about 10 days before elective splenectomy and preoperatively in traumatized patients in whom splenectomy is anticipated, but should be performed postoperatively if preoperative vaccination was neglected. Equivalent response to pneumococcal antigens has been demonstrated for patients vaccinated after splenectomy compared with those vaccinated with the spleen in place. All children whose spleens have been removed should receive penicillin until the age of eighteen. The patients with diseases associated with high infection rates, such as thalassemia, sickle cell anemia, and autoimmune hemolytic anemia and thrombocytopenia, should not be denied splenectomy but should be kept under close surveillance postoperatively.

CHAPTER 32 - Intraabdominal Infections

Joseph S. Solomkin
Dietmar W. Wittman
Michael A. West
Philip S. Barie

INTRODUCTION

Intraabdominal infections are commonly encountered in surgical practice and represent an important problem in decision-making, operative technique, and perioperative management. Improvements in supportive care, diagnostic methods, anti-infective therapy, and interventional techniques have resulted in improved outcomes, decreased mortality, and a decreased incidence of recurrent abscess. Despite state-of-the-art care, infections result in considerable morbidity and mortality because of activation of local and systemic inflammatory responses.

Prompt and effective decision making is critical; delay in treatment for intraabdominal infection risks physiologic deterioration and increased mortality. Diagnostic uncertainty must be balanced against the risk of treatment delay. The precise nature of the operative procedure is a critical determinant of outcome and must be tailored to the pathology encountered.

The patient with findings suggestive of infection, typically with unexplained ileus, in whom no source of nosocomial infection can be identified by routine investigations represents a major diagnostic problem. In patients who have recently undergone abdominal operation, a concern for abscesses is often sufficient to lead to empiric treatment. Such an approach can result in overlooking less common causes of infection, bowel ischemia, pseudomembranous colitis, or pancreatitis.

STRUCTURE AND FUNCTION OF THE PERITONEAL CAVITY

Mesothelium

The total area of the peritoneum is approximately 1.8 m². It is formed by a single layer of mesothelial cells with an underlying supporting layer of highly vascularized loose connective tissue. The mesothelial cells contain microvilli 1.5 to 3.0 mm in length, which greatly increase the surface area of the mesothelial cells. The relative density of microvilli differs throughout the peritoneal cavity. Tight intra-mesothelial cell junctions generally connect these cells, although there also are large intercellular gaps, sometimes as large as 500 angstroms, between these lining cells. Alterations in mesothelial cell metabolism and cellular swelling may influence diffusion across this cell layer.

Mesothelial cells are organized into two discrete populations: cuboidal cells and flattened cells. Gaps (stomata) between neighboring cells of the peritoneal mesothelium are found only among cuboidal cells. Peritonitis increases the width of these stomata. Beneath the mesothelial cells is a basement membrane of loose collagen fibers, which offers little resistance to diffusion of molecules smaller than 30 kD. The basement membrane overlies a complex connective tissue layer that includes collagen and other connective tissue proteins, elastic fibers, fibroblasts, adipose cells, endothelial cells, mast cells, eosinophils, macrophages, and lymphocytes (Fig. 32-1). The capillaries branch and ramify within the peritoneal lining layer. In addition, there is a rich lymphatic network.

Peritoneal fluid is secreted by the peritoneal serosa and has the properties of lymph. Diaphragmatic lymphatic channels provide a means for the entry of peritoneal fluid (and any bacteria and proinflammatory mediators) through the thoracic duct into the venous circulation. Inspiration decreases intrathoracic pressure relative to intraabdominal pressure, creating a pressure gradient favoring fluid movement out of the abdomen. Intravascular entry of proinflammatory substances produces many of the hemodynamic and respiratory findings of severe sepsis. Positive-pressure ventilation likely attenuates this process but has not been well studied as a therapeutic maneuver.

Anatomy

The peritoneal cavity encompasses the potential space defined by the mesothelial serous membrane and extends superiorly from the diaphragm to the pelvis in its most caudad extent (Figs. 32-2 and 32-3). Anteriorly the peritoneal cavity reflects onto the posterior aspect of the anterior abdominal musculature. Posteriorly the peritoneal lining lies superficial to the retroperitoneal viscera, including the aorta, vena cava, ureters, and kidneys. The anterior and posterior peritoneal layers are described collectively as the parietal peritoneum. The visceral peritoneum represents the mesothelial lining cells that are reflected onto the surface of the viscera, including the stomach, small bowel, spleen, liver, gallbladder, ovaries, uterus, and portions of the bladder, colon, and pancreas. The peritoneum covering the intestine is the serosa of the bowel. The peritoneum also lines the lesser sac, which communicates with the remainder of the peritoneal cavity via the epiploic foramen (foramen of Winslow). In women the peritoneal lining is reflected onto the fallopian tubes, which communicate through the open fimbriated ends with the uterus and vagina.

The visceral peritoneal lining of the liver and spleen (the “capsules”) are thicker and can be detached from the underlying organ parenchyma, whereas the visceral lining of the bowel is thin and intimately attached to the lamina muscularis mucosae.

The parietal peritoneum is thicker than the visceral peritoneum and contains a richer capillary network that ramifies extensively within the peritoneal lining. This vascular supply allows the parietal peritoneum to be readily dissected free from deeper structures without altering its viability.

The retroperitoneum, which contains a subfascial plane extending from the pelvis to the posterior pharynx, is located deep to the posterior peritoneal lining. In some types of intraabdominal infection, once the inflammatory process penetrates the serosal lining, it is possible for it to spread laterally, caudad, or cephalad with relative ease.

Under normal circumstances the peritoneal cavity is largely a potential space, as only a thin film of fluid separates the parietal and visceral layers. This fluid layer serves as a lubricant, allowing the abdominal viscera to slide freely within the peritoneal cavity. The capacity of this space is illustrated during peritoneal dialysis, as 2 to 3 L of fluid are instilled into the peritoneal cavity without any patient discomfort. Inflammation of the immense surface area of the peritoneal mesothelium can result in massive fluid shifts. For example, an increase in thickness of the peritoneal lining of 1 mm will sequester around 1.8L of fluid. Peritonitis thus may be regarded as requiring the resuscitation equivalent of an 80 percent burn.

Compartmentalization of the peritoneal cavity by various ligaments and retroperitoneal attachments creates several recesses into which fluid or exudate may pool (see Fig. 32-3).

Inframesocolic Spaces

The area below the transverse mesocolon is subdivided into several gutters, or watersheds, by the ascending and descending colon, the root of the mesentery, and the pelvic mesosigmoid. The *right lateral paracolic gutter* lies between the cecum and ascending colon and the right lateral abdominal wall. The drainage pathway of the right lateral paracolic gutter is in a superior direction when the patient is in the supine position, since the superior portion of this sulcus lies on a more posterior plane than the inferior portion. The right lateral paracolic gutter continues superiorly to the region behind the right lobe of the liver and anterior to the right kidney as the hepatorenal pouch. The hepatorenal pouch communicates through the foramen of Winslow with the lesser sac.

Between the mesentery and the cecum and ascending colon is the *right medial paracolic gutter*. This recess is limited inferiorly by the junction of the mesentery and the jejunum and ileum, where the mesentery meets with the cecum, and superiorly by the transverse mesocolon. The drainage from the right medial paracolic gutter occurs in a superior direction, passing above the root of the mesentery into the *left medial paracolic gutter*. The left medial paracolic gutter is limited by the transverse mesocolon above, by the root of the mesentery on the right, and by the descending and sigmoid colon on the left. Drainage from the left medial paracolic gutter is downward into the pelvis. The *left lateral paracolic gutter* extends superiorly from the phrenicocolic ligament to the sigmoid colon inferiorly and from the descending colon on the right to the left lateral abdominal wall. Fluids in the left lateral paracolic gutter tend to remain there.

Supramesocolic Spaces

With the patient in the supine position, drainage on the right tends to flow superiorly toward the right subphrenic area. This area in turn is divided into two portions, a right and a left, by the falciform ligament, which extends from the anterior abdominal wall and inferior surface of the diaphragm to the anterosuperior surface of the liver. The right subphrenic space is further subdivided by the right lobe of the liver into a suprahepatic portion and an infrahepatic portion. The left subphrenic area is divided by the left lobe of the liver and the horizontally placed stomach and lesser omentum. There are two major subdivisions of this space. The larger area lies anterior to the stomach, the spleen, and the left lobe of the liver and is limited by the diaphragm and the abdominal wall anteriorly. The smaller area, the lesser sac, lies behind the stomach and lesser omentum.

With the body in the supine position, the most dependent recess is in the pelvis. In the upper abdomen, the posterosuperior extension of the subhepatic space known as Morison's pouch also collects fluid in recumbent individuals. Morison's pouch connects via the foramen of Winslow (bounded by the free border of the gastrohepatic omentum and the posterior parietal peritoneum) to the lesser sac, which is the largest recess in the peritoneal cavity. Because of the limited communication of the lesser sac to the main peritoneal cavity, abscesses in the lesser sac may not produce physical signs on examination of the anterior abdominal wall. The left subhepatic and subphrenic spaces communicate freely around the small lateral left hepatic lobe. The falciform ligament limits communication between the right and left subphrenic spaces. This may explain the clinical observation that fewer than 15 percent of subphrenic abscesses are bilateral.

Innervation

Innervation of the peritoneal lining figures prominently in clinical recognition of intraabdominal infections. There are some nerve fibers within the visceral peritoneum, but they are much less numerous than those in the parietal peritoneum. They arise from the visceral structures beneath the mesothelial lining. Stretching of the visceral peritoneum produces nausea and poorly localized pain. Most intraperitoneal visceral structures arise from the embryologic foregut, and, accordingly, their nerve supply arises from the visceral branches of the vagus nerve. Pain usually is localized to the dermatome distribution of the associated visceral organ (Table 32-1). For example, the gallbladder arises from the upper thoracic dermatomes; hence, with stretching of the visceral peritoneum overlying the gallbladder, pain is initially perceived as arising in the epigastrium and right upper back. When the inflammatory process also involves the adjacent diaphragmatic structures, pain also may be perceived in the neck or shoulder because the diaphragm arises from and is innervated by the cervical dermatomes. Visceral peritoneal irritation, usually from distention of a hollow viscus, causes dull, poorly localized, often periumbilical, and often crampy pain. Visceral structures are generally completely insensitive to surgical transection, cauterization, heat, cold, or pinching.

The nerve supply of the parietal peritoneum, the somatic afferents, arises from branches of cutaneous nerves in the anterior abdominal wall. In contrast to the visceral peritoneum, the parietal peritoneum is exquisitely pain sensitive to stretch as well as light touch and cutting, particularly anteriorly. Pain arising from irritation of the parietal peritoneum can usually be very precisely localized by patients and is the basis for the clinical findings of “peritoneal signs.” Anterior parietal peritoneal pain may be associated with tenderness and involuntary muscle spasm (guarding). “Rebound tenderness” can sometimes be elicited from the taut peritoneum even in the absence of inflammation, such as in ileus. Irritation of the peripheral diaphragmatic peritoneum is perceived as pain in the adjacent body wall, whereas central irritation manifests itself as ipsilateral shoulder pain. Diaphragmatic irritation

may arise not only from direct involvement by adjacent inflammation but also from the movement of infected fluid into the subphrenic spaces.

The blood and lymphatic supply of the peritoneum generally follow the distribution of the innervation. The blood supply of the visceral peritoneum arises from the adjacent visceral organ.

PHYSIOLOGY OF THE PERITONEUM

Peritoneal Fluid Exchange

The mesothelial lining cells of the peritoneum secrete serous fluid that circulates within the peritoneal cavity. The peritoneal cavity normally contains 50 to 100 mL of fluid with solute concentrations nearly identical to that of plasma. The protein content of peritoneal fluid is somewhat less than that of plasma, about 3 g/dL. Fluid is absorbed by the peritoneal mesothelial lining cells and subdiaphragmatic lymphatics. Mesothelial cells also absorb solutes by the continuous process of endocytosis. Exchange of solutes across the peritoneal lining is the basis for peritoneal dialysis. Most solutes with a molecular weight less than 30 kD traverse the mesothelial lining with relative ease. Splanchnic blood flow and factors that alter membrane permeability affect the efficiency of fluid exchange. Peritoneal permeability is markedly increased by intraperitoneal inflammation.

Peritoneal Fluid Movement

The routes of normal fluid movement within the peritoneum have been defined by injection of water-soluble contrast material into normal individuals. The right paracolic gutter is the main conduit between the upper and lower peritoneal cavities, because the left gutter is obstructed by the phrenicocolic and splenorenal ligaments. Fluid introduced into the right upper quadrant gravitates inferiorly via the subhepatic space into the right subphrenic space. From there it may travel inferiorly into the pelvis via the right gutter before returning to the upper abdomen. Because of the obstruction on the left, fluid from the left upper quadrant migrates into the left subphrenic space. Fluid introduced into the lower abdomen gravitates first to the pelvis, and thereafter ascends, even with the patient in the upright position, into the subhepatic and subphrenic spaces.

Two primary forces govern the movement of fluid within the peritoneal cavity: gravity and the negative pressure created beneath the diaphragm with each normal respiratory cycle. Fluid flux within the peritoneal cavity is dramatically altered by the presence of adhesions, fibrin, paralytic ileus, or mechanical ventilation. Movement of fluid into the pelvis was in the past an important component of the surgical treatment of intraabdominal infections. Earlier generations of surgeons routinely positioned patients in Fowler's position—almost a sitting position—to facilitate dependent movement of purulent material and formation of a pelvic abscess, which could then be drained transrectally without laparotomy. Today the Fowler position is seldom used and pelvic abscesses are relatively rare. Intraabdominal abscesses are most frequently encountered beneath the liver or diaphragm and between loops of bowel.

Subphrenic purulent fluid collections occur because a relatively negative pressure is created beneath the diaphragm with each exhalation. Intraperitoneal pressure measurements show that the pressure is lowest beneath the diaphragm during expiration. The diaphragm raises during exhalation, producing a transiently larger space in the upper abdomen. As the volume increases the pressure decreases. Lower pressures are encountered whether patients are breathing spontaneously or on mechanical ventilation. With positive-pressure mechanical ventilation there is a significantly impaired capacity of the peritoneal cavity to clear particulate debris.

Peritoneal Response to Injury

Peritoneal Injury and Repair

Any inflammatory event in the peritoneal cavity results in local peritoneal irritation with loss of regional mesothelial cells. The defect in the mesothelial lining is repaired by “metastasis” of nearby mesothelial lining cells. Peritoneal defects heal everywhere simultaneously. A large peritoneal defect heals in the same amount of time as a small defect, usually 3 to 5 days. This process is rapid and usually reconstitutes the peritoneal continuity without adhesion formation. The origin of the migrating mesothelial cells remains obscure; they may arise from submesothelial stem cells.

Adhesion Formation

Fibrin polymerization occurs when platelets and fibrin come into contact with the exposed basement membrane, an automatic accompaniment of intraperitoneal inflammation. Normally, well-oxygenated intact mesothelial cells produce plasminogen activator, which lyses the fibrin clots that form after acute injury. In experimental wounds fibrinolytic activity has been found to be minimal 3 days after injury, before reconstitution of the mesothelial integrity. Fibrinolytic activity increases to supranormal levels 8 days after injury. With hypoxia the fibrous adhesions are invaded by fibroblasts and there is stimulation of angiogenesis and collagen synthesis. Fully developed fibrous adhesions are seen at 10 days and become maximal 2 to 3 weeks after peritoneal injury. This explains the difficulty of reoperation 2 to 4 weeks after an acute insult. With time, fibrous adhesions undergo remodeling and usually become progressively attenuated. In patients with intraabdominal soiling complications, such as patients with enterocutaneous fistulas, mortality is 20 percent in operations performed between 10 and 120 days but 10 percent before 10 days and after 120 days.

Host Defense Against Intraabdominal Infection

The three major intraperitoneal defense mechanisms are (1) mechanical clearance of bacteria via lymphatics, (2) phagocytic killing of bacteria by immune cells, and (3) mechanical sequestration. Experimentally, bacterial clearance occurs rapidly, before influx of phagocytic cells. Particulate material within the peritoneal cavity is cleared through stomata that overlie large lymphatic channels (lacunae) on the subdiaphragmatic surface. Diaphragmatic movement with respiration produces influx of fluid into the lacunae with exhalation, and respiratory contraction empties the lacunae into the thoracic duct and ultimately the left subclavian vein. Bacteria (1 to 2 mm) and red blood cells (7 to 8 mm) readily pass through the stomata (8 to 12 mm) into the thoracic duct and thence into the central venous blood. This rapid access of bacterial products to the systemic circulation explains why patients who develop an acute gastrointestinal perforation often present with rigors and fever.

PATHOPHYSIOLOGY OF THE LOCAL AND SYSTEMIC RESPONSE TO INTRAABDOMINAL INFECTIONS

The cellular defense mechanisms of the peritoneal cavity help to explain the specific pattern of response. Elements of these defenses include resident peritoneal macrophages and large recruitable pools of circulating neutrophils and monocytes, cell types that participate in abscess formation. Ingestion of microorganisms by these cells may result in secretion of a variety of proinflammatory molecules that generate the systemic response (Table [32-2](#)).

The peritoneal host defense system also serves to localize and contain bacterial contamination. Hyperemia and exudation of fluid follow activation of immune cells (macrophages, and probably mast cells) and sloughing of peritoneal mesothelium. Histamine and other permeability-increasing substances mediate this response. Several events favor the deposition of fibrin, including the activation of mesothelial and macrophage-mediated procoagulant activity acting on fibrinogen in reactive peritoneal fluid, coupled with the loss of plasminogen activator from mesothelial cells. The combined effect is the deposition of fibrinous exudates that serve to wall off and trap bacteria. Ileus and adhesion formation accentuate the process, but extensive loculation may impede immune cell migration to sites of infection.

The defense system's recognition that microorganisms are present within the peritoneal cavity occurs primarily through phagocytosis of the microorganisms by resident peritoneal macrophages. This results in activation of the local macrophages, with secretion of proinflammatory signaling molecules that recruit from a large circulating pool of phagocytes.

Cells Involved in the Inflammatory Response in the Peritoneal Cavity

At least four major cell types play key roles in the inflammatory response. These include resident as well as recruited macrophages, mesothelial cells, adjacent capillary endothelial cells, and recruited neutrophils. While the macrophage has been traditionally considered the first line of cellular defense, developments in our understanding of cytokines and the immunologic functions of mesothelial cells suggest that the inflammatory response is actually initiated by interactions between these two cell types. It has been suggested that the mesothelial cell could even be considered an immune cell, if this designation were not dependent on its lineage. The first step in the response to contamination is probably induced by a host response to microbial cell products. In the case of gram-negative organisms, this is most likely *lipopolysaccharide (LPS)*. For gram-positive organisms, the cell wall product teichoic acid and specific cell wall glycans induce a macrophage response. Lipopolysaccharide, present on gram-negative organisms, interacts with monocytes and other cell types, including subpopulations of neutrophils via the CD14 receptor. Interaction with the CD14 receptor is mediated by lipopolysaccharide binding protein (LBP), and leads to macrophage activation, with subsequent production of *tumor necrosis factor- α (TNF- α)*, interleukin (IL)-1, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor (GM-CSF), prostaglandin E₂ (PGE₂), and nitric oxide. LPS is a very potent immunomodulator, with concentrations in the few-picograms-per-milliliter range inducing near maximal responses from human cells.

Macrophages

Macrophages, including resident peritoneal macrophages and those recruited from the circulation, serve as an early line of cellular defense and coordinate the inflammatory response. Macrophage products include IL-1, IL-6, IL-8, IL-10, IL-12, *TNF- α* , GM-CSF, granulocyte colony-stimulating factor (G-CSF), monocyte chemoattractant protein-1 (MCP-1), monocyte inflammatory protein α (MIP- α), and several eicosanoids. These molecules recruit and activate mesothelial cells as secretors of inflammatory molecules. Mechanisms of macrophage microbicidal activity and associated parenchymal injury include the respiratory burst and release of proteolytic enzymes into intracellular vesicles and into the extracellular space. These enzymes include plasminogen activator, collagenase, elastase, gelatinase, acid phosphatase, and cathepsin D.

Mesothelial Cells

Macrophage secretion products and microbes and their products activate and injure mesothelial cells. This mesothelial injury is a prominent feature of most types of inflammation. In response to these products mesothelial cells produce a variety of inflammatory molecules that recruit additional cells to the peritoneal cavity and activate them there. Mesothelial cells secrete IL-8, a neutrophil chemoattractant and activator. Macrophage-secreted components of complement, upon activation, also recruit neutrophils and monocytes. Mesothelial cells also express various adhesion molecules that promote leukocyte–mesothelial cell adherence.

Neutrophils

Neutrophils are the key effector cells in the inflammatory response and are responsible for the parenchymal destruction seen in inflammation. Neutrophils possess an array of granular enzymes that are capable of digesting basement and interstitial proteins, facilitating directed migration and allowing for digestion of injured tissue. Neutrophil-derived proteases also can degrade a variety of functionally important molecules found at sites of inflammation, including immunoglobulins and intermediates of the kinin, complement, fibrinolytic, and clotting cascades. Neutrophil azurophilic granules also contain the cationic antibacterial protein bactericidal permeability increasing (BPI) factor. BPI factor has sequence homology with lipopolysaccharide-binding protein and binds to the lipid A portion of lipopolysaccharide, preventing its interaction with the CD14 receptor and thereby inhibiting its toxic effects. BPI factor is also specifically cytotoxic to gram-negative bacteria. Neutrophil microbicidal activity and cytotoxicity are in part determined by a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which produces reactive oxygen intermediates. NADPH oxidase, a membrane-bound enzyme, produces reactive oxygen species such as hydrogen peroxide. Neutrophils also secrete *TNF- α* , IL-1, and IL-8, which activate cells and recruit additional neutrophils to sites of inflammation; in turn, they are highly responsive to TNF- α , IL-1b, IL-6, and IL-8.

Host defense systems have an obligatory requirement for molecular oxygen to enable the humoral and cellular immune systems to function optimally. Normally, after opsonization a microorganism is phagocytosed by a neutrophil. The phagosome containing the bacteria then fuses with lysosomal granules within the neutrophils. In the presence of molecular oxygen, toxic oxygen radicals, such as hydrogen peroxide or superoxide, are generated, which result in lysis of bacteria. In the presence of devitalized tissue and in many shock states, delivery of oxygen to the neutrophils is inadequate. In these instances, even though phagocytosis may occur, bacteria may not be destroyed and infection develops or persists.

Endothelial Cells

Macrophage, neutrophil, and mesothelial cell products also injure the closely approximated endothelial cell lining and can thereby increase movement of mediators into the vascular space. It is only upon activation or injury, mediated by *TNF- α*, IL-1, or oxygen radicals, that the endothelial cells secrete inflammatory molecules, which enhance leukocyte-endothelial adhesion and leukocyte transendothelial cell migration. Thus activation of the vascular endothelium is a key mechanism of inflammation.

Endothelial cells produce a variety of adhesion molecules, including members of the selectin and immunoglobulin families, that mediate leukocyte trafficking to sites of inflammation. Endothelial cells also produce IL-8 and *platelet-activating factor (PAF)*, which localize on the endothelial surface in association with various extracellular-matrix proteins. Endothelial cell-associated IL-8 and PAF contribute to the arrest of neutrophil locomotion and also activate them. IL-8 also is thought to mediate neutrophil emigration from the vasculature, in part by forming a chemotactic gradient from the luminal side to the basal side of the endothelium.

Other Cells

Additional cell types also are recruited in the acute inflammatory response. Platelet activation and adherence to sites of injury results in the formation of platelet plugs. During activation, platelets release several preformed molecules into the area of evolving inflammation, including platelet basic protein and its proteolytic derivative *neutrophil-activating peptide 2 (NAP- 2)*, a neutrophil chemoattractant. Platelets also produce *PAF*, tumor growth factor b (TGF-b), prostaglandins, thromboxane A₂ (TXA₂), lipoxin A₄ (LXA₄), and nitric oxide, which can modulate the inflammatory response. Vascular smooth muscle cells and fibroblasts also can release cytokines that can modulate the immune response. Additionally, T and B cells participate in the specific inflammatory response by recognition of antigens presented by monocytes, epithelial cells, and endothelial cells.

Mechanisms of Cell Recruitment to Sites of Injury: The Chemokines and Other Chemoattractants

Nonchemokine Chemoattractants

An early epithelial and endothelial event is contraction of these cells, allowing the influx of several important classes of molecules, including components of the complement system. The complement system is a series of proteins whose ordered polymerization results in activation of the coagulation system, the release of inflammatory molecules, recruitment of leukocytes (C5a), opsonization of microorganisms (C3b), and induction of microbial and host cell lysis (membrane attack complex). Released C5a also induces polymorphonuclear cell activation, adherence, and aggregation. C5a can induce the production of *TNF- α*, IL-1, and IL-6 by monocytes. In the lung C5a increases vascular resistance and induces hypoxemia. Complement also synergistically enhances the effects of TNFα in producing hemorrhagic necrosis.

Other chemoattractants recruit cells to the peritoneal cavity, including leukotriene B₄ (LTB₄), formyl-methionyl-leucyl-phenylalanine (FMLP), and platelet activating factor (PAF). LTB₄ is generated by macrophages (and other cells) in response to such stimuli as *LPS*. LTB₄ is chemotactic for neutrophils and increases neutrophil adhesion to endothelium. It also promotes IL-1, IL-6, *TNF- α*, and H₂O₂ production by monocytes. Additionally, LTB₄ increases vascular permeability. FMLP is derived from bacterial cell walls and induces neutrophil and monocyte chemotaxis, degranulation, superoxide production, and phagocytosis. *PAF*, released by neutrophils, monocytes, platelets, and endothelial cells, also stimulates macrophage and neutrophil chemotaxis. PAF also enhances superoxide production by neutrophils at the endothelial surface, increases endothelial permeability, alters vascular reactivity, enhances platelet aggregation, and stimulates production of eicosanoids. PAF release from endothelial cells can be induced by TNF, IL-1, *LPS*, thrombin, phorbol myristate acetate, histamine, leukotrienes, and reactive oxygen species.

Chemokines

Chemokines, or chemotactic cytokines, are the key mediators of leukocyte recruitment to sites of inflammation. Two broad categories of chemokines are the CXC chemokines and the CC chemokines, where “C” refers to the location of cysteine residues in the molecules.

CXC Chemokines

Important cytokines in this category include IL-8, *NAP-2*, and melanoma growth stimulatory activity/growth related oncogene (MGSA/GRO). IL-8 is an 8-kD protein that is produced by macrophages, mesothelial epithelial cells, neutrophils, endothelial cells, fibroblasts, T cells, and hepatocytes. IL- 8 and, to a variable extent, NAP-2 and GRO induce neutrophil chemotaxis, prime neutrophils for enhanced superoxide production, modulate adhesion molecule expression, and enhance transendothelial migration. IL-8 also has some chemotactic activity on lymphocytes.

Several studies have identified elevated plasma levels of IL-8 in various patient groups. However, IL-8 is only functional when bound to matrix and cell surface proteins. Free IL-8 is bound by circulating autoantibodies and to a low-specificity erythrocyte receptor, the Duffy antigen, which may serve as a clearing mechanism. The cell surface-IL-8 interaction is dependent on specific heparin molecules, which provide a high degree of specificity to the response. Heparin sulfate proteoglycan chains self-associate and bind to various extracellular matrix proteins, growth factors, and cell surface enzymes. Heparinase activity releases growth factors from their heparin sulfate storage sites in the extracellular matrix, providing a mechanism for the induction of migration of diverse cell types in normal or pathologic situations. Neutrophils themselves possess and secrete heparinases.

GROα is secreted by endothelial cells, monocytes, and fibroblasts after stimulation with *LPS*, IL-1, or *TNF- α*. *NAP-2* is derived from cleavage of a platelet secretory product, platelet basic protein. Macrophages and neutrophils can cleave it from its precursors, and NAP-2 serves to modify subsequent neutrophil function.

CC Chemokines

The second set of chemokines, CC chemokines, include monocyte inflammatory protein (MIP), monocyte chemoattractant protein (MCP), and RANTES. MCP-1 is a 76 AA polypeptide, produced by monocytes, endothelial cells, lymphocytes, and fibroblasts, that induces monocyte chemotaxis and activation. Mononuclear phagocyte-derived MIP-1α is chemotactic for T cells and monocytes. MIP-1 is produced by monocytes, lymphocytes, and fibroblasts and mediates both T cell chemotaxis and adhesion. RANTES is induced by TNFα and IL-1 in lung epithelial cells and is chemotactic for T lymphocytes.

Leukocyte–Endothelial Cell Adhesion and Emigration from the Vasculature

Binding of the recruited leukocyte to the endothelial cell, emigration from the vasculature and into the parenchyma, and subsequent activation are mediated via a series of adhesion molecules. These include members of the immunoglobulin (intercellular adhesion molecule, ICAM), integrin, and selectin families. A well-accepted model of neutrophil adhesion to endothelium involves at least three sequential events.

Selectin-Mediated Leukocyte Rolling

The first stage, rolling, occurs constantly and involves the transition of the leukocyte from the circulating state, in which it is moving in the center of the vessel, to a slower rolling state, in which it is tumbling along the wall of the capillary or venule. Rolling leukocytes may adhere firmly or may detach and rejoin the mainstream of flowing blood. The prevailing wall sheer rate in postcapillary venules determines in part the level of leukocyte rolling and of firm adhesion and dictates the contact area between rolling leukocytes and the endothelial cell surface.

Rolling involves the selectins, which are calcium-dependent glycoprotein receptors that have a common molecular structure. The selectins are named after the cell type on which they are primarily found: E-selectin (endothelial cell), P-selectin (platelet), and L-selectin (leukocyte). L-selectin mediates rolling in part by presenting neutrophil carbohydrate ligands to the endothelial E- and P-selectins. E-selectin (endothelial leukocyte adhesion molecule-1, ELAM-1) is found exclusively on endothelial cells activated by *TNF- α*, IL-1, *LPS*, interferon-γ, and substance P. It allows endothelial cells to bind to neutrophils, monocytes, and certain memory T cells. L-selectin is expressed by neutrophils and monocytes as well as certain populations of lymphocytes, natural killer (NK) cells, and hematopoietic progenitor cells. It is concentrated on the microvilli projections of unstimulated neutrophils. Rolling also allows neutrophils to pick up endothelial-borne chemical signals such as IL-8 and *PAF*, which then promote integrin-mediated adhesion and subsequent migration of neutrophils.

Integrin-Mediated Leukocyte Activation and Transendothelial Migration

The second event in neutrophil–endothelial cell adhesion is activation, mediated by chemotactic agents that are released from or are attached to the endothelium. Leukocyte surface expression of the β₂ integrin CD11B/CD18 integrin is increased. This activation enables the third stage of firm adhesion and transendothelial migration to occur by promoting the function of integrin adhesion molecules on the leukocyte surface. Subsequent neutrophil transmigration to the extravascular space involves adherence via other leukocyte integrins.

Cytokines in the Systemic Response to Infection

Liver dysfunction is common during the course of intraabdominal infection and occasionally progresses to fatal hepatic failure. There is considerable evidence that various macrophage products, including IL-1, IL-6, and TNF- γ, substantially alter hepatocyte function. Aside from conversion of hepatic synthetic function to acute phase reactants, serum chemistry studies reveal evidence of ductal epithelial cytotoxicity, including elevated levels of alkaline phosphatase and bilirubin. The large number of fixed tissue phagocytes (Kupffer cells) in the liver capable of responding to endotoxin absorbed from systemic or mesenteric blood vessels represents a potentially important source of cytokines and other hepatocyte regulatory substances, although portal endotoxemia has not been detected in humans.

BACTERIOLOGY OF PERITONITIS AND INTRAABDOMINAL INFECTION

Normal Bowel Flora

The vast majority of the bacteria in the colon are anaerobic species that, so far as is known, contribute little to clinical intraabdominal infection. The most common bacteria isolated in clinical infections are *Escherichia coli* and *Enterobacter*, *Klebsiella*, and *Pseudomonas* species (Table 32-3), which make up less than 0.1 percent of the normal colonic flora. Even the most common anaerobic pathogen, *Bacteroides fragilis*, accounts for only 1 percent of the colonic flora. The presence of large numbers of nonpathogenic bacteria provides a measure of protection to the host by suppressing the growth of potentially pathogenic bacteria. Overgrowth of pathogenic gram-negative aerobic bacteria is commonly seen after treatment with broad-spectrum antibiotics. Many of these bacteria are associated with nosocomial infections that are much more difficult to eradicate.

Effect of Level of Gastrointestinal Perforation

The morbidity and mortality of intraabdominal infections vary dramatically with the level of gastrointestinal tract perforation, because the number and type of microorganisms vary throughout the gastrointestinal tract. Under normal circumstances the stomach contains fewer than 10^3 bacteria per cubic millimeter, largely because of the action of hydrochloric acid and the very low pH in the stomach. When patients receive H_2 -receptor blockers and proton-pump inhibitors that raise gastric pH, the number of bacteria rapidly approaches the levels seen in the proximal small bowel. The number of bacteria per cubic millimeter increases with distance down the gastrointestinal tract. In the proximal small bowel there are approximately 10^4 to 10^5 bacteria/mm³, whereas the terminal ileum contains more than 10^9 /mm³. The highest absolute numbers of bacteria are found in the colon, where there are between 10^{10} and 10^{12} bacteria/mm³.

The type of bacteria changes with distance down the gastrointestinal tract as well. In the upper gastrointestinal tract facultative gram-negative aerobic bacteria predominate, whereas the colon contains many more anaerobic than aerobic bacteria. In the colon, gram-negative and gram-positive anaerobic bacteria are present, along with facultative aerobes. The number of species of bacteria isolated also is highest in the colon, with more than 500 species of bacteria and fungi.

Virulence Factors

Virulence factors provide pathogenic bacteria with a selective advantage in that they thwart normal host defense mechanisms by impairing opsonization or phagocytosis. In other cases, extracellular products such as coagulase and catalase are secreted by *Staphylococcus aureus*. In the case of *B. fragilis*, the presence of a polysaccharide capsule is strongly associated with abscess formation. In experimental studies, the injection of a component of the polysaccharide capsule is as efficient as the entire bacteria for causing abscesses.

Microbial Adherence to Peritoneum

Microbial colonization of the peritoneal mesothelial surface is a rapid phenomenon after penetration injury of the distal bowel. Bacteria adherent to the peritoneum are resistant to removal by peritoneal lavage, in contrast to the bacteria present in peritoneal fluid, which are significantly decreased after lavage. Enterobacteriaceae (aerobic *E. coli* and similar organisms) rapidly colonize serosal mesothelium and become the predominant flora within 4h after induction of peritonitis. After 8 h, the *B. fragilis* group is the predominant organism adherent to the peritoneum and is unaffected by extended saline lavage.

Antimicrobial lavage produces an immediate but transitory decrease in the numbers of bacteria; the microbial population exceeds prelavage levels 24 h later. This favors reexploration at 24-h intervals when operative management of intraabdominal infection is done by staged abdominal repair.

Role of Aerobic and Anaerobic Bacteria

Among aerobic bacteria, gram-negative species of the Enterobacteriaceae family (particularly *E. coli*) and the *Klebsiella* and *Enterobacter* genera predominate. Among anaerobic bacteria the most common isolates are *Bacteroides* species. In experimental models that have been reported, when pure cultures of *E. coli* were injected into animals, peritonitis developed in all animals, with a high incidence of *E. coli* bacteremia and significant mortality. Injection with *E. coli* alone did not result in any intraabdominal abscesses, which are usually seen in patients who survive the diffuse inflammatory phase of peritonitis. By contrast, when *B. fragilis* was injected, there was almost no mortality, and very few *B. fragilis* were recovered from the bloodstream, but the incidence of intraabdominal abscesses was almost 100 percent. Injection of the combination of *E. coli* and *B. fragilis* resulted in a picture similar to that seen in human patients, with significant mortality and intraabdominal abscesses in most survivors.

The LPS present on the surface of gram-negative organisms, including those of the Enterobacteriaceae family, is a key virulence mechanism, because it interacts with a broad range of human cell types to induce an inflammatory response. The initial response includes thrombosis, restricting blood supply to an area of contamination. An influx of cells that are profoundly cytotoxic, both for the bacteria and resident tissue, follows. These responses reduce the numbers of organisms needed to establish an infection, a paradoxical consequence of the inflammatory response. This paradox may be explicable if the inflammatory response is a means of generating abscesses with subsequent extrusion to an external surface.

Microbial Synergy

The consequences of synergy are most evident in necrotizing soft tissue infections. Characteristic histologic findings include extensive local thrombosis and dense growth of microorganisms responding only to wide excision with normal tissue. Synergistic interactions between anaerobes, most notably *B. fragilis*, and endotoxin-bearing gram-negative organisms suppress local host defense mechanisms and facilitate the establishment of infection. *B. fragilis* produces a capsular polysaccharide that interferes with complement activation and inhibits leukocyte function. Delivery of phagocytes to the site of infection is restricted, permitting a more rapid rate of bacterial growth.

Aerobic bacteria lower the oxidation-reduction potential, thus favoring the growth of anaerobic bacteria. Anaerobic bacteria elaborate short-chain fatty acids that interfere with neutrophil function. Either type of bacteria may enhance the growth of other bacteria by provision of nutrient factors or destruction of antibiotics. High concentrations of bacteria inhibit the ability of most antimicrobial agents to function optimally. Extracellular products such as proteases facilitate bacterial invasion.

Host Effects on Bacterial Growth

The host neurohumoral response to infection may enhance bacterial growth in that gram-negative bacterial growth is dramatically enhanced by physiologic concentrations of norepinephrine, an effect mediated by a receptorlike mechanism within the bacteria. Some bacterial pathogens may have evolved mechanisms to exploit the inflammatory milieu. This may partially explain the well-known effect of traumatic injury on enhancing the lethality of intraabdominal infection.

Adjuvant Substances

The inoculum of bacteria needed to establish experimental infections is much less if subjects simultaneously are inoculated with adjuvant substances. Adjuvants increase bacterial virulence or interfere with host defenses. In gastrointestinal perforation, a surgical procedure, or trauma, the bacterial inoculum is invariably accompanied by adjuvant substances (Table 32-4).

Clinically, the most important adjuvant substance is blood. Hemoglobin, fibrin, and platelets in blood all impair peritoneal defenses. Hemoglobin decreases the median lethal dose of bacteria in standard rodent models of peritonitis by five orders of magnitude. Hemoglobin increases bacterial growth rates, perhaps because of the liberation of iron, an essential growth factor for *E. coli*. Iron may depress neutrophil migration and phagocytic function. Stroma-free hemoglobin is directly toxic to neutrophils as well. Platelets impair clearance of bacteria from the peritoneal cavity, presumably by physical obstruction of the diaphragmatic lymphatic channels. Fibrin promotes bacterial trapping and abscess formation but may impede the ability of neutrophils to reach the bacteria. Fibrinolytic agents instilled intraperitoneally in experimental animals were found to lyse clots and prevent abscess formation but were associated with higher bacteremia rates and higher lethality.

Other substances that may gain access to the peritoneal cavity during infection include bile salts, gastric mucin, pancreatic secretions, urine, and chyle. Bile salts aid in digestion of lipids because of their detergent action. Bile salt also can result in destruction of leukocytes and impaired host defense. Some bacteria may be digested by bile salts, but others, for example, *Enterococcus faecalis*, can readily grow in media that is 40 percent bile salts—which is the basis of the most common microbiologic test to identify *E. faecalis*. Pancreatic secretions contain proenzymes that can become activated by bacterial infection, resulting in tissue digestion and increased bacterial invasion.

Foreign Materials

Foreign materials may play an important role in the pathogenesis of infection. Microorganisms adherent to foreign materials are far more difficult for phagocytes to kill, and the foreign body may itself induce an inflammatory reaction, reducing the inoculum needed to establish infection. Foreign materials that play a role in the pathogenesis of abdominal infections may be macroscopic or microscopic (Table 32-5). Macroscopic foreign bodies such as drains, suture material, microscopic fragments of cotton gauze sponges shed from laparotomy pads, and hemostatic agents such as collagen or cellulose potentiate infection. Microscopic foreign materials include talc, barium sulfate, necrotic tissue, and fecal material. Some foreign materials may be directly toxic to neutrophils. Mucin and fiber can activate complement. Nylon, including the nylon in sutures, can cause neutrophil degranulation and impairment of oxidative microbial killing. Barium sulfate, a particularly virulent adjuvant, produces its own acute inflammatory insult. The combination of barium and feces is more lethal than either alone. The chemical injury to the peritoneum by barium increases its permeability. Free barium activates the coagulation system by way of the intrinsic pathway, resulting in severe fibrinous peritonitis that carries a mortality of 53 percent even when surgically controlled.

EVOLUTION OF INTRAABDOMINAL INFECTION

Peritoneal Contamination

When peritoneal injury is accompanied by bacterial contamination, degranulation of peritoneal mast cells dramatically increases the permeability of peritoneal endothelial and mesothelial cells. The resultant exudation of protein-rich fluid contains complement, opsonins, and fibrinogen. Increased vascular permeability also results in a significant fluid influx into the peritoneal cavity. This fluid comes at the expense of depleted intravascular volume, resulting in hypotension.

The systemic response to peritonitis includes the release of catecholamines, glucocorticoids, aldosterone, and vasopressin (antidiuretic hormone). These responses, combined with hypovolemia from the copious fluid sequestration within the peritoneum, can create hemodynamic instability with hypotension, reduced cardiac index, increased peripheral resistance, and increased peripheral oxygen consumption. The patient may manifest the hyperdynamic hemodynamic picture of septic (distributive) shock, i.e., increased cardiac output, decreased peripheral resistance, and decreased arteriovenous oxygen difference. Fluid resuscitation may change the patient's condition from a hypodynamic to a hyperdynamic state.

After a free perforation into the intestinal cavity, the contaminating bacteria migrate with the peritoneal fluid to the subdiaphragmatic area, where large numbers are cleared into the systemic circulation via the subdiaphragmatic lymphatic “pump.” The bacteria empty into the systemic circulation through the thoracic duct and into the left subclavian vein within 6 min of inoculation. More than 90 percent of circulating bacteria are cleared by phagocytosis in the reticuloendothelial system, particularly hepatic Kupffer cells.

Concept of the Decisive Period

After peritoneal contamination the ultimate outcome, resolution, or establishment of infection becomes a race between bacterial multiplication and bacterial destruction by the host defenses. Resident peritoneal macrophages are the initial leukocytic cell on the scene capable of phagocytosing bacteria. Normal peritoneal fluid contains less than 300 cells/mm³, with more than 50 percent macrophages, 40 percent lymphocytes, and 5 to 10 percent mast cells or eosinophils. During the first 1 to 2 h after bacterial contamination, macrophages and mast cells are the only phagocytic host defense cells in the peritoneal cavity. Macrophages are capable of phagocytosis on the peritoneal surface even without prior opsonization. Bacterial opsonization, with IgG or C3b, improves phagocytic efficiency. Prompt clinical recognition and appropriate treatment can drastically shift this dichotomy. Miles and Burke suggested the concept of a “decisive period” for bacterial infection. This period refers to the time required for bacterial numbers in fluid or tissue to exceed 10^5 /mm³ (or per gram of tissue) and establish an infection. Surgeons must deal with the infection before bacterial numbers reach these levels or remove the focus of infection so that after

operation the residual numbers of bacteria are less than $10^5/\text{mm}^3$ (Fig. [32-4](#)).

CARE FOR PATIENTS WITH INTRAABDOMINAL INFECTIONS

Diagnosis of Intraabdominal Infection

The history and physical examination of patients with a suspected intraabdominal infection are pivotal in defining the need for and urgency of intervention and the use of diagnostic techniques. A brief history should determine how long the patient has been ill; whether fever or chills are present; whether pain is present, and if so where it is located, what its character is (crampy, dull, burning, etc.), whether it has changed location, character, or intensity, and whether it is associated with anorexia, vomiting, or ileus. A pertinent past medical history, including recent hospitalizations, medications, chronic disease diagnoses, and prior operations, is important.

Stretching of the visceral peritoneum produces nausea and poorly localized pain. Most intraperitoneal visceral structures arise from the embryologic foregut, and, accordingly their nerve supply arises from the visceral branches of the vagus nerve. Pain usually is localized to the dermatome distribution of the associated visceral organ. For example, the gallbladder arises from the upper thoracic dermatomes; hence, stretching of the visceral peritoneum overlying the gallbladder produces epigastric and right upper back pain. When the inflammatory process involves the adjacent diaphragmatic structures, pain may be perceived in the neck or shoulder (fourth cervical nerve), because the diaphragm arises from the embryologic cervical dermatomes.

Visceral peritoneal irritation, usually from distention of a hollow viscus, causes dull, poorly localized, often periumbilical, and often crampy pain. Visceral structures are generally completely insensitive to surgical transection, cauterization, heat, cold, or pinching. Most symptoms result from inflammation of the visceral peritoneum, which receives afferent innervation only from the autonomic nervous system and is relatively insensitive. Visceral afferent nerves respond primarily to traction or distention, but less well to pressure, and are not capable of mediating pain and temperature sensation. Hence stimuli are perceived as poorly localized, dull discomfort.

The root of the small bowel mesentery and the biliary tree are relatively better innervated than the rest of the visceral peritoneum, accounting for more intense and better localized responses to stimulation of these areas. The term *biliary colic* refers to the sensation transduced by visceral afferents from an overdistended gallbladder undergoing muscular spasm because of an obstructing stone. The small bowel itself is not well innervated, and so stimulation of its visceral afferents produces only a vague, dull ache in the midabdomen. Stimulation of the colonic afferents results in a similar dull pain located in the lower abdomen. Pain may start abruptly with a perforation when a highly irritating agent such as pancreatic or gastric juice diffusely inflames the somatic nerve endings of the parietal peritoneum.

A good example of the effects of the dual mechanism of pain perception is in the progression of symptoms in the development of acute appendicitis. Initially inflammation of the appendix is projected via autonomic nerve fibers to the region of the umbilicus and epigastrium, with symptoms of diffuse epigastric pain, nausea, and vomiting. As the somatic pathways of the parietal peritoneum and adjacent structures become involved, the pain seems to “migrate” from the epigastrium and umbilicus to the right lower abdomen and to grow in intensity, and then to localize at McBurney's point. When fully developed, pain in parietal peritonitis is steady, unrelenting, burning, and aggravated by motion, and usually it is most intense in the region of the most advanced peritoneal inflammation.

Assessment of Hemodynamic and Respiratory Status

There are two potential causes of hypotension in patients with intraabdominal infection. Fluid loss occurs through a variable combination of decreased intake, increased respiratory fluid losses from the tachypnea accompanying fever, and intraabdominal fluid sequestration. The extent of fluid sequestration that accompanies infection is a result of both the local peritoneal response and the diffuse capillary leak that accompanies major sepsis. Hypotension also may be caused by the cardiac and vascular dysfunction that is part of septic shock.

Immediate differentiation between these two distinct entities may not be straightforward. Hypotensive patients should receive boluses of 500 mL lactated Ringer's solution until an adequate blood pressure response occurs. If 3 L have been given and a sustained blood pressure response has not occurred, particularly in an elderly patient, a pulmonary artery catheter should be placed to determine hemodynamic function and to monitor fluid and pressor therapy.

Physical Examination

In addition to a review of the vital signs, the general appearance of the patient, including tachypnea or labored breathing, agitation, or evidence of dehydration, should be carefully noted. Each part of the examination should be explained to the patient before it is performed, with reassurances that it will not be painful. The scleras and conjunctivae may reveal icterus or pallor. The chest should be percussed and auscultated to rule out pneumonia, particularly of the lower lobes, which may produce the abdominal findings. In a hypotensive patient, rolling the patient from side to side rather than sitting him or her up is appropriate. A cardiac examination should rule out congestive failure or valvular disease, since aggressive fluid therapy may be required and because acute congestive failure with hepatic distention and capsular stretching may produce abdominal pain.

Inspection and Auscultation

The abdomen should be inspected for distention and any scars noted. The patient should be assured at this point that the examination will cause minimal discomfort but is needed to determine the need for diagnostic measures and therapy. The patient is asked to point with one finger to the area of most severe pain in the abdomen. Auscultation is begun in the quadrant diagonally opposite to this point. Auscultation is performed to simply determine whether bowel sounds are diminished, normoactive (determined according to when the patient last ate), or hyperactive. Hyperactive bowel sounds suggest an obstructive element either as a primary disease process or as part of a localized inflammatory process. Often an inflammatory focus is partially walled off by adherent small bowel. A local ileus occurs, resulting in a functional obstruction. Abdominal distention is a result of concomitant ileus or ascites. Hyperresonance caused by accumulating gas in the distended intestines usually can be demonstrated by percussion. As inflammation spreads, small-bowel sounds disappear and the abdomen becomes nearly silent.

Palpation

The parietal peritoneum is innervated by somatic and visceral afferent nerves and is quite sensitive. The anterior parietal peritoneum is the most sensitive, and the pelvic peritoneum the least sensitive. The ability to localize an inflammatory stimulus affecting the parietal peritoneum, particularly of the anterior abdominal wall, underlies much of our ability to diagnose acute intraabdominal infection.

In addition to the perception of pain as localized tenderness, local inflammation adjacent to the parietal peritoneum leads initially to protective voluntary muscular guarding. If the inflammatory process continues, reflex muscular spasm of the anterior abdominal wall occurs, progressing to various degrees of rigidity. Gentle palpation of the abdomen, the last step in the examination, is intended to determine whether the pain-producing intraabdominal process has resulted in parietal peritoneal inflammation. Palpation starts at the quadrant most removed from the identified point of maximal pain. The purpose of abdominal palpation is to confirm the location of maximal tenderness and the resting tone in various portions of the anterior abdominal wall. To do this, the examiner begins in a part of the abdomen that is asymptomatic and gently presses until the tone of the underlying musculature is determined. In patients with acute peritonitis, a rigid abdomen will be found with no substantial differences from one quadrant to another. For patients with localized tenderness, and a localized increase in abdominal wall tone, voluntary versus involuntary guarding must be distinguished.

Rigidity of the abdominal muscles is produced by voluntary guarding initially and also by reflex muscle spasm. Reflex muscle spasm can become so severe that boardlike abdominal rigidity is produced and the abdominal wall may become scaphoid, as is typically seen after chemical peritonitis caused by peptic ulcer perforation.

Rectal and Vaginal Examinations

Rectal and vaginal examinations are essential to locate the extent of tenderness and whether a pelvic mass or pouch of Douglas abscess is present. Vaginal examination of the cervix may provide clues to the origin of the inflammatory process.

Laboratory and Other Tests

Leukocytosis is common in acute intraabdominal infection, but the total leukocyte count taken alone without a differential count can be very misleading. A leukocyte count of more than $25,000/\text{mm}^3$ or leukopenia with fewer than $4,000/\text{mm}^3$ are both associated with higher mortality. The differential count provides evidence of the presence of acute inflammation by showing relative lymphopenia and moderate-to-marked leftward shift, even if the leukocyte count is normal or subnormal.

Plain radiographs of the abdomen may reveal free air, a uniform indicator of visceral perforation in the absence of recent prior intervention. Free air may be visible on an upright abdominal or lateral decubitus film if a ruptured hollow viscus is the cause of peritonitis. Air beneath the diaphragm may be noted on radiographs of the chest if the patient remains in an upright position for 5 min or more before the film is made. Other findings from plain radiographs that support the diagnosis of intraabdominal infection include intestinal pneumatosis, bowel obstruction, and a mass effect. There are rare benign causes of pneumatosis. More dramatic but less common findings are air in the portal vein or extraluminal gas collections indicative of an abscess; these radiographic signs are sufficiently specific to justify immediate intervention.

The radiologic picture of intraabdominal infection otherwise mimics that of paralytic ileus. Inflammatory exudate and edema of the intestinal wall produce widening of the space between adjacent bowel loops on a plain film of the abdomen. Peritoneal fat lines and the retroperitoneal psoas shadow may be obliterated because of edema. The fat lines in the pelvis may be obliterated, suggesting fluid in the pelvis.

Preoperative Preparation

Acute perforations of the gastrointestinal tract with peritonitis mandate initial treatment in an intensive care environment. In addition, patients with serious intraabdominal infections often require intervention to control infection.

Perforations of the upper gastrointestinal tract cause impressive physical findings of peritonitis but rarely manifest evidence of septic shock. Conversely, perforations of the colon result in massive bacterial contamination and are accompanied by hypotension. In either setting, progressive clinical deterioration will continue until soiling of the peritoneal cavity is terminated. This puts important temporal limits on resuscitation prior to operative intervention. Patients with acute perforations of the gastrointestinal tract should be sufficiently resuscitated to survive the induction of anesthesia, but resuscitation should continue during operation. Rapid volume loading will counter the vasodilatory effects of anesthetics. More refined parameters of completed resuscitation, such as maximization of cardiac output or oxygen delivery, should await the completion of successful intervention.

In addition to intravascular volume loading, other maneuvers are of value in protecting patients from intraoperative hypotension. Infusing low doses of dopamine improves renal blood flow and reduces the incidence of acute renal failure. Positive end-expiratory pressure (PEEP) should be used sparingly, as it decreases venous return and can compromise cardiac output. High inspired oxygen concentrations maintain adequate arterial oxygen saturation until intravascular volume has been satisfactorily restored.

Preoperative preparation of patients with peritonitis involves fluid resuscitation, administration of antibiotics and oxygen, nasogastric intubation, urinary catheterization, and monitoring of vital signs and biochemical and hemodynamic data. Major metabolic derangements and fluid deficits should be corrected before operation, although an inordinate delay is deleterious to outcome. Oxygen is administered to correct the mild hypoxemia in patients with peritonitis secondary to intrapulmonary shunting and the mechanical impairment of pulmonary ventilation by the distended, tender abdomen. Assessment of respiratory function should include apparent tidal volume and work of breathing. If impairment is suspected, ventilatory volume and arterial blood gases should be measured. Ventilatory support should be initiated whenever any of the following is present: (1) inability to maintain adequate alveolar ventilation as evidenced by a Pa_{CO_2} of 50 mmHg or greater; (2) hypoxemia, with a Pa_{O_2} below 60 mmHg and a fraction of inspired oxygen of 1.0; or (3) shallow, rapid respirations, muscle fatigue, or the use of accessory muscles of respiration.

Vital signs—temperature, blood pressure, pulse rate, respiration rate—are continuously recorded. Preoperative biochemical evaluation should include measurement of serum levels of electrolytes, creatinine, glucose, bilirubin, and alkaline phosphatase, and a urinalysis.

Nasogastric intubation is performed to evacuate the stomach, to prevent further vomiting, and to reduce accumulation of additional air in the paralyzed bowel. Urinary catheterization is used to record initial bladder urine volume and to monitor subsequent urinary output. Renal dysfunction requires early corrective measures. Patients with peritonitis develop renal failure as a result of hypovolemic shock, septic shock, increased intraabdominal pressure, and nephrotoxic drugs such as the aminoglycosides. Diuretics are used but may be toxic to tubular cells. If there is cardiopulmonary dysfunction, a Swan-Ganz catheter allows measurement of pulmonary capillary wedge and pulmonary artery pressures, systemic vascular resistance, and cardiac output as indices for pharmacologic intervention.

Once a decision to operate has been made, pain should be relieved with potent narcotics. Morphine is preferred, and should be given intravenously in doses of 1 to 3 mg, repeated every 20 to 30 min or even more frequently, to maintain comfort. Small intravenous doses of morphine are safer than the traditional larger intramuscular doses, particularly in unstable patients whose absorption of intramuscular medication may be unpredictable and variable.

Administration of pharmacologic doses of steroids to septic patients has been advocated in the past, but controlled trials have not shown this treatment to be efficacious. Recent clinical studies support the concept that large doses of steroids may delay mortality in sepsis, particularly if given before the onset of shock or very soon after, but they do not alter the eventual outcome. Steroids are not recommended in the management of bacterial peritonitis.

Patients with hyperthermia or hypothermia should have their temperature corrected toward normal before operation. Administration of acetaminophen is often effective in reducing fever. If not, or if the patient is hypothermic, a cooling or warming mattress should be used.

MANAGEMENT OF DIFFUSE PERITONITIS

The history and physical examination usually are sufficient to make the diagnosis, and no further testing is necessary. Even if infection spreads diffusely throughout the peritoneal cavity, if the source is controlled by early surgical intervention, peritonitis usually responds to vigorous antibiotic and supportive therapy. On the other hand, death nearly always follows continued peritoneal soiling.

Operative management of peritonitis involves immediate evacuation of all purulent collections, with particular attention to subphrenic, subhepatic, interloop, and pelvic collections. The perforated bowel should be resected. Evidence has accumulated from studies of several decades of mortality rates following surgical treatment of perforated diverticulitis that resection with end colostomy significantly decreases acute mortality as compared to transverse loop colostomy and drainage. Primary anastomosis is not recommended in the face of purulent peritonitis; in one study, mortality from primary anastomosis was 23 percent, with most deaths attributed to anastomotic leakage. Controversies in the operative management of peritonitis focus primarily on wound closure techniques and scheduled relaparotomies. Patients with diffuse peritonitis secondary to colonic perforation or anastomotic dehiscence typically develop abdominal wall edema as part of a generalized syndrome of increased capillary permeability. This syndrome is exacerbated by the aggressive restoration of intravascular and extravascular volume. Under these circumstances, primary closure of the abdominal incision may be difficult or even unwise, as increased intraabdominal pressure can result in compression of mesenteric and renal veins, leading in some instances to acute renal failure or bowel necrosis. A fascial prosthesis prevents an overly tight closure. A variety of materials have been employed, including Marlex, Silastic, and polytetrafluoroethylene (PTFE). Each material has its own virtues and problems. Impermeable materials can exacerbate peritonitis and should be used only if a relaparotomy is planned.

Recurrent abscesses and persistent peritonitis largely account for the high mortality in patients with diffuse peritonitis. A continued septic state with renal and/or hepatic dysfunction should raise suspicion of diffuse peritonitis, but there is little satisfaction with current approaches for operative management. A variety of mechanical approaches have been proposed to reduce mortality, generally based on the notion that failure of host defense mechanisms of the peritoneal cavity leads to persistent infection. Planned relaparotomy at present seems most attractive. Patients treated in this fashion undergo standard operative management of their infection, but the fascia is not closed; instead, a prosthetic material is sewn to the fascia as a temporary closure, and at intervals of 24 to 48 h the mesh is opened and the peritoneal cavity debrided and irrigated. Early reports were quite positive, but used historical controls. More recent reports have not found that survival is substantially improved or that the incidence of late abscess formation is reduced. Occasional fistulas have occurred.

We have used planned relaparotomy in conjunction with prosthetic fascial closure for a relatively small number of patients with septic shock and colon-derived peritonitis. The obvious benefits are absence of intraabdominal and wound tension and the ability to obtain sequential microbiologic data to guide antimicrobial therapy. Once the prosthetic mesh is in place, relaparotomy is performed on a scheduled basis, or as dictated by the patient's clinical course and adjunctive tests, particularly computed tomography. The latter, more conservative approach seems worthwhile for patients who recover from their initial episode of shock and who do not manifest progressive organ failure. In such patients, abdominal wall and visceral edema typically resolves over the first week, at which time definitive closure of the abdomen is performed.

Management of Specific Forms of Peritonitis

Perforation of the Stomach and Duodenum

Infection after peptic ulcer perforation presents acutely; the patient is commonly able to give the exact time at which the perforation occurred. This form of peritonitis is initially chemical, but with time it becomes infected. The patient usually seeks help early because of the severe pain, and operative repair often is possible before significant bacterial overgrowth has occurred. The proper management is simple closure of the perforation; some authors have recommended definitive treatment of the ulcer disease in addition if the perforation is less than 12 h old. Parietal cell vagotomy and a Graham patch of the perforation is favored by many.

Small-Bowel Perforation

Infection after small-bowel perforation falls into two categories. In the first, bowel obstruction is present, so that ileus precedes peritonitis. Colic and other features of bowel obstruction are the presenting signs and symptoms, gradually changing to those of localized or diffuse peritonitis, with fever and leukocytosis after perforation. In the second form, bowel wall necrosis as a result of inflammation or impaired vascular supply leads to perforation. Peritonitis may be diagnosed at a late stage because of the lack of initial symptoms, and hence mortality rates can exceed 50 percent.

Colon Perforation

About 20 percent of cases of peritonitis have their origin in the colon. More than half of these are due to inflammatory disease such as diverticulitis and other forms of colitis. The remaining cases are due to perforation proximal to or at stenosis caused by luminal bowel obstruction (tumor) or external bowel obstruction such as incarcerated hernia, intussusception, and volvulus. In colonic obstruction, the colon distends proximally and ruptures as a result of either increased intraluminal pressure or diminished vascular supply to one segment. A malignant growth usually does not cause peritonitis directly but may lead to bowel obstruction with either perforation of dilated segments or bowel ischemia, and/or bacterial migration through the necrotic bowel wall. Carcinoma of the colon, if the ileocecal valve is competent, may lead to diffuse fecal peritonitis as a result of rupture of the cecum or ascending colon.

A ventral midline incision is preferred, as it is quick to open and close and allows easy exploration of the entire abdomen, especially in cases in which the organ source of peritonitis is not clear. Complete control of the source of infection is essential for therapeutic success. The elimination of the infectious source or focus reduces the infectious inoculum to a magnitude that is treatable successfully by antibiotic therapy coupled with active intrinsic host defense mechanisms. When the infectious focus cannot be adequately controlled, the prognosis is poor.

Peritonitis of Genitourinary Origin

Ruptured perinephric abscess and ruptured chronic cystitis after radiation therapy for female reproductive tract cancer can cause peritonitis. A colon anastomosis should be avoided in peritonitis associated with a urine leak. Pelvic peritonitis due to sexually transmitted infection is common in young women; usually there is acute, severe lower abdominal pain, typically just cephalad to the inguinal creases. The condition is diagnosed by Gram stain of cervical discharge. Treatment with antimicrobials is successful in most cases, and operation is reserved for the occasional patient with persisting tubo-ovarian abscess.

Postoperative Peritonitis

Postoperative peritonitis is usually the result of an anastomotic leak and is often discovered only after some delay, typically between the fifth and seventh postoperative day. Delay contributes to a high mortality rate. After duodenal operations, the high mortality of leakage is explained by the fact that the duodenum is fixed in the retroperitoneum and cannot be exteriorized, and the source of infection often cannot be adequately controlled or closed. Consequently, infective material and proteolytic enzymes continue to soil the peritoneal cavity, sustaining the infection. Drainage, controlled fistula formation, exteriorization, repair, or resection and reanastomosis are performed as indicated.

Peritonitis After Trauma

Peritonitis may develop after blunt trauma in patients who have unrecognized intraabdominal injuries such as a ruptured mesentery with loss of the vascular supply to the small or large bowel, or a frank unrecognized bowel perforation. This type of intraabdominal infection usually is severe because the diagnosis is delayed or masked by other injuries elsewhere in the body, particularly head injury. Management in such instances is no different from that of other forms of peritonitis.

Patients suffering penetrating trauma, typically gunshot wound or stab wound, usually are operated on, and the wound is repaired or controlled immediately; these injuries lead to peritonitis only when the initial repair leaks. Perforation of a bacteria-containing hollow viscus by blunt trauma is less frequent but more of a clinical diagnostic problem since symptoms can be masked by pain from the injury. Contamination of the abdominal cavity seen after penetrating abdominal trauma is usually not considered an intraabdominal infection. Only one-third of patients with penetrating trauma to the colon actually sustain documented contamination of the peritoneal cavity.

Cleaning the Abdominal Cavity

Various approaches to cleaning the abdominal cavity include suction, swabbing, lavage, radical debridement, and postoperative irrigation. There is broad agreement about the utility of suction and swabbing to remove pus and necrotic material, followed by local irrigation/lavage and limited debridement—measures typically used in every case. Controversy remains over the efficacy of high-volume lavage, radical debridement, and postoperative irrigation.

Intraoperative High-Volume Lavage

This treatment involves extensive intraoperative lavage of the entire abdominal cavity. Initially, 1 to 1.5 L of physiologic saline or Ringer's solution is placed into the abdominal cavity. The viscera are manipulated so that the fluid reaches all parts of the abdominal cavity to wash out pus, feces, and necrotic material, and then the fluid is suctioned away. This procedure is repeated until the suctioned fluid runs repetitively clear. The total volume of lavage should be at least equal to the estimated volume of the peritoneal cavity, which in adults is 8 to 12 L.

Povidone-Iodine

This should not be used in peritoneal lavage fluid. Iodine is highly toxic to the mesothelial cells of the peritoneum and it kills the phagocytic cells needed to clear bacteria. In animal experiments, use of povidone-iodine increases mortality, and in a controlled clinical trial the outcome with povidone-iodine was worse than with saline.

Radical Debridement

This is a poorly defined technique because it is almost impossible, without causing significant bleeding, to radically debride all necrotic tissue in intraabdominal infections, including intraabdominal abscesses. This may be one explanation for there being no significant outcome advantage in using radical debridement over other techniques. Surgical judgment is the critical element, since the drawbacks of radical debridement must be balanced against the fact that bacteria may be trapped in fibrin, and that necrotic tissue is an excellent medium for bacterial growth. Removal of such foci is the primary goal of the operative procedure, but given the adjuvant effect of hemoglobin, the procedure should not cause additional intraperitoneal hemorrhage.

Continuous Postoperative Irrigation

Four to six Tenckhoff catheters are placed in the abdominal cavity and irrigation fluid infused for 1 h. The abdominal cavity is drained, and the cycle is repeated. The drains often occlude, and there is no way to ensure that all diseased areas of the abdominal cavity are lavaged. Drains also may erode into the intestine to cause new complications. Controlled studies comparing continuous postoperative irrigation to standard therapy have yielded differing results, and in general the numbers of cases examined are small and do not permit any firm conclusions about efficacy.

OTHER FORMS OF PERITONITIS

(Table 32-6)

Primary Peritonitis

Primary peritonitis is an inflammation of the peritoneum from a suspected extraperitoneal source, often via hematogenous spread. It occurs in children and in adults and can be a life-threatening illness, particularly in patients with cirrhosis. The spectrum of bacteria causing this syndrome and the population primarily affected have changed over recent decades. Spontaneous bacterial peritonitis is now more common in adults than in children and shows no differential sex incidence. Children with nephrosis, formerly the group most commonly affected, have been replaced by adults with cirrhosis or systemic lupus erythematosus.

Spontaneous peritonitis in adults is seen most commonly in patients with ascites and is a monomicrobial infection (i.e., only a single species of bacteria is present), in contrast to the polymicrobial infection of typical suppurative (secondary) peritonitis. Although pneumococci formerly were the most frequent infecting organisms at all ages, coliforms now are the chief pathogens in adults, accounting for 70 percent of infections, with *E. coli* being the most common isolate. Gram-positive cocci account for 10 to 20 percent of cases, and anaerobes are seen in 6 to 10 percent. In children the common pathogens are hemolytic streptococci and pneumococci. Two peaks of incidence are characteristic, one in the neonatal period and the other at age four to five. There may be a history of previous ear or upper respiratory infection. Children with nephrotic syndrome and systemic lupus erythematosus are disproportionately affected.

The route by which bacteria are transmitted to the peritoneal cavity is not known. The hypothesis of transmural migration of bacteria from the intestine is supported by the presence of endotoxin in ascitic fluid and blood in many cirrhotic patients with decompensation, even though the bacteria themselves are not present in the ascitic fluid and patients have no clinical evidence of peritonitis. The frequent clinical association of spontaneous peritonitis with urinary tract infection harboring the same organisms, and cases of simultaneous spontaneous pulmonary empyema and pericarditis associated with spontaneous peritonitis, favor the hypothesis that transmission is hematogenous.

Clinical symptoms usually are of short duration in children; onset is more insidious in ascitic adults. Most patients complain of abdominal pain and distention; vomiting, lethargy, and fever are more prominent in children. Diarrhea is typical in neonates but seldom seen in adults. Bowel sounds are variable. Free air usually is not seen on abdominal radiographs. The clinical picture may be nonspecific.

Paracentesis is the most useful diagnostic test. Fluid is examined for neutrophil cell count and pH; a Gram stain should be done and a specimen sent for culture. The neutrophil cell count has the highest sensitivity and specificity in making the diagnosis; a neutrophil count greater than 250 cells/mm³ is positive. Studies of ascitic fluid in patients with suspected spontaneous peritonitis have shown that a wide arterial–fluid pH gradient also correlates with a positive diagnosis. Ascitic fluid pH is low in spontaneous bacterial peritonitis, while in sterile ascitic fluid the pH is the same as in serum. In only one-third of patients with positive fluid cultures are organisms seen on a stain of centrifuged peritoneal fluid, which is a reflection of the low concentration of bacteria in many cases of primary bacterial peritonitis. If the stain shows only gram-positive cocci, spontaneous peritonitis is strongly suggested. If a mixed flora of gram- positive and gram-negative bacteria is present, intestinal perforation is more likely and exploratory laparotomy is necessary. The presence of only gram-negative bacteria on the stain is consistent with either primary or secondary bacterial peritonitis.

When the diagnosis of spontaneous bacterial peritonitis is confirmed, antibiotic therapy should be started and the patient initially managed nonoperatively. Usually a cephalosporin or ampicillin-sulbactam is appropriate, since 90 percent of the organisms causing spontaneous peritonitis are sensitive to these antibiotics.

Peritonitis Related to Peritoneal Dialysis

Peritonitis is the dominant complication of *continuous ambulatory peritoneal dialysis (CAPD)* in patients with end-stage renal disease. Peritonitis occurs more frequently with CAPD than with intermittent peritoneal dialysis. Catheter-related infection is the most common mechanism, with no correlation with catheter location. Other causes of peritonitis in CAPD patients are tunnel infections and cuff extrusion. The bacteriology and treatment of dialysis-related peritonitis are considerably different from those of patients with other types of peritoneal infections. The incidence of dialysis-related peritonitis varies from center to center, but an overall average of 1.3 episodes per patient per year is estimated. In contrast to other causes of intraabdominal infection, dialysis-related peritonitis usually is caused by a single organism, and fungal infections are more common in this group. Two-thirds of patients with positive cultures have a gram-positive coccus as the causative organism, usually *Staph. aureus* or *Staph. epidermidis*. Gram-negative bacteria usually are found only in patients with recurring episodes of peritonitis, which may reflect antibiotic administration for prior episodes. Patients with dialysis-related peritonitis rarely have a positive blood culture, in contrast to patients with other causes of peritonitis. Anaerobes rarely are recovered. The presence of anaerobes or a mixed flora suggests intestinal perforation or other intraabdominal disease (e.g., diverticulitis or cholecystitis). Yeasts and tubercle bacilli are rare. Culture-negative peritonitis in dialysis patients ranges from 10 to 27 percent. *Pseudomonas aeruginosa* has been reported to cause around 3 percent of cases and generally cannot be cured by antibiotic therapy alone; the dialysis catheter must be removed in these patients.

Turbidity of the dialysate is the earliest sign, and the only finding in one- fourth of cases. If accompanied by abdominal pain or fever, prompt diagnostic laboratory studies and therapy are required. The diagnosis is established when any of the following is present: (1) positive culture from the peritoneal fluid; (2) a cloudy dialysate effluent; and (3) clinical signs of peritonitis. The stain of dialysis effluent is frequently negative in dialysis catheter-related peritonitis. Attention to sterile technique, use of topical povidone-iodine about the catheter wound, and use of sterile dialysate prepackaged in plastic bags all reduce the incidence of infection.

The initial treatment of dialysis-related peritonitis is administration of antibiotics and heparin in the dialysate as well as an increase in the dwell time of dialysate fluid. The indications for catheter removal include persistence of peritonitis after 4 to 5 days of treatment, the presence of fungal or tuberculous peritonitis, fecal peritonitis, or a severe skin infection at the catheter site.

Patients with a chronically implanted peritoneal catheter may develop sclerosing peritonitis, with a reported incidence of 1 to 6 percent. The cause is unknown, although a relationship with antecedent infection is possible. Affected patients usually have had frequent previous bouts of peritonitis. Treatment is directed at such complications as bowel obstruction.

A related form of peritonitis, due to infection of a ventriculoperitoneal shunt, exhibits clinical signs and symptoms similar to those of peritoneal dialysis catheter peritonitis. Peritonitis should be suspected in any patient having such a shunt who develops any abdominal symptoms.

Tuberculous Peritonitis

Tuberculous peritonitis, formerly frequently fatal as a manifestation of uncontrolled generalized tuberculosis, now is undergoing a renaissance in Europe and North America because of the increasing prevalence of acquired immunodeficiency syndrome (AIDS) due to human immunodeficiency virus (HIV) infection and of other immunocompromised states. It has always been a serious problem in India, Southeast Asia, Africa, and Latin America. Some cases are the result of reactivation of latent peritoneal tuberculosis established by hematogenous spread from a pulmonary focus during an earlier episode of acute disease. The tubercle bacillus presumably gains entry to the peritoneal cavity transmurally from diseased bowel, from the fallopian tube in tuberculous salpingitis, from the kidney in nephritis, or from some other distant source. Clinically, most patients lack an obvious source; however, a primary focus can be identified in all patients at autopsy. Patients usually have a positive tuberculin skin test.

Clinical Manifestations

Clinically, tuberculous peritonitis is insidious, presenting with fever, anorexia, weakness, and weight loss. Some ascites almost always is present, and more than half of affected patients have dull, diffuse abdominal pain.

In the past the disease was classified into “moist” and “dry” phases. The moist phase refers to the early, subacute stage with fever, ascites, abdominal pain, and weakness. Ascites is progressive and may become massive. The dry form presents later without ascites, following resolution, during which dense adhesions are formed. On examination, the abdomen is somewhat tender, but the classically described “doughy abdomen” is rarely seen today. Clinical manifestations of generalized tuberculous infection are seen in about one-third of

patients and include anorexia, weight loss, and night sweats.

Diagnosis

A peritoneal fluid tap will show mostly lymphocytes. Tubercle bacilli can be retrieved from ascitic fluid 80 percent of the time if more than 1 L of fluid is cultured. The ascitic fluid has an increased protein concentration, lymphocytic pleocytosis, and a glucose concentration below 30 mg/dL. If the fluid tap analysis does not establish the diagnosis, peritoneoscopy and direct biopsy of the peritoneum are recommended. On laparoscopy, the appearance of tuberculous peritonitis includes stalactite-like fibrinous masses hanging from the parietal peritoneum in the lower part of the abdomen. A directed, percutaneous needle biopsy specimen of a granulomatous lesion as well as samples of peritoneal fluid for direct smear examination and injection into a guinea pig should be obtained. As a last resort, exploratory laparotomy may establish the diagnosis. At laparotomy a peritoneal biopsy should be taken; the placement of drains or exteriorization of bowel should be avoided.

Treatment

Treatment is administration of antituberculous drugs. Given reports in recent years of resistance to commonly used tuberculostatic drugs, triple antituberculous drug therapy is instituted early in the course of the disease, generally with good results. Therapy should be continued for at least 2 years after the patient becomes asymptomatic. Tuberculous peritonitis may heal with formation of dense fibrous adhesions; treatment with prednisone during the initial few months of antituberculous drug therapy may reduce adhesion formation and subsequent obstruction.

Operation should be reserved for diagnosis if needle biopsy fails, or for the treatment of such complications as fecal fistula. Because tuberculous peritonitis heals with formation of dense fibrous adhesions, patients with this disease are prone to developing an intestinal obstruction.

Typhoid Perforation

Typhoid perforation usually is seen in the third week of infection with *Salmonella typhi* in patients with acute disease. The disease is rarely seen in Europe or North America but is endemic in regions with poor hygienic conditions and water contamination, such as India, Pakistan, and countries in South America and Africa. Typhoid bacilli are thought to penetrate the Peyer's patches of the intestine wall, mainly in the distal ileum. These collections of lymphoid cells hypertrophy, leading to hemorrhage and then perforation.

Perforation often is not appreciated in an already severely diseased patient, and it is superinfection resulting from leakage of intestinal bacteria that leads to the full-blown picture of suppurative bacterial peritonitis. Treatment consists of closure of the punched-out lesions and evacuation of pus from the peritoneal cavity. Staged abdominal repair may be indicated if abdominal toilet is incomplete during the first operation. Trimethoprim- sulfamethoxazole is the treatment of choice for uncomplicated typhoid, but in patients with peritonitis cefotaxime plus metronidazole is preferable.

Amebic Perforation

Entamoeba histolytica infection of the intestine usually causes a dysentery-like illness, but sometimes liver abscess or perforation of the large bowel occurs. Liver abscesses also can perforate secondarily and cause diffuse peritonitis. The clinical picture is that of bacterial peritonitis. Treatment consists of resection of the diseased bowel segment with anastomosis, application of the general principles of treating peritonitis, and the administration of metronidazole in combination with a third- generation cephalosporin.

Aseptic/Sterile Peritonitis

This form of peritonitis develops from irritant material (talc or foreign bodies) that has gained entry to the peritoneal cavity. Aseptic peritonitis can be caused by a variety of substances. They all act as adjuvants when secondary bacterial contamination occurs, promoting proliferation of microorganisms and transition to suppurative peritonitis. The soilage initially is sterile or nearly so, which distinguishes chemical peritonitis at onset from suppurative peritonitis. In chemical peritonitis following peptic ulcer perforation, cultures are initially sterile, but as time progresses, positive cultures are recovered. After 24 h, all cultures are positive and the patient has developed suppurative peritonitis. A similar shift from initially aseptic to bacterially infected peritonitis can occur with all forms of chemical peritonitis.

Foreign-Body Peritonitis

Foreign bodies may be deposited in the peritoneal cavity during operations (sponge or instrument inadvertently left behind) or may result from penetrating injuries or perforation of the intestines following ingestion. A larger foreign body can lead to the formation of an abscess in the presence of bacteria, but otherwise foreign bodies are sealed off and encapsulated.

Periodic Peritonitis

Recurrent episodes of abdominal pain, fever, and leukocytosis occur in certain population groups in and around the Levant, notably in Armenians, Jews, and Arabs. The disease appears to be familial. The major point for the surgeon is that laparotomy is not required in these episodes. Laparotomy is often performed for the first episode, since an acute intraabdominal process requiring surgical cure cannot be ruled out. At operation, the peritoneal surfaces may be inflamed and there is free fluid, but no bacteria. The appendix should be removed even if normal to eliminate the possibility of acute appendicitis in the differential diagnosis of future episodes. Colchicine is effective in preventing recurrent attacks, and a favorable response to chronic administration of colchicine is a definitive diagnostic test.

Drug-Related Peritonitis

Administration of isoniazid and erythromycin estolate have been reported to cause acute abdominal symptoms mimicking peritonitis, but not development of true peritonitis. A number of cases have been reported in which beta-blocking drugs have resulted in striking thickening of the visceral peritoneum. The most frequent clinical presentation is as a typical small- bowel obstruction, often subtle at onset, associated with weight loss and with an abdominal mass on physical examination. The operative findings are striking: the whole small bowel usually is caught up in a thick sac, which sometimes can be lifted as a single mass from the peritoneal cavity. The agglomeration of the small bowel produces the mass that is palpable preoperatively.

Lead Peritonitis

Lead peritonitis has the same clinical picture as acute intermittent porphyria. It is associated with lead intoxication (occurring in painters, smelter workers, pica in children), and a careful history will lead to the correct diagnosis. Unlike true intraabdominal infection, in this disorder sudden stretching of the peritoneum by rebound palpation usually does not cause peritoneal irritation and guarding.

Hyperlipemic Peritonitis

Abdominal pain mimicking peritonitis may be seen in patients with type I and type V hyperlipoproteinemia, a group of heterogeneous disorders resulting from increased concentration of chylomicrons or very-low-density lipoproteins in the blood. These disorders usually lead to pancreatitis. If erroneously operated on during early stages, the abdominal cavity is found to be full of chylous milky material. A careful family history will clarify the differential diagnosis.

Porphyric Peritonitis

This is a condition of perceived abdominal pain rather than an inflammation of the peritoneum. It is seen in patients with acute intermittent porphyria, who suffer from acute attacks that cause nervous system damage, especially to the autonomic system. The pain may be localized or general and is often accompanied by vomiting and constipation. It may be colicky or constant and is associated with abdominal tenderness. With low-grade fever and mild leukocytosis the disorder further imitates intraabdominal infection. The diagnosis is established by the demonstration of porphobilinogen in the Watson-Schwartz test.

Talc Peritonitis

Peritoneal inflammation, exudation and formation of pseudotumors (chronic inflammatory omental tumors), and formation of dense adhesions may follow contamination of the peritoneal cavity by glove lubricants (talc, lycopodium, mineral oil, cornstarch, rice starch) or by cellulose fibers from disposable gauze pads, drapes, and gowns. The reaction, particularly that to rice starch, is largely a hypersensitivity response.

The clinical features include migratory abdominal pain, fever, physical signs of peritonitis, and, often, the presence of an abdominal mass, all developing within 3 weeks after an otherwise uncomplicated abdominal operation. The surgical wound may appear normal or may be moderately indurated. Plain abdominal films are nonspecific. The total white blood cell count is normal; eosinophilia of 4 to 9 percent may be present.

When the diagnosis remains unclear, laparoscopy may be helpful. If talc peritonitis is recognized, reoperation may be avoided and corticosteroids or nonsteroidal anti-inflammatory agents administered. Eventually the peritonitis resolves. If laparotomy is undertaken because the diagnosis is obscure, a thickened peritoneum studded with white nodules is found. Histologically, nodules that contain starch granules are doubly refractive under polarized light and are surrounded by granulomatous foreign-body inflammation.

The cornerstone of management of this problem is prevention. Talc should not be used in glove manufacture or as a glove lubricant. Current techniques of wiping and washing gloves do not remove all the starch; nonetheless, gloves should be washed or wiped before gloved hands are put into the peritoneal cavity, and care should be taken to avoid spillage of glove contents should a glove be torn during an operation. Sodium bicarbonate has been used successfully as a gloving agent, but it requires special sterilization measures. Silicones also have been suggested.

Tertiary Peritonitis

Patients in whom peritonitis and sepsis initially have been controlled operatively and in whom bacteria have been eliminated by successful antibiotic therapy may progress to tertiary peritonitis, a state in which host defense systems produce a syndrome of continued systemic inflammation.

The clinical picture is one mimicking occult sepsis, as manifested by a hyperdynamic cardiovascular state, low-grade fever, and general hypermetabolism. The patient has the clinical picture of sepsis without the presence of a focus of infection. Such patients sometimes are subjected to laparotomy in an attempt to provide drainage of anticipated recurrent or residual collections of infected fluid. On operation no pathogens are present. Empiric anti-infective therapy is of no value.

DIAGNOSTIC IMAGING FOR SUSPECTED INTRAABDOMINAL INFECTIONS

In the absence of physical findings of diffuse peritonitis, diagnostic imaging with computed tomography (CT) or ultrasonography should be routinely performed in seriously ill patients with suspected intraabdominal infection. The urgency of investigation is dictated by the degree of hemodynamic instability present. Most patients should be evaluated within hours of presentation. Interventional radiology has replaced operative treatment for many localized processes, including diverticular abscesses.

CT is the single best modality for fully evaluating the extent of disease. Ultrasonography is also quite versatile and has the added advantage of being portable, allowing certain procedures to be performed at bedside. Ultrasonography is limited by bowel gas, body habitus, and a lower sensitivity for retroperitoneal processes and parenchymal infection. Usually the choice of modality is based on the experience and preference of the interventional radiologist.

When feasible, nonoperative (i.e., percutaneous) drainage of purulent collections is preferable to open surgical intervention, because of the initial deterioration that almost always occurs after operative manipulation in the presence of intraabdominal infection. The exact basis for this is unclear, but a substantial proportion of patients undergoing emergency operation for intraabdominal infection suffer acute hemodynamic compromise in the early postoperative period. When used for appropriate indications, *percutaneous abscess drainage (PAD)* is at least as effective as operation and is associated with less morbidity. Percutaneous drainage of an intraabdominal abscess usually is successful if the following criteria are met: (1) there is a well-established, unilocular fluid collection; (2) a safe percutaneous route of access is available; this often means that the abscess is adjacent to the body wall; (3) joint evaluation by a surgeon and a radiologist is done so that correct judgments and decisions are made; and (4) there is immediate operative backup available in case of failure or complications.

OPERATIVE MANAGEMENT OF ABSCESES

The indications for open surgical drainage are failure of percutaneous drainage, inability to safely drain percutaneously, the presence of a pancreatic or carcinomatous abscess, an association with a high-output bowel fistula, the involvement of the lesser sac, or the presence of multiple, isolated interloop abscesses. Additionally, exploration and open drainage are undertaken whenever the presence of an abscess is suspected clinically but cannot be localized by CT or ultrasonography. Abscesses in the pelvis usually are drained directly through the rectum or vagina, obviating the need for either percutaneous drainage or an abdominal procedure.

If the abscess is in contact with the abdominal wall or the diaphragm, a direct and, when possible, extraperitoneal approach is preferred. Subphrenic abscesses on either side and right subhepatic abscesses are best approached via the lateral extraserous route. A left subphrenic abscess also can be drained posteriorly through the bed of the twelfth rib. The point at which the abscess is encountered during dissection is usually much deeper than expected.

A lesser sac abscess is approached directly via an upper abdominal incision. Drains are placed dependently; sump-suction drains are frequently helpful. Interloop abscesses are explored through a midabdominal incision. Each abscess cavity is thoroughly debrided, but drains are not generally used. If exploration of the abdomen is being done to find an occult abscess, a midline approach is more efficient, but a transverse incision may be better tolerated. The initial exploration should be limited to the area either above or below the transverse colon and mesocolon, the choice depending on clinical suspicion of the origin of infection.

Confirmation of the presence of pus is obtained by needle aspiration. It is essential to obtain specimens of the abscess content for stain, aerobic and anaerobic culture, and sensitivity studies. All of the abscess contents should be evacuated by suction. The cavity should be thoroughly explored digitally and all loculations within it broken down to create a single residual space. The cavity is irrigated and debrided of nonviable tissue. Multiple drains then should be brought from the abscess cavity to the exterior as directly and dependently as possible. If the abscess cavity is particularly large, or if thorough dependent drainage cannot be established, sump-suction drains should be employed in addition.

After percutaneous or open drainage of an abscess, the drains are left in place until external drainage stops or is clear. The drainage tract should then be irrigated and a sinogram obtained to verify collapse of the cavity before the drains are moved. It may take 2 to 3 weeks for a large cavity to become small enough to permit drains to be slowly advanced, allowing the drainage tract to seal as they are withdrawn.

Left Subphrenic Abscess

Formerly uncommon, these are now the most common variety of upper abdominal abscess after peritonitis or leakage from a viscus. Left subphrenic abscess also follows splenectomy, particularly when the splenic fossa is drained, and also is a consequence of pancreatitis. Unlike the subdiaphragmatic space on the right, which is divided by the liver into suprahepatic and subhepatic spaces, on the left side all these spaces are contiguous. The physical signs are costal tenderness on the left, sometimes pain in the shoulder (Kehr's sign), the presence of a left pleural effusion, and limitation of diaphragmatic motion noted by physical examination or radiography.

Lesser Sac Abscess

Technically the lesser sac abscess is a variety of left subhepatic-subphrenic abscess, since the lesser peritoneal sac anatomically is a portion of the left subhepatic space. However, the anatomic features of this abscess—and the surgical maneuvers required for drainage—are distinctly different. Lesser sac abscess is an unusual complication of diseases of the stomach, duodenum, and pancreas. The most common cause is a pancreatic abscess or a secondarily contaminated pancreatic pseudocyst that involves the lesser sac by direct extension. Perforation of a gastric ulcer or, less commonly, of a duodenal ulcer, and occasionally rupture of an ulcerating malignant gastric tumor, also may result in formation of a lesser sac abscess.

Diagnosis of a lesser sac abscess can be difficult, since much of this space is overlapped anteriorly by the left lobe of the liver. Tenderness to palpation in the midepigastrium usually is present but is a nonspecific sign. Ultrasonography is a most useful diagnostic test. Radiographic studies may show displacement of the stomach; occasionally plain radiographs show fine gas bubbles within the lesser sac, indicative of the presence of purulent material.

Lesser sac abscess has been associated with a poorer prognosis than abscesses located in other portions of the abdominal cavity. This abscess must be drained adequately; the location often dictates the use of suction drains; dependent drainage may not be easily established.

Right Subphrenic Abscess

The right subphrenic space is a potential space between the liver and the diaphragm, above the posterior attachments of the coronary and triangular ligaments to the diaphragm and posterior body wall, and extending anteriorly to the costal margin. Because the potential space is so limited in the vertical dimension, a right subphrenic abscess tends to be localized to only a portion of the total potential space, loculating either anteriorly or posteriorly. Abscesses within this space are most frequently secondary to rupture of a hepatic abscess and sometimes to operations on the stomach or duodenum.

Signs and symptoms of a right subphrenic abscess may be quite minimal. Pain is occasionally reported in the upper part of the abdomen or the lower part of the chest, sometimes referred to the back or to the right shoulder. Chest radiographs show a pleural effusion or platelike atelectasis in the right lower lung in 90 percent of patients, and the diaphragm is elevated and shows reduced motion on inspiration in sniffing or physical examination in two-thirds of patients. An air fluid level can be demonstrated in about one-fourth of those affected and establishes the diagnosis. An abscess in the right subphrenic space cannot be drained through a posterior approach unless the route of drainage transgresses the pleural space, a step that is not desirable.

Right Subhepatic Abscess

The right subhepatic space lies under the liver, bounded inferiorly by the hepatic flexure and the transverse mesocolon, medially by the duodenum and the hepatoduodenal ligament, and laterally by the body wall. The most posterior (deepest) part of this space is Morison's pouch. A gastric procedure, especially an emergency operation for complications of ulcer disease, is the most common antecedent event. Biliary tract procedures are second in etiologic frequency. Appendicitis has declined in importance and accounts for only 8 percent of right subhepatic abscesses. Complications of colonic surgery are increasing in importance. A right subhepatic abscess usually produces some tenderness in the right upper quadrant, and the patient may complain of pain, particularly exacerbated by coughing or similar activities that produce visceral motion in the region.

Interloop Abscess

Interloop abscesses often are multiple abscesses that arise as loculations between loops of bowel, mesentery, abdominal wall, and omentum. The transverse mesocolon acts as a barrier to superior extension so that interloop abscesses usually do not involve the upper part of the abdomen. They are commonly associated with a simultaneous abscess in the pelvis.

There are no reliable symptoms or signs. A huge abscess containing more than 1 L of pus may occur without any significant physical findings. Occasionally an interloop abscess may produce a palpable, enlarging abdominal mass. The possible presence of an interloop abscess must be suspected if there has been a preceding episode of peritonitis with incomplete clinical resolution. Occasionally abdominal films show edema in the wall of loops of bowel involved in the loculation or separation or fixation of involved structures. CT examination is the most reliable diagnostic tool.

Halasz emphasized the serious problem of failure to recognize synchronous or multiple abscesses and recommended transperitoneal exploration as preferable to more limited exploration. In his series of 43 patients, one-fourth had synchronous abscesses elsewhere in the abdomen. Failure to find and drain the concomitant abscess resulted in therapeutic failure. Today, with CT diagnosis to demonstrate whether the multiple loculations are interconnected or separate, a choice between percutaneous and open drainage is more easily made. If the multiple pockets do not interconnect, open drainage is preferable; otherwise, initial percutaneous drainage is preferred.

Pelvic Abscess

This form of abscess most often follows a ruptured colonic diverticulum, pelvic inflammatory disease, ruptured appendix, or drainage into the pelvis during resolution of generalized peritonitis. Unless the abscess involves the anterior abdominal wall, few symptoms or physical signs are present on examination of the abdomen. The patient may complain only of poorly localized, dull, lower abdominal pain. Irritation of the urinary system and the rectum produces symptoms of urgency and frequency or diarrhea and tenesmus.

A localized purulent collection in the pelvis is easy to diagnose. The abscess usually can be palpated directly by rectal or vaginal examination. The typical pelvic abscess bulges as a tender mass into the anterior rectal wall. In general, pelvic inflammatory masses involving the fallopian tubes do not bulge into the rectum and tend to become less tender and to resolve over serial examinations, whereas a true pelvic abscess tends to enlarge and finally to rupture.

Pelvic drainage should be accomplished, whenever possible, directly through the rectum or vagina. Drainage should be delayed until formation of the pyogenic membrane has effectively excluded the small bowel and other intraabdominal viscera. Readiness for drainage is apparent when the most prominent aspect of the abscess presenting vaginally or rectally begins to soften. Using a speculum or anoscope, the abscess should be exposed and the presence of pus confirmed by needle aspiration. The needle is left in place as a guide; sharp incision with a knife is preferred to blunt digital entry into the abscess cavity. To ensure continued drainage and obliteration of the cavity, daily dilation of the tract digitally or with an instrument should be done until the cavity becomes obliterated. Alternatively, a Penrose drain may be placed under direct vision.

Retroperitoneal Abscess

Abscesses within the retroperitoneal spaces are not common. An abscess located in the upper retroperitoneum usually is secondary to infection of the pancreas. Retroperitoneal abscesses in other locations may be caused by primary or secondary infections of the kidneys, ureters, or colon, or by osteomyelitis of the spine, or they may be secondary to trauma. They are usually insidious in onset, thereby causing a delay in diagnosis and therapy. Commonly fever is present and there is tenderness over the involved site.

CT is helpful in defining the anatomic location and the extent of the abscess. Treatment consists of intravenous antibiotic therapy and surgical drainage, preferably via an extraperitoneal approach. Percutaneous catheter drainage with CT or ultrasound guidance may be attempted and serves as a temporizing measure in patients who are poor candidates for prompt open surgical drainage. Despite aggressive therapy, overall mortality remains higher than 50 percent in the presence of multiple organ system failure.

Percutaneous Drainage Procedures for Intraabdominal Abscesses

Percutaneous abscess drainage (PAD) and open operative intervention are best viewed as complementary rather than competitive techniques. There are many situations for which PAD is the definitive procedure of choice, others for which surgery alone is indicated, and some for which both techniques are applicable, alone or in conjunction. Inflammation may present as a phlegmon (viable inflamed tissue), a liquefied abscess, infected necrotic (nonviable) tissue, or a combination. Liquefied abscesses are drainable, whereas phlegmonous or necrotic tissue is not. Decisions regarding which modality to employ are largely based on CT findings and require experience, clinical judgment, and careful consideration of underlying and coexistent disease processes. Close cooperation between the surgeon, the interventional radiologist, and other physicians involved in the patient's care is mandatory. Specific indications for PAD have expanded significantly over the past decade and now include many conditions previously thought undrainable, such as multiple or multiloculated abscesses, abscesses with enteric communication, and infected hematomas.

The basic requirements for *PAD* include a safe route of percutaneous access and the presence of a fluid collection of drainable consistency. Bleeding dyscrasias are a relative contraindication. It is generally possible to distinguish drainable fluid from phlegmonous or necrotic tissue using a combination of imaging and fine-needle aspiration. Not all fluid collections require drainage, although it is generally required for infected collections and for sterile collections that cause symptoms because of their mass. The determination of whether drainage is required is made on a case-by-case basis. A *cure* is achieved when the abscess is resolved by the drainage procedure. *Temporization* refers to resolution of an abscess and clinical improvement, with operative intervention needed to treat the underlying cause. *Palliation* refers to improvement in the patient's condition as a result of abscess drainage.

The possibility of underlying neoplastic disease must be considered in enteric perforation, especially in the elderly. Significant soft-tissue thickening of the bowel wall, especially if localized and noncircumferential, should raise the possibility of underlying tumor, as should the demonstration of potential metastatic disease such as adenopathy or liver lesions. A "target" appearance, with circumferential low-attenuation submucosal thickening sandwiched between the enhancing mucosa and submucosa, is likely to be specific for inflammatory disease. To fully exclude the possibility of neoplasia, follow-up imaging is used to verify resolution of the abscess, or confirmatory tests such as barium studies or endoscopy may be performed.

Technical Aspects

Imaging permits precise localization and characterization of disease, appropriate access route planning, and, after drainage, immediate assessment of whether the procedure was successful. Imaging also is needed for adequate follow-up to identify any problems and to gauge outcome. The drainage route should not cross a sterile fluid collection or other infected space, because of the risk of cross-contamination. Crossing the pleural space for thoracic and upper abdominal drainage carries the risk of empyema formation. Collections in the upper abdomen thus often require an angled subcostal or low intercostal approach. It is acceptable to cross the peritoneal space in order to drain an extraperitoneal abscess. Placement of a catheter through the small bowel or colon should always be avoided. Transgastric drainage of lesser sac pseudocysts has been advocated by some authors and appears to be safe, although this approach remains controversial. Lesser sac collections also can be approached transhepatically through the left lobe of the liver, although traversing solid organs should be avoided whenever possible. It is important to be aware of and to avoid major vascular structures.

In most cases drainage is performed after fine-needle (18–22 gauge) aspiration, with the aspirate being used to document infection and to gauge the viscosity of the fluid. Immediate Gram stain of the fluid is useful to determine the need for drainage. In some situations single-step aspiration of the fluid may suffice, without the need for tube placement. Examples include clearly aseptic collections, small abscesses (2 to 3 cm) into which tube placement would be difficult, and relatively nonviscous collections that can be completely evacuated. For most collections, a drain should be placed to ensure complete evacuation and to minimize the chances of recurrence. The aspiration needle can be used for placement of a guide wire or as a guide for tandem insertion of the drain. Antimicrobial therapy should be initiated before the drainage procedure to minimize any infectious complications of contaminating sterile tissue and the systemic consequences of drainage.

A wide variety of techniques and equipment are available for catheter placement, the majority falling into two categories. The *trocarr technique* involves the one-step insertion of a catheter that is loaded coaxially onto a stiffening cannula and needle. This is the technically simpler approach and is applicable to most superficial and large collections. The *Seldinger technique* is preferable for deep abscesses with difficult access, for drainages whose access route crosses exceptionally firm tissue, and for placement of catheters larger than 14F. A needle is first inserted into the collection. A guide wire is then passed through the needle, and the needle is withdrawn. The tract is sequentially dilated over the guide wire until it is possible to insert the catheter.

A variety of catheters are available for percutaneous insertion. The choice of catheter size is determined primarily by the viscosity of the fluid to be drained. In the majority of cases, 8F to 12F drains are sufficient. Larger drains may be needed for collections containing debris or higher-viscosity fluid, although the likelihood of success decreases. If needed, larger drains can be placed by exchange over a guide wire. There is no absolute limit on the number of drains that can be placed. While most abscesses can be drained with a single catheter, there should be no hesitation in placing as many drains as are needed to effectively evacuate the abscess(es).

After catheter placement, the cavity should be evacuated as completely as possible and irrigated with saline or antibiotic solution until the fluid is clear. Initial manipulation of the catheter(s) and irrigation should be done as gently as possible to minimize the induction of bacteremia. Immediate imaging determines the need for repositioning of the catheter, for placing a larger-bore catheter, or for placing additional drains. For cavities that are completely evacuated at the initial drainage and for which there are no abnormal communications to viscera, simple gravity drainage generally suffices. For larger or more viscous collections and for those with ongoing output from fistulous connections, suction drainage with sump catheters is more effective, although success is less likely. Thoracic drains always should be placed with water-seal suction.

Proper catheter management after the initial placement is a critical determinant of success and requires the interventional radiologist to remain an active member of the management team. Drains should be checked regularly (at least daily) to monitor the volume and nature of the output, to ensure adequate function and clinical response, and to recognize early and quickly correct any catheter-related problems. Periodic irrigation of the drains, once or several times per day, with sterile saline solution is recommended. In general, irrigation with proteolytic agents (e.g., acetylcysteine) or antibiotics is of no value, although fibrinolytic agents may be useful for evacuation of fibrinous or hemorrhagic collections. There is no standard protocol for follow-up imaging. Serial imaging studies and catheter injections are frequently used to monitor progress and identify problems. Occasionally it is necessary to replace or reposition tubes or to add additional catheters. The need for follow-up imaging studies should be determined on a case-by-case basis by monitoring clinical progress and drainage output.
