Preface

CHAPTER 1 - The Systemic Response to Injury
CHAPTER 2 - Fluid and Electrolyte Management
CHAPTER 3 - Hemostasis, Surgical Bleeding, and Transfusion
CHAPTER 4 - Shock
CHAPTER 5 - Surgical Infections
CHAPTER 6 - Trauma
CHAPTER 7 - Burns
CHAPTER 8 - Wound Care and Wound Healing
CHAPTER 9 - Oncology
CHAPTER 10 - Transplantation
CHAPTER 11 - Surgical Complications
CHAPTER 12 - Physiologic Monitoring of the Surgical Patient

CHAPTER 13 - Skin and Subcutaneous Tissue
CHAPTER 14 - Breast
CHAPTER 15 - Tumors of the Head and Neck
CHAPTER 16 - Chest Wall, Pleura, Lung, and Mediastinum
CHAPTER 17 - Congenital Heart Disease
CHAPTER 18 - Acquired Heart Disease
CHAPTER 19 - Thoracic Aneurysms and Aortic Dissection
CHAPTER 20 - Arterial Disease
CHAPTER 21 - Venous and Lymphatic Disease
CHAPTER 22 - Manifestations of Gastrointestinal Disease
CHAPTER 23 - Esophagus and Diaphragmatic Hernia
CHAPTER 24 - Stomach
CHAPTER 25 - Small Intestine
CHAPTER 26 - Colon, Rectum, and Anus
CHAPTER 27 - The Appendix
CHAPTER 28 - Liver
CHAPTER 29 - Gallbladder and Extrahepatic Biliary System
CHAPTER 30 - Pancreas
CHAPTER 31 - Spleen
CHAPTER 32 - Intraabdominal Infections
CHAPTER 33 - Abdominal Wall, Omentum, Mesentery, and Retroperitoneum
CHAPTER 34 - Abdominal Wall Hernias
CHAPTER 35 - Pituitary and Adrenal
CHAPTER 36 - Thyroid and Parathyroid
CHAPTER 37 - Pediatric Surgery
CHAPTER 38 - Urology
CHAPTER 39 - Gynecology
CHAPTER 40 - Neurosurgery
CHAPTER 41 - Orthopaedics
CHAPTER 42 - Surgery of the Hand
CHAPTER 43 - Plastic and Reconstructive Surgery
CHAPTER 44 - Minimally Invasive Surgery

Version 1.1

PRINCIPLES OF SURGERY
SEVENTH EDITION
Editor-in-Chief

Seymour I. Schwartz, M.D.

Distinguished Alumni Professor and Chair
Department of Surgery
University of Rochester Medical Center
Rochester, New York

Associate Editors

G. Tom Shires, M.D.

Professor of Surgery
Director, Trauma Institute
University of Nevada School of Medicine
Las Vegas, Nevada

Frank C. Spencer, M.D.

Professor and Chairman
Department of Surgery
New York University Medical Center
New York, New York

John M. Daly, M.D

Lewis Atterbury Stimson Professor and Chairman
Department of Surgery
Cornell University Medical College
New York, New York

Josef E. Fischer, M.D.

Christian R. Holmes Professor and Chairman
Department of Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio

Aubrey C. Galloway, M.D.

Professor of Surgery
Director of Surgical Research
New York University Medical Center
New York, New York

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The editors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possiblity of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they are not responsible for any errors or omissions or for the results obtained from use of such information. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Preface

The Seventh Edition of ***Principles of Surgery*** completes our participation in the surgical education of an entire generation of medical students and surgical residents throughout the world. We also were pleased to have played a role in the continuing education of practicing surgeons.

Many have regarded teachers as the noblest of people; others attach that designation to healers. As one who has been privileged to serve in both roles, namely, to have provided a vehicle for educating those who will perpetuate the healing profession in the realm of Surgery, and, at the same time, to have had the opportunity to participate in relieving patients of their disease, I consider myself twice blessed.

As a surgeon I have been satisfied by successes in patient care. As a teacher, I have been literally rewarded by expressions of appreciation by our readers who have indicated that we have enhanced their education.

Thirty-two years have passed since we accepted the publisher's and our own self-generated challenge to develop a "new and modern" textbook of Surgery. The favorable reception and the text's longevity suggest that we have succeeded. As the landmark of the Seventh Edition is completed, the frustrations and toils are erased and what remains is an immeasurable sense of gratification.

Seymour I. Schwartz, M.D.
June, 1998

ACKNOWLEDGMENT

We are particularly appreciative of the efforts of Andrea Weinstein, who had an integral role in each of the processes throughout the development of this edition. John Guardiano also contributed significantly to the technical editing of the manuscript.

Preface to the First Edition

The raison d'être for a new textbook in a discipline which has been served by standard works for many years was the Editorial Board's initial conviction that a distinct need for a modern approach in the dissemination of surgical knowledge existed. As incoming chapters were reviewed, both the need and satisfaction became increasingly apparent and, at the completion, we felt a sense of excitement at having the opportunity to contribute to the education of modern and future students concerned with the care of surgical patients.

The recent explosion of factual knowledge has emphasized the need for a presentation which would provide the student an opportunity to assimilate pertinent facts in a logical fashion. This would then permit correlation, synthesis of concepts, and eventual extrapolation to specific situations. The physiologic bases for diseases are therefore emphasized and the manifestations and diagnostic studies are considered as a reflection of pathophysiology. Therapy then becomes logical in this schema and the necessity to regurgitate facts is minimized. In appreciation of the impact which Harrison's PRINCIPLES OF INTERNAL MEDICINE has had, the clinical manifestations of the disease processes are considered in detail for each area. Since the operative procedure represents the one element in the therapeutic armamentarium unique to the surgeon, the indications, important technical considerations, and complications receive appropriate emphasis. While we appreciate that a textbook cannot hope to incorporate an atlas of surgical procedures, we have provided the student a single book which will satisfy the sequential demands in the care and considerations of surgical patients.

The ultimate goal of the Editorial Board has been to collate a book which is deserving of the adjective "modern." We have therefore selected as authors dynamic and active contributors to their particular fields. The au courant concept is hopefully apparent throughout the entire work and is exemplified by appropriate emphasis on diseases of modern surgical interest, such as trauma, transplantation, and the recently appreciated importance of rehabilitation. Cardiovascular surgery is presented in keeping with the exponential strides recently achieved.

There are two major subdivisions to the text. In the first twelve chapters, subjects that transcend several organ systems are presented. The second portion of the book represents a consideration of specific organ systems and surgical specialties.

Throughout the text, the authors have addressed themselves to a sophisticated audience, regarding the medical student as a graduate student, incorporating material generally sought after by the surgeon in training and presenting information appropriate for the continuing education of the practicing surgeon. The need for a text such as we have envisioned is great and the goal admittedly high. It is our hope that this effort fulfills the expressed demands.

Seymour I. Schwartz, M.D.

CHAPTER 1 - The Systemic Response to Injury

Edward Lin
Stephen F. Lowry
Steve E. Calvano

INTRODUCTION

The host response to injury—surgical, traumatic, or infectious—is characterized by various endocrine, metabolic, and immunologic alterations. If the inciting injury is minor and of limited duration, wound healing and restoration of metabolic and immune homeostasis readily occurs. More significant insults lead to further deterioration of the host regulatory processes, which, without appropriate intervention, often precludes full restoration of cellular and organ function or results in death. The spectrum of cellular metabolic and immunologic dysfunction resulting from injury suggests a complex mechanism for identifying and initially quantifying the injurious event. This initial response is inherently inflammatory, inciting the activation of cellular processes designed to restore or maintain function in tissues while also promoting the eradication or repair of dysfunctional cells. These dynamic processes imply the existence of antiinflammatory or counterregulatory processes that promote the restoration of homeostasis (Fig. 1-1). A discussion of the response to injury must account for the collective dynamics of neuroendocrine, immunologic, and metabolic alterations characteristic of the injured patient. This chapter discusses concepts related to macroendocrine and microendocrine contributions to the basic metabolic and immunological consequences of injury and also the current concepts of metabolism and nutritional support for the surgical patient as a practical and readily applicable adjunct for the provision of essential substrates. The dynamics of hormonal and immunologic influences on the metabolic and substrate requirements of the injured patient are emphasized.

ENDOCRINE RESPONSE TO INJURY

Overview of Hormone-Mediated Response

The classic response to injury comprises multiple axes. These hormone response pathways are activated by (1) mediators released by the injured tissue, (2) neural and nociceptive input originating from the site of injury, or (3) baroreceptor stimulation from intravascular volume depletion. The hormones released in response to these activating stimuli may be divided into those primarily under hypothalamopituitary control and those primarily under autonomic nervous system control (Table 1-1). The interaction between these origins form the basis of the hypothalamic-pituitary axis, which represents a series of signaling and feedback loops regulating the endocrine response to injury (Fig. 1-2).

Hormone-Mediated Receptor Activity

Hormones may be classified according to chemical structure and to the mechanisms by which they elicit biologic effects (Tables 1-2 and 1-3). Central to the hormone-mediated response at the cellular level is the hormone (ligand)–receptor interaction and subsequent postreceptor activity. Most macroendocrine hormone receptors can be categorized on the basis of their mechanisms of signal transduction into three major types: (1) receptor kinases with ligands such as insulin and insulinlike growth factors; (2) guanine nucleotide–binding or G protein–coupled receptors that are activated by peptide hormones, neurotransmitters, and prostaglandins; and (3) ligand-gated ion channels that permit ion transport upon ligand-receptor binding (Fig. 1-3).

Hormone-Mediated Intracellular Pathways

One of the most common intracellular second messengers by which hormones exert their effects is the modulation of cyclic adenosine monophosphate (cAMP). Receptor occupation by stimulatory hormones induces a cell membrane alteration that activates the enzyme adenylate cyclase. Adenylate cyclase catalyzes the conversion of adenosine triphosphate (ATP) to cAMP, which activates various intracellular protein kinases. Substances that decrease cAMP generally exert an influence opposite to those observed for substances that increase cAMP. Increases in intracellular cAMP are associated with functional lymphocyte responses that generally are immunosuppressive. In T lymphocytes, agents that increase cAMP levels diminish proliferation, lymphokine production, and cytotoxic functions. Plasma cell production of immunoglobulins is markedly attenuated. Neutrophils manifest decreased chemotaxis and reduced production of superoxides, H₂O₂, and lysosomal enzymes. Basophils or mast cells demonstrate a decreased release of histamine. Many prolonged hormone-mediated responses to injury increase intracellular cAMP levels through a direct action on membrane receptors or by increasing the sensitivity of leukocytes to substances that directly increase cAMP. Hormonal actions are further mediated by intracellular receptors. These intracellular receptors have binding affinities for the hormone and for the targeted gene sequence on the DNA. These intracellular receptors may be located within the cytosol or may already be localized in the nucleus, bound to the DNA. The classic example of a cytosolic hormonal receptor is glucocorticoid receptor. Intracellular glucocorticoid receptors are maintained in an active state by linking to the stress-induced protein, heat-shock protein (HSP). When the hormone ligand binds to the receptor, the dissociation of HSP from the receptor activates the receptor-ligand complex and is transported to the nucleus (Fig. 1-4).

Hormones Under Anterior Pituitary Regulation

Corticotropin-Releasing Hormone

Pain, fear, anxiety, or emotional arousal generate neural signals to the paraventricular nucleus of the hypothalamus, stimulating the synthesis of corticotropin-releasing hormone (CRH), which is then delivered by way of the hypothalamic-hypophyseal portal circulation to the anterior pituitary (Fig. 1-5). Proinflammatory cytokines and arginine vasopressin (AVP) also can induce CRH synthesis and release. In the anterior pituitary, CRH serves as the major stimulant of adrenocorticotrophic hormone (ACTH, adrenocorticotropin) production and release (Fig. 1-6). This is accomplished by CRH-mediated activation of adenylate cyclase in the ACTH-producing corticotrophs, which increases intracellular cAMP levels and activates the pathway leading to increased ACTH production. CRH, formerly referred to as corticotropin-releasing factor, has induced, in laboratory animals, hyperdynamic cardiovascular and catecholamine release characteristic of the sympathetic stress response. CRH secretion can be activated by angiotensin II, neuropeptide Y (NPY), serotonin, acetylcholine, interleukin-1, and interleukin-6. The release of CRH can be inhibited by g- aminobutyric acid (GABA), substance P, atrial natriuretic peptide (ANP), endogenous opioids, and l-arginine. Receptors for CRH in primates have been described not only in the pituitary gland and the central nervous system but also in the renal medulla, in the marginal zone and red pulp of the spleen, and in the sympathetic ganglia. Circulating glucocorticoids serve as potent negative feedback signals to the hypothalamus and have demonstrated in animal models an ability to reduce CRH mRNA transcription. Conversely, adrenalectomized animals demonstrate elevated CRH mRNA transcriptional activities that are reversed with exogenous administration of dexamethasone or prednisolone. CRH-binding proteins (CRH-BP) synthesized by the liver also serve as regulators of CRH activity. These collectively demonstrate endogenous pathways that may potentially regulate or preclude excessive CRH-mediated responses to injury. Injured tissues also produce CRH that may contribute locally to the inflammatory response. Experimental studies suggest a role for CRH in preventing vascular leakage in injured or inflamed tissues, although the implications have not been identified.

Adrenocorticotrophic Hormone

ACTH is synthesized, stored, and released by the anterior pituitary upon CRH stimulation. ACTH is a 39–amino acid peptide that is synthesized as a larger precursor complex known as proopiomelanocortin (POMC). POMC is cleaved within the cytosol to the components a-melanocyte stimulating hormone (a-MSH), b-lipotropin, the endogenous opioid b-endorphin, and ACTH. In the nonstressed healthy human being, ACTH release is regulated by circadian signals; the greatest elevation of ACTH occurs late at night and lasts until just before sunrise. This pattern is dramatically altered or obliterated in injured subjects. Most injury is characterized by elevations in CRH and ACTH that are proportional to the severity of injury. While pain and anxiety are prominent mediators of ACTH release in the conscious injured patient, other ACTH-promoting mediators may become relatively more active in the injured patient. These include vasopressin, angiotensin II, cholecystokinin, vasoactive intestinal polypeptide (VIP), catecholamines, oxytocin, and proinflammatory cytokines. Within the zona fasciculata of the adrenal gland, ACTH signaling activates intracellular adenylate cyclase, the cAMP-dependent protein kinase pathway, and mitochondrial cytochrome P-450 system. This chain of activities leads to increased glucocorticoid production via desmolase-catalyzed side-chain cleavage of cholesterol (Fig. 1-7). Conditions of excess ACTH stimulation result in adrenal cortical hypertrophy.

Cortisol/Glucocorticoids

Cortisol is the major glucocorticoid in human beings and is essential for survival after significant physiological stress. Cortisol levels in response to injury are not under the influence of normal diurnal variations and can remain persistently elevated, depending on the type of systemic stress. Burn patients have demonstrated elevated circulating cortisol levels for up to 4 weeks, and soft-tissue injury and hemorrhage may sustain elevated cortisol levels for up to a week. Circulating cortisol rapidly returns to normal levels on restoration of blood volume after hemorrhage. Conversely, adequate cortisol levels after mild hemorrhage is a prerequisite for timely restitution of blood volume in experimental animals. Coexisting systemic stress, such as infections, also can prolong the elevated cortisol levels after injury. Cortisol is a major effector of host metabolism. It potentiates the actions of glucagon and epinephrine, leading to hyperglycemia in the host. In the liver, cortisol stimulates the enzymatic activities favoring gluconeogenesis, including induction of phosphoenol pyruvate carboxykinase and transaminases. Peripherally, it decreases insulin-binding to insulin receptors in muscles and adipose tissue. In skeletal muscle, cortisol induces proteolysis and augments the release of lactate. The release of available lactate and amino acids has the net effect of shifting substrates for hepatic gluconeogenesis. Cortisol also stimulates lipolysis and inhibits glucose uptake by adipose tissues. It increases the lipolytic activities of ACTH, growth hormones, glucagon, and epinephrine. The resulting rises in plasma free fatty acids, triglycerides, and glycerol from adipose tissue mobilization serve as available energy sources and additional substrates for hepatic gluconeogenesis. About 10 percent of plasma cortisol is present in the free, biologically active form. The remaining 90 percent is bound to corticosteroid-binding globulin (CBG) and albumin. With injury, total plasma cortisol concentrations increase, but CBG and albumin levels decrease by as much as 50 percent. This can lead to an increase in free cortisol level of as much as ten times the normal level. Acute adrenal insufficiency is a life-threatening complication most commonly associated with adrenal suppression from the use of exogenous glucocorticoids with consequent atrophy of the adrenal glands. These patients present with weakness, nausea, vomiting, fever, and hypotension. Objective findings include hypoglycemia from decreased gluconeogenesis, hyponatremia from impaired renal tubular sodium resorption, and hyperkalemia from diminished kaliuresis. Although hyponatremia and hyperkalemia generally are a result of insufficient mineralocorticoid (aldosterone) activity, the loss of cortisol activity also contributes to electrolyte abnormalities. Glucocorticoids have long been used as effective immunosuppressive agents. Administration of glucocorticoids can induce rapid lymphopenia, monocytopenia, eosinopenia, and neutrophilia. Immunologic changes include thymic involution, depressed cell-mediated immune responses reflected by decreases in T killer and natural killer functions, T lymphocyte blastogenesis, mixed lymphocyte responsiveness, graft-versus-host reactions, and delayed hypersensitivity responses. With glucocorticoid administration, monocytes lose the capacity for intracellular killing, but they appear to maintain normal chemotactic and phagocytic properties. Neutrophil function is affected by glucocorticoid treatment in terms of intracellular superoxide reactivity and depressed chemotaxis. Phagocytosis of polymorphonuclear leukocytes (PMNs) remains unchanged. Glucocorticoids are omnibus inhibitors of immunocyte proinflammatory cytokine synthesis and secretion. This glucocorticoid-induced down-regulation of cytokine stimulation serves an important negative regulatory function in the inflammatory response to injury.

Macrophage Inhibitory Factor

Initially identified as a T lymphocyte–derived inhibitor of macrophage migration, macrophage inhibitory factor (MIF) is a glucocorticoid antagonist produced by the anterior pituitary.

This hormone can potentially reverse the immunosuppressive effects of glucocorticoids systemically via anterior pituitary secretion and at local sites of inflammation where MIF is produced by T lymphocytes. In experiments in which anti-MIF antibodies were administered to endotoxemic mice, survival increased presumably because glucocorticoid antiinflammatory effects were not counterregulated by MIF.

Thyrotropin-Releasing Hormone and Thyroid Stimulating Hormone

Thyrotropin-releasing hormone (TRH) serves as the primary stimulant for the synthesis, storage, and release of *thyroid-stimulating hormone (TSH)* in the anterior pituitary. TSH in turn stimulates thyroxine (T₄) production from the thyroid gland. T₄ is converted to triiodothyronine (T₃) by peripheral tissues. T₃ is more potent than T₄, but both are transported intracellularly by cytosolic receptors, which then bind DNA to mediate the transcription of multiple protein products. Free forms of T₄ and T₃ in the circulation can inhibit the hypothalamic release of TRH and pituitary release of TSH via negative feedback loops. TRH and estrogen stimulate TSH release by the pituitary, and T₃, T₄, corticosteroids, growth hormones, somatostatin, and fasting inhibit TSH release.

Thyroid hormones (thyronines), when elevated above normal levels, exert various influences on cellular metabolism and function. Thyronines enhance membrane transport of glucose and increase glucose oxidation. These hormones increase the formation and storage of fat when carbohydrate intake is excessive, but this process decreases during starvation. The increase in cellular metabolism from excess thyroid hormone production leads to proportional elevations in overall oxygen consumption as well as heat production. Although T₃ levels are frequently decreased after injury, there is no compensatory rise in TSH release. After major injury, reduced available T₃ and circulating TSH levels are observed and peripheral conversion of T₄ to T₃ is impaired. This impaired conversion may be explained in part by the inhibitory effects of cortisol and an increased conversion of T₄ to the biologically inactive molecule known as reverse T₃ (rT₃). Proinflammatory cytokines also may also contribute to this effect. Elevated rT₃, but reduced T₄ and T₃, is an observation characteristic of acute injury or trauma, referred to as *euthyroid sick syndrome* or *nonthyroidal illness*. Experimental mild endotoxemia in otherwise healthy human subjects has shown that thyroid hormone alterations in systemic inflammation is not mediated by endogenous IL-1.

While total T₄ (protein bound and free) levels may be reduced after injury, free T₄ concentrations remain relatively constant. In severely injured or critically ill patients, a reduced free T₄ concentration has been predictive of high mortality (Fig. 1-8).

Lymphoid cells have high-affinity nuclear and cytoplasmic binding sites for thyronines. One consequence of exposure to thyronines is an increase in the uptake of amino acids and glucose into the cell. Whether this is a direct effect of thyroid hormones or a secondary effect of increased cellular metabolism is unknown. Leukocyte metabolism measured by oxygen consumption is increased in hyperthyroid individuals and subjects to whom thyroid hormones have been administered. Animal studies have demonstrated that surgically or chemically induced thyroid hormone depletion significantly decreases cellular and humoral immunity. Conversely, thyroid hormone repletion is associated with enhancement of both types of immunity. Human monocytes, natural killer cells, and activated B lymphocytes express receptors for TSH. Exposure of B cells to TSH in vitro induces a moderate increase in immunoglobulin secretion.

Growth Hormones

Hypothalamic *growth hormone releasing hormone (GHRH)* travels through the hypothalamic-hypophyseal portal circulation to the anterior pituitary and stimulates the release of *growth hormone (GH)* in a pulsatile fashion mostly during the sleeping hours. In addition to GHRH, GH release is influenced by autonomic stimulation, thyroxine, AVP, ACTH, α -melanocyte stimulating hormone, glucagon, and sex hormones. Other stimuli for GH release include physical exercise, sleep, stress, hypovolemia, fasting hypoglycemia, decreased circulating fatty acids, and increased amino acid levels. Conditions that inhibit GH release include hyperglycemia, hypertriglyceridemia, somatostatin, beta-adrenergic stimulation, and cortisol.

The role of GH during stress is to promote protein synthesis while enhancing the mobilization of fat stores. Fat mobilization occurs by direct stimulation in conjunction with potentiation of adrenergic lipolytic effects on adipose stores. In the liver, hepatic ketogenesis also is promoted by GH. GH inhibits insulin release and decreases glucose oxidation, leading to elevated glucose levels.

The protein synthesis properties of GH after injury are partially mediated by the secondary release of *insulinlike growth factor-1 (IGF-1)*. This hormone, which circulates predominantly in bound form with several binding proteins, promotes amino acid incorporation and cellular proliferation and attenuates proteolysis in skeletal muscle and in the liver. IGFs, formerly referred to as somatomedins, are mediators of hepatic protein synthesis and glycogenesis. In the adipose tissue, IGF increases glucose uptake and lipid synthesis. In skeletal muscles, it increases glucose uptake and protein synthesis. IGF also has a role in skeletal growth by promoting the incorporation of sulfate and proteoglycans into cartilage. In vitro studies using proteoglycan synthesis as a marker for IGF-1 activity have demonstrated that interleukin-1 α , tumor necrosis factor- α (TNF- α), and interleukin-6 can inhibit the effects of IGF-1.

There is a rise in circulating GH levels after injury, major surgery, and anesthesia. The associated decrease in protein synthesis and observed negative nitrogen balance is attributed to a reduction in IGF-1 levels. GH administration has improved the clinical course of pediatric burn patients. Its use in injured adult patients is unproven. The liver is the predominant source of IGF-1 and preexisting hepatic dysfunction may contribute to the negative nitrogen balance after injury. IGF-binding proteins also are produced within the liver and are necessary for effective binding of IGF to the cell. IGF has the potential for attenuating the catabolic effects after surgical insults.

Leukocytes express high-affinity surface receptors for GH. GH and IGF-1 are immunostimulatory and promote tissue proliferation. In vitro, GH augments the proliferation of T lymphocytes to mitogens and the cytotoxicity of T killer cells to allogenic stimuli. Macrophages also respond to GH with a modest respiratory burst. GH-deficient mice manifest immune deficiencies that can be partially reversed by the administration of GH. GH-deficient human beings do not demonstrate any significant immunologic abnormalities. Normal subjects given intravenous GH demonstrate no significant immunological changes except for neutrophilia. GH has immunomodulating effects, but the relevance of this influence remains to be determined.

Somatostatin

Somatostatin is a 14-amino acid polypeptide produced by various cell types, including gastric antrum cells and pancreatic islet D cells. It is a potent inhibitor of GH, TSH, renin, insulin, and glucagon release. The role of somatostatin in the response to injury is unclear, but it may regulate excessive nutrient absorption and the activities of GH and IGF during convalescence from injury.

Gonadotrophins and Sex Hormones

Luteinizing-hormone releasing hormone (LHRH) or gonadotropin-releasing hormone (GnRH) is released from the hypothalamus and stimulates follicle-stimulating hormone (FSH) and *luteinizing hormone (LH)* release from the anterior pituitary. The release of these hormones can be effectively blocked by CRH, prolactin, estrogen, progestins, and androgens. The most relevant clinical correlation is seen after injury, stress, or severe illness, when LH and FSH release is suppressed. The reduction in LH and FSH consequently reduces estrogen and androgen secretion. This is attributed to the inhibitory activities of CRH on LH and FSH release and accounts for the menstrual irregularity and decreased libido reported after surgical stress and other injuries.

Estrogens inhibit cell-mediated immunity, natural killer cell activity, and neutrophil function, but are stimulatory for antibody-mediated immunity. Conditions associated with high-estrogen levels appear to predispose the patient to increased infectious complications. Androgens appear to be predominantly immunosuppressive. Castration is associated with enhanced immune function that can be reversed by exogenous androgens.

Prolactin

The hypothalamus suppresses prolactin secretion from the anterior pituitary by the activities of LHRH/GnRH and dopamine. Stimulants for prolactin release are CRH, TRH, GHRH, serotonin, and vasoactive intestinal polypeptide (VIP).

Elevated prolactin levels after injury have been reported in adults, whereas reduced levels are noted in children. The hyperprolactinemia also may account for the amenorrhea frequently seen in women after injury or major operations.

Like growth hormone, prolactin has immunostimulatory properties. Chemically induced inhibition of prolactin in animals has demonstrated increased susceptibility to infection, decreased lymphocyte proliferation, decreased interleukin-2 production and receptor expression, decreased interferon- γ production, and macrophage dysfunction. Exogenous administration of prolactin reversed these effects. There is increasing evidence that prolactin also is synthesized and secreted by T lymphocytes and may function in an autocrine or paracrine fashion.

Endogenous Opioids

Elevated endogenous opioids are measurable after major operations or insults to the patient (Table 1-4). The b-endorphins have a role in attenuating pain perception, and they are capable of inducing hypotension through a serotonin-mediated pathway. Conversely, the enkephalins produce hypertension. In the gastrointestinal tract, the activation of opioid receptors reduces peristaltic activity and suppresses fluid secretion.

The role of endogenous opioids in glucose metabolism is complex. While b-endorphins and morphine induce hyperglycemia, they also increase insulin and glucagon release by the pancreas. In animal models, endogenous opioids, such as dynorphins, have demonstrated a paracrine role in modulation of vasopressin and oxytocin secretion. Studies demonstrating the presence of opioid receptors in the adrenal medulla also suggest a role in regulating catecholamine release.

Certain immune cells also release endorphins that share an antinociceptive role in modulating the response of local sensory neurons to noxious stimuli. Endorphins also influence the immune system by increasing natural killer cell cytotoxicity and T cell blastogenesis. Interleukin-1 activates the release of POMC from the pituitary gland. Endogenous opioids (endorphin and enkephalin) and exogenous opiates both mediate their effects through mammalian delta, kappa, and mu receptors. Opioids compromise the natural (innate) and specific (adaptive) immune system. They inhibit the proliferation and differentiation of lymphocytes and monocytes/macrophages. The immunoinhibitory effects of exogenous opiates can be dose dependent and sensitive to the state of activation of the immune system.

Hormones Under Posterior Pituitary Regulation

Arginine Vasopressin

Vasopressin or arginine vasopressin (AVP) (or antidiuretic hormone, ADH) is synthesized in the anterior hypothalamus and transported by axoplasmic flow to the posterior pituitary for storage. The major stimulus for AVP release is elevated plasma osmolality, which is detected by sodium-sensitive hypothalamic osmoreceptors. There is evidence of extracerebral osmoreceptors for AVP release in the liver or the portal circulation. AVP release is enhanced by beta-adrenergic agonists, angiotensin II stimulation, opioids, anesthetic agents, pain, and elevated glucose concentrations. Changes in effective circulating volume by as little as 10 percent can be sensed by baroreceptors, left atrial stretch receptors, and chemoreceptors, leading to AVP release. Release is inhibited by alpha-adrenergic agonists, and atrial natriuretic peptide (ANP).

In the kidney, AVP promotes reabsorption of water from the distal tubules and collecting ducts. Peripherally, AVP mediates vasoconstriction. This effect in the splanchnic circulation may cause the trauma-induced ischemia/reperfusion phenomenon that precedes gut barrier impairment. AVP, on a molar basis, is more potent than glucagon in stimulating hepatic glycogenolysis and gluconeogenesis. The resulting hyperglycemia increases the osmotic effect that contributes to the restoration of effective circulating volume. Elevated AVP secretion is another characteristic of trauma, hemorrhage, open-heart surgery, and other major operations. This elevated level typically persists for 1 week after the insult.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) refers to the excessive vasopressin release that is manifested by low urine output, highly concentrated urine, and dilutional hyponatremia. This diagnosis can be made only if the patient is euvolemic. Once normal volume is established, a plasma osmolality below 275 mOsm/kg H₂O and a urine osmolality above 100 mOsm/kg H₂O is indicative of SIADH. SIADH is commonly seen in patients with head trauma and burns.

In the absence of AVP, central diabetes insipidus occurs and there is voluminous output of dilute urine. Frequently seen in comatose patients, the polyuria in untreated diabetes insipidus can precipitate a state of hypernatremia and hypovolemic shock. Attempts at reversal should include free water and exogenous vasopressin (desmopressin).

Oxytocin

Oxytocin and AVP are the only known hormones secreted by the posterior pituitary. They share structural similarities, but the role of oxytocin in the injury response is unknown. In human beings, the only consistent stimulus for secretion of oxytocin is suckling or other nipple stimulation in lactating women. This stimulates contraction of lactating mammary glands and induces uterine contractions in parturition. There is no recognized stimulus for oxytocin release, nor are there any known functions in men.

Hormones of the Autonomic System

Catecholamines

Catecholamines exert significant influence in the physiologic response to stress and injury. The hypermetabolic state observed after severe injury has been attributed to activation of the adrenergic system. Both of the major catecholamines, norepinephrine and epinephrine, are increased in plasma after injury, with average elevations of three to four times above baseline immediately after injury, reaching their peak in 24 to 48 h before returning to baseline levels. The patterns of norepinephrine and epinephrine appearance parallel each other after injury. Most of the norepinephrine in plasma results from synaptic leakage during sympathetic nervous system activity, while virtually all plasma epinephrine derives from the secretions of chromaffin cells of the adrenal medulla.

Catecholamines exert metabolic, hormonal, and hemodynamic influences on diverse cell populations. In the liver, epinephrine promotes glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis. It causes decreased insulin secretion but increased glucagon secretion. Peripherally, epinephrine increases lipolysis in adipose tissues and inhibits insulin-facilitated glucose uptake by skeletal muscle. These collectively promote the often evident stress-induced hyperglycemia, not unlike the effects of cortisol on blood glucose. Catecholamines also increase the secretion of thyroid and parathyroid hormones, T₄ and T₃, and renin, but inhibit the release of aldosterone.

Catecholamines exert discernible influences on immune function, e.g., epinephrine occupation of beta receptors on leukocytes increases intracellular cAMP. This ultimately decreases immune responsiveness in lymphocytes. Like cortisol, epinephrine enhances leukocyte demargination with resultant neutrophilia and lymphocytosis. Epinephrine also lowers the ratio of CD4 to CD8 T lymphocytes. Immunologic tissue such as the spleen, thymus, and lymph nodes possess extensive adrenergic innervation. Chemical sympathectomy of peripheral nerves has been demonstrated to augment antibody response after immunization with a specific antigen. It also reverses the depressed mitogenic response of splenocytes preincubated with endotoxin. Normal volunteers infused with epinephrine exhibit depressed mitogen-induced T lymphocyte proliferation.

Aldosterone

The mineralocorticoid aldosterone is synthesized, stored, and released in the adrenal zona glomerulosa. Its release may be induced by angiotensin II, hyperkalemia, and the pituitary hormone known as aldosterone stimulating factor (ASF), but ACTH is the most potent stimulus for aldosterone release in the injured patient.

The major function of aldosterone is to maintain intravascular volume by conserving sodium and eliminating potassium and hydrogen ions. While the major effect is exerted in the kidneys, this hormone also is active in the intestines, salivary glands, sweat glands, vascular endothelium, and the brain. In the early distal convoluted tubule, aldosterone increases sodium and chloride reabsorption and excretion of hydrogen ions. In the late distal convoluted tubule, further sodium reabsorption takes place while potassium ions are excreted. Vasopressin also acts in concert with aldosterone to increase osmotic water flux into the tubules.

Patients with aldosterone deficiency develop hypotension and hyperkalemia, whereas patients with aldosterone excess develop edema, hypertension, hypokalemia, and metabolic alkalosis. After injury, ACTH stimulates a brief burst of aldosterone release. Angiotensin II induces a protracted aldosterone release that persists well after ACTH returns to baseline. As with cortisol, normal aldosterone release also is influenced by the circadian cycle, though this effect is lost in the injured patient.

Renin-Angiotensin

Renin is synthesized and stored primarily within the renal juxtaglomerular apparatus near the afferent arteriole. The juxtaglomerular apparatus comprises the juxtaglomerular neurogenic receptor, the juxtaglomerular cell, and the macula densa. Renin initially exists in an inactive form as prorenin. The activation of renin and its release is mediated by ACTH, AVP, glucagon, prostaglandins, potassium, magnesium, and calcium. The juxtaglomerular cells are baroreceptors that respond to a decrease in blood pressure by increasing renin secretion. The macula densa detects changes in chloride concentration in the renal tubules.

Angiotensinogen is a protein primarily synthesized by the liver but also identified in the kidney. Renin catalyzes the conversion of angiotensinogen to angiotensin I within the kidney. Angiotensin I remains physiologically inactive until it is converted in the pulmonary circulation to angiotensin II by angiotensin-converting enzyme present on endothelial surfaces.

Angiotensin II is a potent vasoconstrictor that also stimulates aldosterone and vasopressin synthesis. It also is capable of regulating thirst. Angiotensin II stimulates heart rate and myocardial contractility. It also potentiates the release of epinephrine by the adrenal medulla, increases CRH release, and activates the sympathetic nervous system. It can induce glycogenolysis and gluconeogenesis. The renin-angiotensin system participates in the response to injury by maintaining volume homeostasis.

Insulin

Insulin is derived from pancreatic beta islet cells and released upon stimulation by certain substrates, autonomic neural input, and other hormones. In normal metabolism, glucose is the major stimulant of insulin secretion. Other substrate stimulants include amino acids, free fatty acids, and ketone bodies. Hormonal and neural influences during stress alter this response. Epinephrine and sympathetic stimulation inhibit insulin release. Other factors that diminish insulin release include glucagon, somatostatin, gastrointestinal hormones, b-endorphins, and interleukin-1. Peripherally, cortisol, estrogen, and progesterone interfere with glucose uptake. The net result of impaired insulin production and function after injury is stress-induced hyperglycemia, which is in keeping with the general catabolic state.

Insulin exerts a global anabolic effect; it promotes hepatic glycogenesis and glycolysis, glucose transport into cells, adipose tissue lipogenesis, and protein synthesis. In the injured patient, a biphasic pattern of insulin release is observed. The first phase occurs within a few hours after injury and is manifested as a relative suppression of insulin release, reflecting the influence of catecholamines and sympathetic stimulation. The later phase is characterized by a return to normal or excessive insulin production but with persistent hyperglycemia, demonstrating a peripheral resistance to insulin. The ratio of insulin to glucose (not their individual values) is used as a predictor of mortality and survival.

Activated lymphocytes express receptors for insulin. Insulin enhances T lymphocyte proliferation and cytotoxicity. Mouse spleen cells transiently exposed to a mitogen can continue to proliferate and maintain cytotoxicity if insulin is added to the medium. Institution of insulin therapy to newly diagnosed diabetics is associated with increased B and T lymphocyte populations.

Glucagon

Glucagon is a product of pancreatic alpha islet cells. As with insulin, the release of glucagon also is mediated by its substrates, autonomic neural input, and other hormones. Whereas insulin is an anabolic hormone, glucagon serves more of a catabolic role. The primary stimulants of glucagon secretion are plasma glucose concentrations and exercise. Glucagon stimulates hepatic glycogenolysis and gluconeogenesis, which under basal conditions account for approximately 75 percent of the glucose produced by the liver. In contrast to insulin, glucagon promotes hepatic ketogenesis and lipolysis in adipose tissue. The release of glucagon after injury is initially decreased, but returns to normal 12 h later. By 24 h, glucagon levels are supranormal and can persist for up to 3 days.

IMMUNE RESPONSE TO INJURY

While the classic neuroendocrine response to injury has been extensively investigated, many characteristics of the inflammatory response associated with injury remain unexplained. Even after the normalization of macroendocrine hormone function after the primary injury, the persistence of systemic inflammation, the progression of organ dysfunction, and even late mortality indicate the presence of other potent mediators influencing the injury response. These mediators usually are small proteins or lipids that are synthesized and secreted by immunocytes. These micromolecules, collectively referred to as cytokines, are indispensable in tissue healing and in the immune response generated against microbial invasions. As mounting evidence suggests, the activities of these cytokine mediators are integrally related to classic hormone function and metabolic responses to injury.

Cytokine-Mediated Response

Patients with injuries or infections exhibit hemodynamic, metabolic, and immune responses partially orchestrated by endogenous cytokines. Unlike classical hormonal mediators such as catecholamines and glucocorticoids, which are produced by specialized tissues and exert their influence predominantly by endocrine routes, cytokines are produced by diverse cell types at the site of injury and by systemic immune cells (Table 1-5). Cytokine activity is primarily exerted locally via cell-to-cell interaction (paracrine).

Cytokines are small polypeptides or glycoproteins that exert their influence at very low concentrations. In their monomeric form, most are less than 30 kilodaltons (kD). In their biologically active form, some of these cytokines function as oligomers (e.g., trimeric tumor necrosis factor- α) with higher molecular weights. Most cytokines also differ from classical hormones in that they are not stored as preformed molecules. Their relatively rapid appearance after injury reflects active gene transcription and translation by the injured or stimulated cell.

Cytokines exert their influence by binding to specific cell receptors and activating intracellular signaling pathways leading to modulation of gene transcription. By this mechanism, cytokines influence immune cell production, differentiation, proliferation, and survival. These mediators also regulate the production and actions of other cytokines, which may either potentiate (proinflammatory) or attenuate (antiinflammatory) the inflammatory response. The capacity of cytokines to activate diverse cell types and to incite equally diverse responses underscores the pleiotropism of these inflammatory mediators (Table 1-6). There is also a marked degree of overlapping activity among different cytokines.

Cytokines are effector molecules that direct the inflammatory response to infections (bacterial, viral, and fungal) and injury and actively promote wound healing. These responses are manifested by fever, leukocytosis, and alterations in respiratory and heart rates. It is the exaggerated, acute production of proinflammatory cytokines that is responsible for the hemodynamic instability characteristic of septic shock. The chronic and excessive production of these cytokines is partly responsible for the metabolic derangements of the injured patients, such as debilitating muscle wasting and cachexia. Preexisting cytokine production can contribute to end-organ injury leading to multiple organ failure and late mortality in severely injured or infected patients. The presence of antiinflammatory cytokines may serve to attenuate some of these exaggerated responses. The excessive release of antiinflammatory cytokines may render the patient immunocompromised and increase susceptibility to infections.

Understanding of the pathophysiology of inflammatory cytokine mediators has been derived largely from patients with endotoxemia or sepsis. Inflammatory mediator responses to infections and traumatic injury are not dissimilar, particularly in the temporal sequence of cytokine expression. The cytokine response evidenced by fever, leukocytosis, hyperventilation, and tachycardia commonly seen in injury is referred to as systemic inflammatory response syndrome (SIRS) and is not necessarily the result of an identifiable infectious process. Central to the insult suffered by the host and the subsequent inflammatory response is the activity of the host's immunocyte population, circulating and tissue-fixed. Discussions of the inflammatory response should not be dissociated from these cellular entities.

The cytokine cascade activated in response to injury consists of a complex network with diverse effects on all aspects of physiological regulatory mechanisms. Cytokines are pivotal determinants of the host response after injury and a proper perspective of their immunobiologic sequelae can have important applications in the comprehensive care of the surgical patient. The number of cytokines identified has expanded to nearly 30, but their functions and elicited responses, particularly in injury, are incompletely understood largely because of the pleiotropic, redundant, and mutual interactions among these mediators. The cytokines described here represent a limited list of better-characterized mediators related to injury and the inflammatory response.

Tumor Necrosis Factor- α

The inflammatory response to severe cross-sectional tissue injury or infectious agents evokes a complex cascade of proinflammatory cytokines. Among these, *tumor necrosis factor- α* (TNF- α) is the earliest and one of the most potent mediators of the subsequent host response. The sources of TNF- α synthesis include monocytes/macrophages and T cells, which are abundant in the peritoneum and splanchnic tissues. Kupffer cells represent the single largest concentrated population of macrophages in the human body. Surgical

or traumatic injuries to the viscera may have profound influences on the generation of inflammatory mediators and homeostatic responses such as acute phase protein production (Fig. 1-9).

The release of TNF- α in response to acute injury is rapid and short-lived. Experiments simulating an acute inflammatory response by means of endotoxin challenge in human subjects have demonstrated a monophasic *tumor necrosis factor (TNF)* appearance curve, peaking at approximately 90 min and followed by a return to undetectable levels within 4 h (Fig. 1-10). Even with a half-life of 15 to 18 min, the brief appearance of TNF can induce marked metabolic and hemodynamic changes and activate cytokines distally in the cascade. The abbreviated production of TNF implies the presence of effective endogenous modulators, which serve to prevent any propagation of unregulated TNF- α activity. This has been proved because several natural mechanisms that antagonize TNF production or activity have been identified. Endogenous inhibitors in the form of cleaved extracellular domains of the transmembrane TNF receptors (*soluble TNF receptors, sTNFRs*) are readily detectable in the circulation. These receptors may serve a protective role by competitively sequestering excess circulating TNF, but are probably only capable of doing so against low levels of TNF activity and for brief periods.

TNF- α also is a major cytokine related to muscle catabolism and cachexia during stress. Amino acids are mobilized from skeletal muscles and shunted toward the hepatic circulation as fuel substrates. Studies have demonstrated that TNF- α -induced muscle catabolism occurs through a ubiquitin-proteasome proteolytic pathway with increased expression of the ubiquitin gene.

Other associated functions of TNF- α include coagulation activation and promoting the release of prostaglandin E₂ (PGE₂), platelet-activating factor (PAF), glucocorticoids, and eicosanoids.

Interleukin-1

TNF- α also induces the biosynthesis and release of interleukin-1 (IL-1) from macrophages and endothelial cells. There are two known proinflammatory species of IL-1, IL-1 α and IL-1 β . IL-1 α is predominantly cell membrane-associated and exerts its influence via cellular contacts. The more detectable form released in the circulation is IL-1 β , which is produced in greater quantities than IL-1 α and capable of inducing the characteristic systemic derangements after injury. The potency and effects of IL-1 reflect those of TNF- α , eliciting similar physiologic and metabolic alterations. At high doses of IL-1 and TNF- α , these cytokines independently initiate a state of hemodynamic decompensation. At low doses, they can produce the same response only if administered simultaneously. These observations emphasize the synergism of TNF- α and IL-1 in eliciting some proinflammatory responses. The half-life of IL-1 is approximately 6 min, which, along with its primary role as a local inflammatory mediator, makes its detectability in acute injury or illness even less likely than that of TNF- α .

Among its effects, IL-1 induces the classic inflammatory febrile response to injury by stimulating local prostaglandin activity in the anterior hypothalamus. Associated with the hypothalamic activity is the induction of anorexia by an IL-1 effect on the satiety center. This cytokine also augments T cell proliferation by enhancing the production of IL-2 and also may influence skeletal muscle proteolysis, characteristic of cachexia. Attenuated pain perception after surgery can be mediated by IL-1 by promoting the release of β -endorphins from the pituitary gland and increasing the number of central opioid-like receptors. Like TNF, IL-1 is a potent stimulant for ACTH and glucocorticoid release via its actions on the hypothalamus and pituitary gland.

A non-agonist IL-1 species, known as *IL-1 receptor antagonists (IL-1ra)*, also is released during injury. This molecule effectively competes for binding to IL-1 receptors yet exacts no overt signal transduction. IL-1ra, which is often detectable during inflammation or injury, serves as a potent regulator of IL-1 activity.

Distal cytokine mediators, released as part of the inflammatory cascade initiated by TNF- α and IL-1, include IL-2, IL-4, IL-6, IL-8, *granulocyte/macrophage colony-stimulating factor (GM-CSF)*, and *interferon- γ (IFN- γ)*.

Interleukin-2

Although necessary as an inflammatory mediator in promoting T lymphocyte proliferation, immunoglobulin production, and gut barrier integrity, IL-2 has not been readily detectable in the circulation during acute injury. Similar to IL-1, its short half-life of less than 10 min adds to the difficulty in detecting it after injury. IL-2 secretion by lymphocytes is impaired after acute injury and several disease states, notably cancer and acquired immunodeficiency syndrome (AIDS). Perioperative blood transfusions also are associated with reduced IL-2 production. Attenuated IL-2 expression contributes to the transient immunocompromised state of the surgical patient. A low point in gut barrier IL-2 activity resulting from injuries can predispose the patient to enteric organism activation of the inflammatory cytokine cascade. There is evidence for accelerated lymphocyte programmed cell death (apoptosis), in association with diminished IL-2 activity, mediated by the proapoptotic Fas/CD95 cell receptor in the early postoperative period. The combined diminution of lymphocyte survival and IL-2 activity may contribute to the immunocompromised phenotype of the injured patient.

Studies have demonstrated a population density shift from type 1 T helper cells (T_H1, cell-mediated and opsonizing antibody immune responses, including IL-2, IL-12, and IFN- γ production) to type 2 T helper cells (T_H2, IgE antibody-mediated immune response, including IL-4, IL-6, IL-10, IL-13 production) after surgical stress. The immune activities of the T_H2 response usually are less effective against microorganisms, and they accentuate the risks for postoperative infections (Fig. 1-11).

Interleukin-4

IL-4 is a glycoprotein molecule, produced by activated T_H2 cells, with diverse biologic effects on hemopoietic cells, including induction of B lymphocyte proliferation. Of particular importance in its role in antibody-mediated immunity is the capacity to enhance macrophage major histocompatibility complex class II (HLA-DR and HLA-DP) expression and adhesion molecules, making them efficient antigen-presenting cells. IL-4 also induces class switching in differentiating B lymphocytes to produce predominantly IgG₄ and IgE, which are important immunoglobulins in allergic and antihelminthic responses.

As a potent antiinflammatory cytokine, IL-4 down-regulates several functions associated with activated human macrophages, namely, the effects of IL-1 β , TNF- α , IL-6, IL-8, and superoxide production. These antiinflammatory effects of IL-4 are not seen in resting monocytes. The importance of this cytokine is the capacity to down-regulate the response of inflammatory macrophages exposed to stimuli such as bacterial endotoxin or proinflammatory cytokines. IL-4 can induce programmed cell death in inflammatory macrophages, but this effect is abrogated by IFN- γ . IL-4 and IFN- γ antagonize one another's effects on B cells. IL-4 also appears to increase macrophage susceptibility to the antiinflammatory effects of glucocorticoids. IL-13 may share several properties with IL-4.

Interleukin-6

Because of the elevated blood levels of IL-6 often observed during acute injury or stress, it is used frequently as an indicator of the systemic inflammatory response and a predictor of preoperative morbidity. TNF- α and IL-1 are major inducers of IL-6. IL-6 can be produced by virtually all cell types, including the intestines. After injury, IL-6 levels in the circulation are detectable by 60 min, peak between 4 to 6 h, and can persist for as long as 10 days. The relatively long half-life partially explains its ease of detectability. IL-6 levels appear to be proportional to the extent of tissue injury during an operation rather than the duration of the surgical procedure itself.

Evidence suggests a complex role for IL-6 in mediating proinflammatory and antiinflammatory activities. IL-1 and IL-6 are important mediators of the hepatic acute-phase protein response during injury and appear to enhance C-reactive protein, fibrinogen, haptoglobin, amyloid A, α -1-antitrypsin, and complement production (see Fig. 1-9). IL-6 not only induces PMN activation during injury and inflammation but also may delay the phagocytic disposal of senescent or dysfunctional PMNs during injury. The persistence of inflammatory PMNs after injury might explain the injurious effects on distant tissues, such as the pulmonary or renal system.

IL-6 mediates the antiinflammatory pathway during injury through different mechanisms. It is capable of attenuating TNF and IL-1 activity while promoting the release of sTNFRs and IL-1ra. Prolonged and persistent expression of IL-6 is associated with immunosuppression and postoperative infectious morbidity. Elevated IL-6 levels postoperatively can impair glutaminase activity, causing a reduction in plasma glutamine.

Interleukin-8

The appearance of IL-8 activity is temporally associated with IL-6 after injury and has been proposed as an additional biomarker for the risk of multiple organ failure.

IL-8 does not produce the hemodynamic instability characteristic of TNF- α and IL-1 but rather serves as a PMN activator and potent chemoattractant. IL-8 is being established as a major contributor to organ injury such as the acute lung injury.

Interleukin-10

IL-10 is an important endogenous regulatory mediator during the inflammatory response; it acts primarily by modulating TNF- α activity. Its appearance in the circulation during endotoxemia closely follows the appearance TNF- α . Supporting experiments have demonstrated that neutralization of IL-10 during endotoxemia increases monocyte TNF- α production and mortality, but restitution of IL-10 reduces TNF- α levels and the associated deleterious effects. IL-10 may have additional protective roles after injury-induced inflammation by promoting IL-1ra and sTNFR production. In animal experiments, the sustained systemic production of IL-10 during septic peritonitis modulates the systemic inflammatory response. Murine experiments have demonstrated rapid induction of IL-10 messenger RNA (mRNA) activity after cecal ligation and puncture, and higher mortality when this activity is blocked with anti-IL-10. This immunomodulatory effect also may abrogate the proinflammatory response necessary for local clearance of invading organisms.

Interleukin-12

The capacity of IL-12 to promote the differentiation of T_H1 cells and the production of IFN- γ makes it a pivotal molecule in cell-mediated immunity after injury or infection. In mice with fecal peritonitis, survival increases with IL-12 administration. IL-12 also is implicated in preventing programmed cell death (apoptosis) in certain T lymphocyte populations after their activation.

Interleukin-13

IL-13 is a pleiotropic cytokine that shares many of the properties of IL-4 as well as a modest amino acid sequence (about 30 percent). IL-13 is produced during T_H2 responses. IL-4 and IL-13 modulate macrophage function, but IL-13 has no identifiable effect on T lymphocytes and only has influence on subpopulations of B lymphocytes. IL-4 and IL-13 receptors share a common signaling component. IL-13 can up-regulate macrophage major histocompatibility complex class I and II antigens and other surface antigens, such as CD23. IL-13 can inhibit nitric oxide production and the expression of proinflammatory cytokines, and it can enhance the production of IL-1ra. The net effect of IL-13, along with IL-4 and IL-10, is antiinflammatory.

Interferon- γ

Much of IL-12 biology is mediated through the production and activities of IFN- γ . Human T helper (T_H) cells activated by the bacterial antigens IL-2 or IL-12 readily produce IFN- γ .

Conversely, IFN- γ can induce the production of IL-2 and IL-12 by T helper cells. With its release from activated T cells, IFN- γ is detectable in vivo by 6 h and has a half-life of approximately 30 min. IFN- γ levels peak at 48 to 72 h and may persist for 7 to 8 days. Injured tissues, such as operative wounds, also demonstrate the presence of IFN- γ production 5 to 7 days after injury. Natural killer cells are potent inducers of IL-12 production.

IFN- γ has important roles in activating circulating and tissue macrophages. Alveolar macrophage activation mediated by IFN- γ may induce acute lung inflammation after major surgery or trauma.

Granulocyte/Macrophage-Colony Stimulating Factor

Granulocyte/macrophage-colony stimulating factor (GM-CSF) production is induced by IL-2 and endotoxin. In vitro studies have demonstrated a prominent role for GM-CSF in delaying apoptosis of macrophages and PMNs. This growth factor is effective in promoting the maturation and recruitment of functional leukocytes necessary for normal inflammatory cytokine response, and potentially in wound healing. The mechanisms may be the result of the suppression of IL-10 production. Results of perioperative GM-CSF administration in patients undergoing major oncologic procedures have demonstrated augmentation of neutrophil numbers and function.

Regulation of Inflammatory Cell Death

Programmed Cell Death

During systemic inflammation, the response mounted by the host to injury and infection manifests the collective activities of circulating and tissue-fixed immunocytes and endothelial cell populations. In the normal host, programmed cell death (apoptosis) is the principal mechanism by which senescent or dysfunctional cells, including macrophages and PMNs, are systematically disposed of without activating other immunocytes or the release of proinflammatory contents. The signals inducing normal apoptosis differ from cell to cell but most likely converge at a common final pathway. These signals arise from the extracellular environment and may include hormonal and paracrine activities (Fig. 1-12). The inflammatory milieu disrupts the normal apoptotic machinery in dysfunctional or aging cells, consequently delaying the disposal of activated macrophages and PMNs. Several proinflammatory cytokines delay the normal temporal sequence of macrophage and PMN apoptosis in vitro. These include TNF, IL-1, IL-3, IL-6, GM-CSF, granulocyte colony-stimulating factor (G-CSF), and IFN-g. By contrast, IL-4 and IL-10 accelerate apoptosis in activated monocytes. The prolonged survival of inflammatory immunocytes may perpetuate and augment the inflammatory response to injury and infection, precipitating multiple organ failure and eventual death in severely injured and critically ill patients.

TNF Receptor-Mediated Programmed Cell Death

Tumor necrosis factor receptors (TNFRs) belong to a superfamily of approximately 15 transmembrane proteins that are present on virtually all cells, including immunocytes. Members of this family, which are linked by their conserved extracellular sequences, also include lymphotoxin-b receptor, Fas/CD95 (APO-1), nerve growth factor receptors (NGFR), CD27, CD30, OX40, 4-1BB, DR3 (WSL-1, APO-3, TRAMP), and DR4 (APO-2). Activation of these receptors induce specific cell responses that may include initiation of programmed cell death. There are two specific transmembrane TNFRs (type I, p55; and type II, p75), but they have distinct intracellular domains. The p55 TNFR induces apoptosis, cytotoxicity, expression of adhesion molecules on endothelial cells, and activation of the sphingomyelin pathway and nuclear factor-kappa B (NF-kB). The p75 TNFR induces proliferation of T cells, fibroblasts, natural killer cells, and proinflammatory cytokine release. The p55 TNFR has the dominant role in triggering apoptosis, but the concurrent participation of type I and type II TNFRs is necessary for initiating this process. The participation of both receptors is required, because activated intracellular p75 TNFR-related protein transducers are shared by the p55 TNFR signaling complex. During sepsis and experimental endotoxemia, down-regulation of macrophage and PMN TNFR activity is observed. This attenuation in TNFR activity may delay apoptosis of inflammatory macrophages and PMNs, prolonging the inflammatory response (Fig. 1-13). The p55 TNFR and Fas receptors exhibit similar cytoplasmic sequence motifs, known as the "death domain." These death domains interact with other intracellular proteins to propagate downstream signaling for programmed cell death. While TNFR I is found on virtually all cell types, Fas (CD95, APO-1) expression in murine models is predominantly expressed in the liver, lung, heart, intestine, skin, and lymphocytes. In human beings, Fas expression also is tissue-specific. When triggered by its specific ligand, FasL, Fas induces its only known function, which is to initiate apoptosis. Mutations of Fas or FasL are implicated as a cause for lymphoproliferative disorders and delayed disposal of inflammatory macrophages.

Fas/CD95 Receptor-Mediated Programmed Cell Death

The only known role of the Fas receptor is to initiate programmed cell death. Because of the intracellular homology of Fas to p55 TNFR, they both induce apoptosis via similar mechanisms, but Fas-mediated apoptosis occurs with greater speed (within hours) than that mediated by p55 TNFR. This may indicate a more direct (i.e., less complex) pathway for Fas-mediated apoptosis than that of the TNFR type I pathway. While the induction of apoptosis via Fas/FasL cross-linking in activated immunocytes may be advantageous during systemic inflammation, this activity at the tissue level may be detrimental to the host. Fas-mediated activity in the liver during inflammation may precipitate or exacerbate ongoing hepatic injury. There is hepatic parenchymal up-regulation of Fas receptors with acute toxic injury simultaneously enhanced by FasL expression of infiltrating lymphocytes. Studies also suggest a role for Fas/FasL interaction in thyroid gland destruction and thyroiditis. Therapeutic strategies derived from Fas/FasL interaction requires selectivity to minimize inadvertent organ injury.

Immunocyte Receptor Activity in Inflammation

Membrane TNFR

In human endotoxemia, TNFR expression in macrophages and PMNs is down-regulated. In macrophages, the decrease in surface TNFR reaches a low point 2h after endotoxin infusion and recovers to normal levels in 6h (Fig. 1-14). This receptor recovery continues to supranormal levels at 24 h. PMNs exhibit a more sustained decrease in surface TNFRs under the same conditions. Among signs such as fevers, leukocytosis, and chills, macrophage TNFR expression pattern is the most sensitive correlate identified for human response to endotoxin exposure. There is a reduction of cell-surface TNFRs in septic patients. Nonsurviving patients with severe sepsis have an immediate reduction in cell-surface TNFR expression, while surviving patients have almost normal receptor levels from the outset. TNFR expression can potentially be used as an indicator of outcome in patients with severe sepsis.

Soluble TNFR

Soluble TNFRs, proteolytically cleaved extracellular domains of membrane-associated TNFRs, also are elevated in patients with severe sepsis. sTNFRs retain their affinity for TNF and therefore compete with the cellular receptors for the binding of free TNF. This represents a counterregulatory response to excessive systemic TNF activity. In contrast to macrophage membrane TNFRs, nonsurviving septic patients demonstrate a significant elevation only in the p55 sTNFR compared to surviving patients. Cell-associated TNFR expression is more reliable than sTNFR as an early predictor of risk and outcome in human sepsis (Fig. 1-15).

Hormones and Cytokine Interactions

Cortisol/Glucocorticoids

Hypercortisolemia differentially influences leukocyte counts and cytokine expression in a temporal fashion. Glucocorticoid administration immediately before or concomitantly with endotoxin infusion in healthy human beings is able to attenuate the symptoms (e.g., fever, tachycardia), catecholamine response, and acute phase response, but it increases IL-10 release. Increased IL-10 release may contribute to the acute antiinflammatory effect of glucocorticoids. Hypercortisolemia induced by 6 h or more of glucocorticoid administration before endotoxin infusion does not attenuate the responses that are seen from endotoxin infusion alone. Infusion of cortisol for more than 12 h before endotoxin infusion increases TNF and IL-6 release. This may explain the varied systemic responses to infection in critically ill or severely injured patients who have associated hypercortisolemia. Such responses are influenced by antecedent events that alter the hormonal milieu. Glucocorticoids also can influence the regulation of T lymphocyte proliferation or programmed cell death, as demonstrated by in vitro dexamethasone-induced apoptosis of human T lymphocytes. CD8+ T cells are more sensitive to glucocorticoid-induced apoptosis than CD4+ cells. Glucocorticoid-induced apoptosis of T lymphocytes requires elevations of intracellular cAMP. IL-2, IL-4, and IL-10 protects these T lymphocytes from glucocorticoid-induced apoptosis. The proinflammatory cytokine IL-1 and, probably, TNF and IL-6 can activate the hypothalamus-pituitary-adrenal axis and induce the release of CRH and ACTH, leading to increased circulatory glucocorticoid levels. Glucocorticoids, in turn, inhibit endotoxin-induced production of TNF at the level of mRNA translation. Dexamethasone also inhibits neutrophil apoptosis and prolongs their functional responsiveness. This can be detrimental to the patient because the delay in clearance from tissues may perpetuate the injurious effects of activated neutrophils.

Catecholamines

Catecholamines inhibit endotoxin-induced macrophage production of TNF-a in vitro and in human whole blood ex vivo. In normal human subjects, short-term preexposure to epinephrine effectively inhibits endotoxin-induced TNF production. Concurrently, this short-term preexposure to epinephrine increases the production of the antiinflammatory cytokine IL-10. Longer preexposure, 24 h, had a less pronounced antiinflammatory effect. Endogenous epinephrine or exogenous administration as a component of sepsis treatment may serve to limit excessive proinflammatory effects of the cytokine network during the early phase of systemic infection. Epinephrine attenuates endotoxin-induced down-regulation of TNFR expression on human monocytes in vivo, an effect that is beta-receptor mediated and cAMP dependent. The use of catecholamines in treatment may have the potential for influencing immune cell function.

OTHER MEDIATORS OF INJURY RESPONSE

Endothelial Cell Mediators

Endothelial Cell Function

In addition to modulating coagulation and vasomotor activities, mediators elaborated by the vascular endothelium in response to injury are well-documented contributors to the inflammatory process. In a paracrine fashion, local mediators such as TNF-a, IL-1, endotoxin, thrombin, histamine, and IFN-g are capable of stimulating or activating the endothelial cell during local tissue injury. In response, the endothelial cell releases several mediators, including IL-1, platelet-activating factor (PAF), prostaglandins (PGI₂ and PGE₂), GM-CSF, growth factors, endothelin, nitric oxide, and small amounts of thromboxane A₂ (TxA₂). Activated endothelial cells also release collagenases capable of autodigesting their own basement membranes. This permits neovascularization and vascular remodeling at sites of injury in order to facilitate adequate oxygen supply and immunocyte transport. Angiotensin-converting enzymes (ACE) convert angiotensin I to angiotensin II on the surface of endothelial cells, making it a potent regulator of vascular tone. Endothelial cell mediators can modulate cardiovascular and renal function and influence the hypothalamus-pituitary-adrenal axis (Fig. 1-16). The activated endothelial cell up-regulates its expression of leukocyte adhesion receptor molecules such as E-selectin (formerly referred to as endothelial-leukocyte adhesion molecule-1, ELAM-1), P-selectin, and intercellular adhesion molecules (ICAM-1, ICAM-2). The adhesion of leukocytes and platelets to the endothelial surface occurs early in the endothelial-derived inflammatory process. In cultured endothelial cells, basal expression of E-selectin during inflammation requires the stimulation of TNF-a and IL-1. Within 1 h after treatment with either of these two cytokines, mRNA activity for E-selectin is detectable. The expression of E-selectin on endothelial cell surfaces is maximal at 4 to 6 h. Recovery from the inflammatory process also is characterized by internalization of these adhesion molecules within the endothelial cell. Neutrophil adhesion to the endothelium during injury has important clinical implications for increasing vascular permeability and passage of leukocytes into injured tissues. These are important in the etiology of conditions such as acute lung and ischemia-reperfusion injuries. In the nonstressed state, the endothelium possesses little capacity to recognize and bind circulating leukocytes. Local injuries and inflammatory mediator stimulation promote the margination of circulating PMNs to the endothelial surfaces. These marginated PMNs are deformable and travel along the endothelial surfaces at markedly reduced velocities, which is referred to as *rolling*. Rolling represents a process of transient attachment and detachment between receptors of PMNs and the endothelium. The subsequent development of stronger receptor adhesions, PMN activation by the endothelial mediators, and release of PMN proteinases at endothelial junctions precedes the migration of PMNs out of the vascular compartment, a process referred to as *diapedesis*. Although necessary for local tissue inflammation and eradication of microbes, activated PMNs and the subsequent release of inflammatory mediators and reactive oxygen metabolites are implicated in capillary leakage, acute lung injury, and postischemic injury (Fig. 1-17). The release of mediators by the endothelium and their subsequent influence on neighboring and distant tissues ascribes endocrine properties to endothelial cells during injury. The ability to attract leukocytes and produce inflammatory mediators makes endothelial cells important participants in the immune response to injury.

Endothelium-Derived Nitric Oxide

Endothelium-derived nitric oxide or relaxing factor (EDNO or EDRF) can be released in response to acetylcholine stimulation, hypoxia, endotoxin, cellular injury, or mechanical

shear stress from circulating blood. Its vasodilatory activity has been demonstrated in large (conduit) arteries and in resistance vessels of most mammalian species, including human beings. Induction of vascular smooth muscle relaxation by EDNO requires the activation of soluble guanylate cyclase and an increase in cytosolic cyclic guanosine monophosphate (cGMP) within the myocytes. Methylene blue inhibits guanylate cyclase, prevents the production of cGMP, and inhibits vascular relaxation. cGMP also is present in platelets and can be activated by EDNO. Increased cGMP in platelets is associated with reduced adhesion and aggregation. EDNO induces vasodilation and platelet deactivation (Fig. 1-18). EDNO also mediates protein synthesis in hepatocytes and electron transport in hepatocyte mitochondria. It is a readily diffusible substance with a half-life of a few seconds. EDNO spontaneously decomposes into nitrate and nitrite.

EDNO is formed from oxidation of L-arginine, a process catalyzed by nitric oxide synthase (NO-synthase). Cofactors of NO-synthase activity include calmodulin, ionized calcium, and NADPH. In addition to the endothelium, this enzymatic activity also is present in PMNs, macrophages, renal cells, Kupffer cells, and cerebellar neurons.

In normal vasculature, experiments blocking EDNO activity induce a state of vasoconstriction that is readily reversed with L-arginine administration. This demonstrates that the vasculature is in a constant state of vasodilation because of the continuous basal release of EDNO. Endogenous inhibitors of EDNO have been identified that are autoregulators of endothelial tone.

Elevations of EDNO in septic shock and trauma, as measured by its nitrite and nitrate metabolites, are evidenced in association with low systemic vascular resistance and elevated endotoxin levels.

Prostacyclin

Prostacyclin (PGI₂) is an important endothelium-derived vasodilator synthesized in response to vascular shear stress and hypoxia. It has functions similar to those of EDNO.

Prostacyclin is derived from arachidonic acid and causes relaxation and platelet deactivation by increasing cAMP. It has been used to reduce pulmonary hypertension, particularly in pediatric patients.

Endothelins

Endothelins (ET) are elaborated by vascular endothelial cells in response to injury, thrombin, transforming growth factor- β (TGF- β), IL-1, angiotensin II, arginine vasopressin, catecholamines, and anoxia. Structurally formed from a 38–amino acid precursor molecule, ET is a 21–amino acid peptide with potent vasoconstrictor properties. Among the peptides in this family (ET-1, ET-2, ET-3), endothelial cells produce only ET-1. ET-1 is the most biologically active and potent vasoconstrictor known, estimated to be ten times more potent than angiotensin II. Three endothelin receptors, referred to as ET_A, ET_B, ET_C, function by the G protein–coupled receptor mechanism. ET_B receptors are linked to the formation of EDNO and PGI₂, which are negative feedback mechanisms. This may explain the transient vasodilation obtained with low-dose administration of ET-1 and the need for EDNO and ET to maintain physiologic tone in vascular smooth muscles. The vasoconstrictor activity of ET can be reversed by the administration of acetylcholine, which stimulates EDNO production. Increased serum levels of ET are correlated with the severity of injury after major trauma, major surgical procedures, and in cardiogenic or septic shock.

Platelet-Activating Factor

Another endothelium-derived product is PAF, a phospholipid constituent of cell membranes that can be induced by TNF, IL-1, AVP, and angiotensin II. This potent inflammatory mediator stimulates production of TxA₂ through the cyclooxygenase pathway and promotes platelet aggregation. TxA₂ is also a potent vasoconstrictor. Experimentally, PAF has increased glucagon and catecholamine activity. It can induce hypotension, increase vascular permeability, hemoconcentration, pulmonary hypertension, bronchoconstriction, primed PMN activity, eosinophil chemotaxis/degranulation, and thrombocytopenia. It induces a general leukocytopenia by way of margination. Administration of antagonists to PAF in experimental human endotoxemia demonstrates partial attenuation of symptoms such as myalgias and rigors, but these inhibitors are ineffective in reversing hemodynamic derangements.

PAF alters the shape of endothelial cells, causing them to contract and increase permeability. In cultured endothelial cells, cell contraction permits the passage of macromolecules, such as albumin, across cell junctions. PAF is a chemotactant for leukocyte adherence to the vascular wall and facilitates migration out of the vascular compartment. The disparity between PAF-induced vascular permeability and PAF-induced vasoconstriction is most likely the result of differential receptor types and affinity found in different vascular segments. Other cells that secrete PAF include macrophages, PMNs, basophils, mast cells, and eosinophils.

Atrial Natriuretic Peptides

Atrial natriuretic peptides (ANPs) are peptides released by the central nervous system and by specialized endothelium found in atrial tissues in response to wall tension. ANPs are potent inhibitors of aldosterone secretion and prevent reabsorption of sodium. In rats, the myocardial endothelium-derived nitric oxide (EDNO) inhibits the release of ANP, while ET-1 is a potent secretagogue of ANP. The role of ANP in human response to injury is unknown.

Intracellular Mediators

Heat-Shock Proteins

In addition to heat stimulation, stimuli such as hypoxia, trauma, heavy metals, local trauma, and hemorrhage induce the production of intracellular heat-shock proteins (HSPs).

These proteins are presumed to protect cells from the deleterious effects of traumatic stress. HSPs function intracellularly in the assembly, disassembly, stability, and transport of proteins. The classic example of HSP activity is the intracellular transport of steroid molecules. The formation of HSPs require gene induction by the heat-shock transcription factor (HSF). Gene expression occurs in parallel with hormonal activities of the hypothalamus-pituitary-adrenal axis. This response may be ACTH-sensitive, and the production may decline with age. Although HSPs are important intracellular effectors, their relevance in the human response to injury can only be inferred from animal data.

Reactive Oxygen Metabolites

Reactive oxygen metabolites (ROMs) are short-lived, highly reactive molecular oxygen species with an unpaired outer orbit. They cause tissue injury by peroxidation of cell membrane unsaturated fatty acids.

ROMs are produced by complex processes that involve anaerobic glucose oxidation coupled with the reduction of oxygen to superoxide anion. Superoxide anion is a potent ROM but can be metabolized to other reactive species such as hydrogen peroxide and hydroxyl radical. Cells are not immune to damage by their own ROMs but are generally protected by oxygen scavengers that include glutathione and catalases. In ischemic tissues, the intracellular mechanisms for production of ROMs become fully activated but are nonfunctional because of a lack of oxygen supply. With restoration of blood flow and oxygen supply, large quantities of ROMs are produced that induce reperfusion injury.

In response to a stimulus, activated leukocytes are potent generators of reactive oxygen metabolites. ROMs also can induce apoptosis. Studies using T lymphocytes have demonstrated a major apoptotic mechanism mediated by depletion of intracellular glutathione or ROM scavenger. The proapoptotic Fas/CD95 receptor activation is implicated in depleting GSH with resultant intracellular ROM accumulation and cell death. Repletion of GSH in these cells can reverse these effects.

Other Inflammatory Mediators

Eicosanoids

The eicosanoid class of mediators, which encompasses prostaglandins (PG), thromboxanes (Tx), leukotrienes (LT), hydroxyeicosatetraenoic acids (HETE), and lipoxins (Lx), are oxidation derivatives of the membrane phospholipid, arachidonic acid (eicosatetraenoic acid). They are secreted by virtually all nucleated cells except lymphocytes. The synthesis of arachidonic acid from phospholipids requires enzymatic activation of phospholipase A₂ (Fig. 1-19). The cyclooxygenase and the lipoxygenase pathways are two major routes by which arachidonic acid is oxygenated. Most eicosanoids generated from the cyclooxygenase pathway are given the subscript designation of 2 (e.g., TxA₂), while products of the lipoxygenase pathway are designated 4 (e.g., LTE₄). These subscripts indicate the number of carbon double bonds present in the side chains. Products of the cyclooxygenase pathway include all of the prostaglandins and thromboxanes. The formation of prostacyclin (PGI₂) requires further enzymatic activity by prostacyclin synthetase, and the formation of TxA₂ requires the activity of thromboxane synthetase. The lipoxygenase pathway generates the leukotrienes and HETE.

Initial phospholipase A₂ activation can be achieved by compounds such as epinephrine, angiotensin II, bradykinin, histamine, and thrombin. Conversely, phospholipase A₂ can be inhibited by lipocortin, which is induced by cortisol. The synthesis of prostaglandins and thromboxanes also are inhibited by nonsteroidal antiinflammatory drugs and salicylates, which are cyclooxygenase inhibitors.

Eicosanoids are not stored in cells but are synthesized rapidly upon stimulation by hypoxic and ischemic injury, direct tissue injury, endotoxin, norepinephrine, AVP, angiotensin II, bradykinin, serotonin, acetylcholine, and histamine. Many of these stimuli also induce a second cyclooxygenase enzyme, referred to as COX-2, that enhances the production of arachidonic acid metabolites. COX-2 activity can be inhibited by glucocorticoids, which provide specific inhibition of cyclooxygenase metabolites, as opposed to lipocortin, which inhibits production of arachidonic acid metabolites. The products of arachidonic acid metabolism are functionally cell/tissue specific. Vascular endothelium primarily synthesizes PGI₂, which causes vasodilation and platelet deactivation. Thromboxane synthetase converts platelet prostaglandins to TxA₂, a potent vasoconstrictor and platelet aggregator. Macrophages are capable of synthesizing cyclooxygenase and lipoxygenase products.

Second messengers mediate much of eicosanoid activity. For example, PGE compounds, in a manner similar to ACTH, TSH, and LH, inhibit AVP activity and hormone-stimulated lipolysis by activating adenylate cyclase activity and generating intracellular cAMP. Thromboxane and leukotrienes have opposite effects from PGE by increasing intracellular free calcium via the phosphatidylinositol pathway.

Eicosanoids have diverse effects systemically on endocrine and immune function, neurotransmission, and vasomotor regulation (Table 1-7). Eicosanoids are major components of the inflammatory response in injured tissue, characterized by vascular permeability, leukocyte migration, and vasodilation. Collectively, their deleterious effects are implicated in acute lung injury, pancreatitis, and renal failure. Leukotrienes are produced by cells of the lung, connective tissue, smooth muscle, macrophages, and mast cells that mediate the reactions characteristic of anaphylaxis. Leukotrienes are 1,000 times more potent than histamines in promoting capillary leakage. They also are effective promoters of leukocyte adherence, neutrophil activation, bronchoconstriction, and vasoconstriction. The role of lipoxins is not well understood but they are believed to induce neutrophil activation and production of superoxides and degranulation.

The metabolic effects of eicosanoids are well recognized. In the regulation of glucose, products of the cyclooxygenase pathway inhibit pancreatic beta cell release of insulin while products of the lipoxygenase pathway promote beta cell activity. Hepatocytes also express specific receptors for PGE₂ that, when activated, inhibit gluconeogenesis. PGE₂ inhibits hormone-stimulated lipolysis.

Eicosanoids modulate the immune response in multiple ways. Small amounts of PGE₂ suppress proliferation of human T lymphocytes by mitogens, an effect mediated by down-regulation of IL-2 production. Enhanced lymphocyte activation by mitogens can be achieved with the administration of indomethacin, a PGE₂ inhibitor. During phagocytosis, PMNs release eicosanoids such as LTB₄ to serve as chemoattractants for other leukocytes. PGE₂ and LTD₄ are commonly present in local areas of injury and are believed to have a direct influence on the inflammatory response.

Kallikrein-Kinin System

Bradykinins are potent vasodilators produced through kininogen degradation by the serine protease kallikrein. Kallikrein exists in blood and tissues as inactive prekallikrein and is activated by various chemical and physical factors. Among these are Hageman factor, trypsin, plasmin, factor XI, glass surfaces, kaolin, and collagen. Kinins are rapidly metabolized by kinase I and II. Kinase I degrades the anaphylatoxins C3a, C4a, and C5a. Kinase II is identical to angiotensin-converting enzyme. The use of angiotensin-converting enzyme inhibitors (ACE inhibitors) in controlling hypertension may serve partially to block kinin degradation in some patients and enhance the kinin-induced injurious effects on the bronchial tree.

Kinins increase capillary permeability and tissue edema, evoke pain, and increase bronchoconstriction. They also increase renal vasodilation and consequently reduce renal blood flow. The resulting increase in renin formation activates sodium and water retention via the renin-angiotensin system.

Bradykinin release is stimulated by hypoxic and ischemic injury. Increased kallikrein activity and bradykinin levels have been detected after hemorrhage, sepsis, endotoxemia, and tissue injury. These observations are positively correlated with the magnitude of injury and mortality. Clinical trials using bradykinin antagonists in attempts to reduce the deleterious sequelae of septic shock have demonstrated only modest reversal in gram- negative sepsis and no overall improvement in survival. Metabolically, kinins increase glucose clearance by inhibiting gluconeogenesis. Bradykinin infusion also may increase nitrogen retention.

Serotonin

The neurotransmitter serotonin (5-hydroxytryptamine, 5-HT) is a tryptophan derivative that is found in enterochromaffin cells of the intestine and in platelets. Patients with midgut carcinoid tumors often secrete excessive 5-HT. This neurotransmitter stimulates vasoconstriction, bronchoconstriction, and platelet aggregation. It also is capable of acting as a myocardial chronotrope and inotrope. Although it is released at sites of injury, its role in the injury response is unclear.

Histamine

Histamine is derived from histidine and stored in neurons, skin, gastric mucosa, mast cells, basophils, and platelets. Its release is activated by increased calcium levels. There are two receptor types for histamine binding. H₁ binding mediates increased histamine precursor uptake, I- histidine, and stimulates bronchoconstriction, intestinal motility, and myocardial contractility. H₂ binding inhibits histamine release. H₁ and H₂ receptor activation induces vasodilation and increases vascular permeability. Histamine administration causes hypotension, peripheral pooling of blood, increased capillary permeability, decreased venous return, and myocardial failure. Histamine is released in hemorrhagic shock, trauma, thermal injury, endotoxemia, and sepsis. Histamine levels are correlated with mortality from septic shock.

METABOLIC RESPONSE TO INJURY

The description of human biochemical responses to injury and the classification of such responses into an ebb and flow phase by Cuthbertson and others provides a useful model by which the metabolic response to injury may be characterized (Fig. 1-20). The ebb phase corresponds to the earliest moments to hours after injury, often in association with hemodynamic instability or reductions in effective circulating blood volume. The metabolic consequences of this phase are less well studied but are generally associated with reductions in total body energy expenditure and losses of urinary nitrogen. The ebb phase is characterized by an early enhancement of neuroendocrine hormone appearance, including catecholamines and cortisol. Less is known about the microendocrine mediator response. It is difficult to analyze the immune cell mediator response engendered during the ebb phase separately from that occurring in response to fluid or volume resuscitation, and the resultant tissue reperfusion and reoxygenation that initiates the onset of the flow phase.

Except with the most minor injury, the flow phase is ushered in by compensatory mechanisms resulting from volume repletion and cessation of initial injury conditions. The metabolic response associated with the flow phase serves to direct energy and protein substrates so as to preserve critical organ function and repair damaged tissues. This includes an increase in whole-body oxygen consumption and metabolic rate, enhancement of critical enzyme pathways for readily oxidizable substrates such as glucose, and stimulation of immune system functions required for repair of tissue destruction and protection from additional breaks in epithelial barriers. A reprioritization of substrate processing occurs to support the production of acute-phase reactants, immunoreactive proteins, and coagulation factors. The biologic priority of wound healing also is established during the early flow phase.

Metabolic Response to Fasting

A comparison between the metabolic physiology of injury to that of unstressed fasting is useful for assessing the relative magnitudes of altered physiology under these widely varying conditions. Factors such as antecedent health status, age, and lean body mass also influence the absolute rates of substrate turnover after fasting and injury.

Substrate Metabolism

A healthy adult of 70 kg body weight expends 1700 to 1800 kcal/day of energy obtained from lipid, carbohydrate, and protein sources (Fig. 1-21). Obligate glycolytic cells, such as neurons, leukocytes, and erythrocytes, require 180 g glucose per 24 h for basal energy needs. During acute starvation, glucose is derived from existing storage pools, including approximately 75 g glucose stored as hepatic glycogen. Skeletal muscle cannot directly release free glucose, because it lacks the glucose-6- phosphatase necessary for free glucose release. The reduction of circulating glucose during prolonged fasting serves as a primary stimulus to hormonal release that modulates gluconeogenesis and substrate substitution for those tissues that require glucose for energy. Glucose concentration falls within hours after the onset of fasting in association with decreases in insulin release and sustained increases of circulating glucagon and more transient elevations of GH, catecholamines, AVP, and angiotensin II. Glucagon and epinephrine enhance cAMP to promote glycogenolysis, and cortisol and glucagon promote gluconeogenesis. The actions of norepinephrine, AVP, and angiotensin II are mediated by the intracellular signals of phosphatidylinositol and calcium to promote glycogenolysis. Cortisol and epinephrine limit pyruvate use. The effect of these actions is an increase in glucose production. Sustained glucose production depends on presentation of amino acids, glycerol, and fatty acids to the liver (Figs. 1-22 and 1-23). The primary gluconeogenic precursors used by the liver and to a lesser extent by the kidney for gluconeogenesis are lactate, glycerol, and amino acids such as alanine and glutamine. Skeletal muscle releases lactate by breakdown of endogenous glycogen stores and by glycolysis of transported glucose. Lactate also is released by erythrocytes and white blood cells after aerobic glycolysis and release of newly formed lactate into the circulation. This lactate is reconverted to glucose in the liver by the Cori cycle (Fig. 1-24).

The quantity of glucose made from lactate produced by skeletal muscle is not sufficient to maintain glucose homeostasis. Consequently, approximately 75 g of protein must be degraded daily during fasting and starvation to provide gluconeogenic amino acids to the liver. Proteolysis, which results primarily from decreased insulin and increased cortisol, is associated with an increase in urinary nitrogen excretion from the normal 6 to 8 g/day to approximately 8 to 11 g within the initial 5 days of fasting. Protein mobilized in starvation is derived primarily from skeletal muscle, but the loss of protein from other organs also occurs.

The amino nitrogen load resulting from deamination of amino acids for gluconeogenesis increases urinary ammonia excretion. The renal excretion of ammonium ion becomes the primary route of elimination of alpha-amino nitrogen during starvation because the normally active hepatic enzymes are diminished. Renal gluconeogenesis increases through metabolism of glutamine and glutamate. The kidney may account for up to 45 percent of glucose production during late starvation.

After approximately 5 days, the rate of whole-body proteolysis diminishes to a level of 15 to 20 g/day and urinary nitrogen excretion stabilizes at 2 to 5 g/day for several weeks. This reduction in proteolysis occurs as the nervous system and other previous glucose-utilizing tissues adapt to ketone oxidation as the predominant energy source. During starvation, transport systems in the blood-brain barrier increase the rate of ketone body transport, and metabolism of ketone bodies by the brain increases. Consequently, the amount of protein required for gluconeogenesis is significantly reduced (see Fig. 1-23). A reduction in anabolic growth factors such as IGF-1 (formerly somatomedin C) also is observed during the first several days of fasting (Fig. 1-25). The reduction in this factor and its associated binding proteins reduces an important signal for transcellular amino acid transport. Tissue protein synthesis also falls correspondingly with reduced proteolysis.

Energy requirements for gluconeogenesis and basal enzymatic and muscular function, such as neural transmission and cardiac contraction, can be met by the mobilization of approximately 160 g of triglycerides from adipose tissue in the form of free fatty acids and glycerol in a resting, fasting 70-kg subject (Fig. 1-26). Free fatty acid release is stimulated by a reduction in the serum insulin concentration. Increased glucagon may participate in this alteration, as do catecholamines. The free fatty acids and ketone bodies generated by the liver are used as a source of energy by tissues such as the heart, kidney, muscle, and liver. Lipid stores provide up to 40 percent of the caloric expenditure during starvation. Lipid oxidation during starvation diminishes the absolute glucose requirement to sustain tissue and body energy expenditure. Fatty acid use occurs at a rate that is proportional to serum fatty acid concentration. Ketone bodies spare glucose by inhibition of pyruvate dehydrogenase in most tissues. The use of fat as a main fuel source decreases the amount of mandatory glycolysis, which diminishes the requirements for gluconeogenesis and protein degradation.

Once the initial obligatory neuroendocrine stress hormone response recedes, whole-body energy expenditure also decreases during prolonged fasting. This reduction in resting energy expenditure is a consequence of decreased sympathetic nervous system activity and reduced skeletal muscle activity. Reduced secretory enzyme production and intestinal metabolic demands contribute to this adjustment.

Metabolism After Injury

The metabolic consequences of injury differ in many fundamental ways from those of simple starvation. Well-defined changes in hormone levels and associated substrates accompany injury. These changes can reflect the degree of underlying injury (Fig. 1-27). A useful construct in the attendant changes in interorgan substrate flux has been proposed by Cahill (Fig. 1-28). It is the sustained activities of macroendocrine hormones in conjunction with immune cell activation that provides the signals that differentiate injury metabolism from unstressed starvation.

Energy Balance

Injury of any magnitude beyond the most trivial is associated with an increase in energy expenditure and increases in oxygen consumption that vary directly with the severity of injury (Fig. 1-29) or burn surface area (Fig. 1-30). A linear relationship between body cell mass and resting energy expenditure often is observed in injured patients. The increase in energy expenditure observed after injury results initially from the increased activity of the sympathetic nervous system and increased circulating concentrations of catecholamines. Increases in energy expenditure can be replicated by the administration of catecholamines to healthy subjects. Conversely, glucocorticoid excess does not significantly enhance energy expenditure. The mechanism for this catecholamine effect may be related to influences on cell membrane sodium permeability and the energy required for ion pump action to maintain normal transmembrane concentrations. This influence is observed during the endotoxin/cytokine interactivity, in which reductions in muscle resting transmembrane potential are readily observed. Under these conditions, increases in circulating catecholamines occur with restoration of membrane potential and before changes in energy expenditure. Young estimated that such cellular ion pumping and transport activities may account for over 40 percent of total body energy expenditure.

Lipid Metabolism

Free fatty acids are a principal source of energy after injury. Lipolysis is enhanced by the immediate elevations in ACTH, cortisol, catecholamines, glucagon, and growth hormone levels, reduction in insulin level, and increased sympathetic nervous system activity. Catecholamines are the chief stimulus to hormone-sensitive lipase. The sympathetic nervous system and circulating catecholamines are important in the lipolytic response to stress. Investigations into the mechanism of catecholamine- induced posttraumatic lipolysis suggest that lipolysis may be increased by changes in adrenergic postreceptor (protein kinase hormone-sensitive lipase) response after elective operation.

Lipolysis observed during the ebb phase results in elevated levels of plasma free fatty acids and glycerol. Increased reesterification of fatty acids, such as that seen in the presence of high concentrations of lactate, may decrease net free fatty acid release. This explanation is supported by the observed rise in plasma glycerol level noted after injury, which suggests that lipolysis is occurring, and by increased concentrations of lactate in studies in which there is no change in free fatty acid concentration. Acidosis, hyperglycemia, and anesthetic agents also alter lipid mobilization after injury. For example, lipolysis is directly inhibited by pentobarbital anesthesia, and hemorrhage in the presence of pentobarbital usually results in a fall in the plasma free fatty acid and ketone body concentrations. Experimental hemorrhage using other anesthetic agents or in awake animals increases free fatty acid and ketone body concentrations.

During the flow phase, net lipolysis continues, as reflected by increased concentrations and clearance of plasma free fatty acids. In the presence of oxygen, the released fatty acids can be oxidized by cardiac and skeletal muscle to produce energy.

The precise role of fatty acids in the inhibition of glycolysis after injury is controversial. Evidence suggests that fatty acid-induced inhibition of glycolysis may be a major mechanism for reduced glycolysis during the flow phase after minor to moderate injury. This mechanism may not operate in severe injury, hemorrhage, or sepsis, conditions in which persistent glycolysis and net proteolysis are observed. Lipoprotein lipase, the endothelial cell membrane enzyme responsible for clearing plasma triglycerides, is suppressed in adipose tissue after trauma, but not in muscle. In sepsis this enzyme activity is suppressed in both muscle and adipose tissue. The roles of cytokines, such as TNF (which inhibits lipogenesis and decreases lipoprotein lipase activity), IL-1, and PGE, in fat metabolism are not fully understood.

The high concentrations of intracellular fatty acids and the elevated concentration of glucagon during the ebb and flow phases inhibit fatty acid synthesis. In hepatocytes, this also stimulates the transport of acyl coenzyme A (acyl CoA) into the mitochondria for oxidation and ketogenesis. Ketogenesis is variable and is inversely correlated with the severity of injury. Ketogenesis is decreased after major injury, severe shock, and sepsis and is suppressed by increases in levels of insulin and other energy substrates, by increased uptake and oxidation of free fatty acids, and by an associated counterregulatory hormone response. After minor injury or mild infection, ketogenesis increases but to a lesser extent than that seen during nonstressed starvation. Injuries that are associated with minor ketone body formation also appear to be associated with a small or absent increase in plasma free fatty acid concentrations.

Carbohydrate Metabolism

Systemic glucose intolerance is well documented in injured patients. By contrast, basal insulin levels are elevated by several times during the early flow phase, indicating a state of relative insulin resistance. Regional tissue catheterization and isotope dilution studies provide a more precise description of this insulin resistance. A 50 to 60 percent increase in net splanchnic glucose output is observed in septic patients, and a 50 to 100 percent increase is noted in thermally injured patients. The associated macroendocrine hormone milieu contributes to this net gluconeogenic response and is believed to be largely under the active control of glucagon with permissive requirement for cortisol. The precise contributions of other macroendocrine hormones are unclear, although there is evidence to suggest that proinflammatory mediators such as IL-6 also may exert an influence on hepatic glucose production. Definable acute changes in substrate turnover are associated with the proinflammatory mediator activity induced by endotoxin administration or TNF infusion (Table 1-8).

Increases in plasma glucose levels are proportional to the severity of injury and to some extent are correlated with survival. With the presence of hyperglycemia, resulting largely from increased hepatic production, a ready source of substrate is provided to tissues such as those of the nervous system, wound, and red blood cells, which do not require insulin for glucose transport. Elevated concentrations of glucose and of some amino acids may be necessary for leukocyte energy requirements in inflamed tissues and in defense of epithelial barriers or other sites of microbial invasion. Insulin resistance is of teleologic benefit to the host in that the accompanying neuroendocrine hormone response precludes the adaptation to ketone body production. To a large extent, the deprivation of glucose to nonessential organs such as skeletal muscle and adipose tissues is mediated by catecholamines. This relationship is suggested by a close correlation between plasma glucose and prevailing catecholamine levels (Fig. 1-31). Peripheral insulin resistance has been noted in isolated catecholamine excess in healthy subjects, as has been increased hepatic glucose production. Conversely, glucocorticoids do not alter these parameters (Fig. 1-32). Although the mechanisms for reduced glucose oxidation are not fully understood, a mediator-induced reduction of skeletal muscle pyruvate dehydrogenase activity diminishes the conversion of glucose to acetyl CoA and subsequent entry into the tricarboxylic acid cycle. The consequent accumulation and shunting of three carbon skeletons to the liver provides substrate for gluconeogenesis.

Glucose must be provided to inflammatory and healing cells in the wound environment. Glucose uptake and lactate production in wounded tissue are significantly increased. Wound inflammatory cells require glucose as an energy substrate and accelerated glucose uptake in wounded and burned tissue is correlated with the inflammatory cellular infiltrate.

The increase in glucose uptake in wounded tissue is associated with an increase in the activity of phosphofructokinase, a major rate-limiting enzyme in glycolysis. Despite the increase in glucose uptake and phosphofructokinase activity, wounded and burned tissues demonstrate decreased insulin sensitivity and fail to normally increase glucose uptake or glycogenesis in response to insulin.

Protein and Amino Acid Metabolism

The intake of protein for a healthy young adult is approximately 80 to 120 g, or 13 to 20 g of nitrogen per day. Daily fecal and urinary excretion of nitrogen is 2 to 3 g and 13 to 20 g, respectively. After injury, daily nitrogen excretion in the urine increases to 30 to 50 g as urea nitrogen and represents net proteolysis. The increased excretion of urea after injury also is associated with the urinary loss of sulfur, phosphorus, potassium, magnesium, and creatinine, which indicates breakdown of intracellular compounds. Isotope dilution studies suggest that decreases in cell mass are responsible for the increased loss of these metabolites. Sophisticated methods of body mass assessment, such as neutron activation analysis, confirm a loss of lean tissues after significant injury. A predominant loss of skeletal muscle protein is suggested by increased urinary 3- methylhistidine/creatinine ratios. Radiolabeled amino acid incorporation studies and protein analyses confirm that skeletal muscle is depleted while visceral tissues, such as liver and kidney, are relatively preserved. The mechanisms for this visceral protein preservation are unclear, but animal studies suggest that proinflammatory cytokine activity may contribute to this process.

Data on total body protein turnover suggest that after injury the net changes in catabolism and synthesis depend on the severity of the injury. Elective operations and minor injuries result in decreased protein synthesis and normal rates of protein breakdown. Severe trauma, burns, and sepsis are associated with increased whole-body protein turnover and increased net protein catabolism (Table 1-9). Accelerated proteolysis and gluconeogenesis persist after major injury and during sepsis. The rise in urinary nitrogen and negative nitrogen balance begins shortly after injury, reaches a peak about the first week and may continue for 3 to 7 weeks. The magnitude of nitrogen loss also is related to the age, sex, and physical condition of the patient. Young healthy males lose more protein in response to an injury than do women or the elderly, presumably because they have a higher lean body mass than the latter two patient subsets.

The amino acid composition of normal human beings varies according to tissue origin. After trauma, substrate cycling occurs between skeletal muscle, liver, and the wound (see Fig. 1-28). Quantitatively, the major source of amino acids is skeletal muscle, in which the proportions of specific amino acids as protein and free intracellular components varies dramatically from that in normal plasma (Fig. 1-33). Increases by several times in the splanchnic uptake of alanine and glutamine in conjunction with similar trends for peripheral tissue efflux are observed after injury. Although the precise mechanisms for the net increase in skeletal muscle protein breakdown remain unclear, the combined extracellular hormonal milieu of relative insulin resistance, cortisol excess, and proinflammatory cytokine activity exert a synergistic influence. Within the cell, enhanced oxidative species and diminished antioxidant activities, such as glutathione, all enhance the potential for protein instability. Many of these same mediators serve to increase ubiquitin-dependent proteolytic pathways (Fig. 1-34), one of several potential pathways for degradation of cellular proteins. The ubiquitin-proteasome pathway may not be operative in all catabolic conditions. For example, this pathway is of major importance for muscle protein degradation during sepsis, but it is only partly responsible for the protein catabolism seen after burn injury.

The intracellular muscle concentrations of several essential amino acids decrease at the same time that net efflux is occurring from skeletal muscle. The release of glutamine and alanine are greater than can be predicted from its relative abundance in muscle tissue protein, indicating their net synthesis in muscle before release. Glutamine is a major energy source for lymphocytes, fibroblasts, and the gastrointestinal tract, especially during conditions of increased stress. Glutamine may act as a conditional essential amino acid during periods of catabolism, since depletion of this substrate has pronounced negative effects on enterocytes and mucosal integrity and since administration of glutamine reverses these effects. Although it is hypothesized that provision of this amino acid might preserve or enhance immune cell and enterocyte function during stress, clinical studies documenting such beneficial effects during injury in human subjects are lacking.

NUTRITION IN THE SURGICAL PATIENT

Most patients undergoing elective surgical operations withstand the brief period of catabolism and starvation without noticeable difficulty. Maintaining an adequate nutritional regimen may be of critical importance in managing seriously ill surgical patients with preexisting weight loss and depleted energy reserves. Between these two extremes are patients for whom nutritional support is not essential for life but may serve to shorten the postoperative recovery phase and minimize the number of complications. Frequently, a patient may become ill or even die from complications secondary to starvation rather than the underlying disorder. It is essential that the surgeon have a sound grasp of the fundamental metabolic changes associated with surgery, trauma, and sepsis and an awareness of the methods available to reverse or ameliorate these events.

Surgery, Trauma, Sepsis

In contrast to the whole-body and tissue-specific energy and protein conservation response exhibited during unstressed starvation, the injured patient manifests variable, but obligatory, increases in energy expenditure and nitrogen excretion (Fig. 1-35). While the extent and duration of this response to injury are modified by a variety of factors, including the adequacy of resuscitation, infection, and medication, the inability to down- regulate body energy expenditure and nitrogen losses may rapidly deplete labile and functional energy stores. The postinjury metabolic environment precludes the efficient oxidation of fat and ketone production, thereby promoting the continued erosion of protein pools. This enhanced net protein catabolic process, if unchecked by effective disease-specific therapy and allowed to progress for an extended period without nutritional intervention, eventuates in critical organ failure.

The sequence of flow phase metabolic and endocrine events occasioned by injury may be divided into several phases. The magnitude of the changes and the duration of each phase vary considerably and are directly related to the severity of the injury. The benefits of exogenous nutritional support in each of these recovery phases is controversial. Nevertheless, the integrative biology of endocrine and immune system interactions would predict a greater likelihood of achieving lean tissue restoration and substrate- dependent immune competence during periods of attenuated mediator activity. Such observations do not preclude a rationale for earlier efforts at nutritional intervention. Rather, they provide a biologic basis for reasonable expectations of therapy and for the design of future therapeutic adjuncts.

Catabolic Phase

Once patients have received initial resuscitation and stabilization of wounds, the earliest definable metabolic response is one of catabolism. This phase has been termed the *adrenergic-corticoid phase*, because it corresponds to the period during which changes induced by adrenergic and adrenal corticoid hormones are most striking. It is also likely that components of the micromediator systems exert significant influences during this phase. The detection of proinflammatory mediators or their surrogate markers (such as soluble receptors) usually is noted to peak during this period, and the maximum changes in substrate turnover are observed during this period (see Table 1-9). To variable degrees, rates of gluconeogenesis, acute phase protein production, and immune cell activity are all altered during the catabolic phase. The administration of moderate amounts of glucose to these individuals produces little or no change in the rate of protein catabolism, although evidence using isotopic determinations suggests that provision of sufficient nonprotein calories in combination with amino acids may reduce the rate of body protein breakdown (Table 1-10).

In the catabolic phase, glucose turnover is increased, while Cori cycle activity is stimulated and three-carbon intermediates are converted back to glucose in the liver by pyruvate carboxylase and phosphoenolpyruvate carboxylase. Increased synthesis of these two enzymes occurs in the presence of elevated levels of glucagon, glucocorticoids, and catecholamines and low concentration of insulin—the hormonal environment present during the catabolic phase of injury. Lipolysis also is stimulated by this hormonal milieu, and an obligatory oxidation of fatty acids is evident.

Efforts directed at interruption of afferent neurogenic stimuli by extradural anesthesia have met with partial success in attenuating some of these abnormalities of energy substrate turnover. The impact of such therapy on nitrogen loss has been far less dramatic, suggesting that circulating or tissue paracrine factors other than classical neuroendocrine hormones are of major importance in early postinjury metabolic responses. It has been widely speculated that one or more proinflammatory cytokine mediators are major determinants of increased rates of energy expenditure and substrate turnover after injury, but no clear evidence of this influence in human beings has been presented. Blockade of TNF and IL-1 activities during conditions of human endotoxemia does not prevent the characteristic increase in metabolic rate and glucose or protein turnover.

Early Anabolic Phase

Depending on the severity of injury, the body turns from a catabolic to an anabolic phase. This may occur within 3 to 8 days after uncomplicated elective surgery or after weeks in patients with extensive cross-sectional tissue injury, sepsis, or ungrafted thermal injury. This turning point, also known as the *corticoid-withdrawal phase*, is characterized by a sharp decline in nitrogen excretion and restoration of appropriate potassium- nitrogen balance. This phase is also biochemically characterized by a reprioritization of acute phase reactants, as early inflammatory response proteins are supplanted by tissue repair and anabolic factors, such as IGF- 1. Clinical manifestations of this transition period are brief and coincide with initial diuresis of retained water and renewed interest in oral nutrition.

The early anabolic phase may last from a few weeks to a few months depending on the capacity to ingest adequate nutrition and the extent to which erosion of protein stores has occurred. Nitrogen balance is positive, indicating synthesis of proteins, and there is a rapid and progressive gain in weight and muscular strength. Positive nitrogen balance reaches

a maximum of approximately 4 g/day, which represents the synthesis of approximately 25 g of protein and the gain of over 100 g of lean body mass/day. The total amount of nitrogen gain ultimately equals the amount lost during the catabolic phase, although the rate of gain will be much slower than the rate of initial loss.

Late Anabolic Phase

The final period of convalescence or the late anabolic phase may last from several weeks to several months after a severe injury. This phase is associated with the gradual restoration of adipose stores as the previously positive nitrogen balance declines toward normal. Weight gain is much slower during this phase because of the higher caloric content of fat and can be realized only if intake is in excess of caloric expenditure. In most individuals, the phase ends with a gradual return to the previously normal body weight. The patient who is partially immobilized during this period of time, however, may exhibit a marked gain in weight as a result of decreased energy expenditure.

Assessment and Requirements

Nutritional homeostasis assumes that proper timing and administration of nutrients has a favorable impact on the outcome of therapy. Nutritional assessment is undertaken to determine the severity of nutrient deficiencies or excesses and to aid in predicting nutritional requirements (Fig. 1-36). Important information is obtained by determining the presence of weight loss and of chronic illnesses or dietary habits influencing the quantity and quality of food intake. Social habits predisposing to malnutrition and the use of medications that may influence food intake or urination should be investigated. Physical examination seeks to assess loss of muscle and adipose tissues, organ dysfunction, and subtle change in skin, hair, or neuromuscular function reflecting an impending nutritional deficiency. Anthropometric data (weight change, skin fold thickness, and arm circumference muscle area) and biochemical determinations (levels of creatinine excretion, albumin, and transferrin) can be used to substantiate the patient's history and physical findings. It is imprecise to rely on any single or fixed combination of these findings to assess nutritional status or morbidity. Appreciation for the stresses and natural history of the disease process, in combination with nutritional assessment, is the basis for identifying patients in acute or anticipated need of nutritional support.

The caloric and nitrogen requirements necessary to maintain an individual in balance after severe injury depend on the extent of injury, the source and route of administered nutrients, and, to some extent, the degree of antecedent malnutrition. A fundamental goal of nutritional support is to meet the energy requirements for metabolic processes, core temperature maintenance, and tissue repair. Failure to provide adequate nonprotein energy sources leads to dissolution of lean tissue stores. The requirements for energy may be measured by indirect calorimetry or estimated from urinary nitrogen excretion, which is proportional to resting energy expenditure. Basal energy expenditure (BEE) also can be estimated by the equations of Harris and Benedict:

BEE (men)

$$= 66.47 + 13.75(W) + 5.0(H) - 6.76(A) \text{ kcal/day}$$

BEE (women)

$$= 655.1 + 9.56(W) + 1.85(H) - 4.68(A) \text{ kcal/day}$$

where W = weight, kg

H = height, cm

A = age, years

These equations are suitable for estimating energy requirements in at least 80 percent of hospitalized patients. Nonprotein calories are supplied in excess of energy expenditure because the use of exogenous nutrients is decreased and energy substrate demands are increased after traumatic or septic insult. Appropriate nonprotein caloric needs are 1.2 to 1.5 times resting energy expenditure (REE) during enteral nutrition and 1.5 to 2.0 times REE during intravenous nutrition. It is seldom, if ever, appropriate to exceed this level of nonprotein energy intake during the height of the catabolic phase. Some authorities have suggested that targeted underfeeding might be a more appropriate strategy in such patients.

The second objective of nutritional support is to meet the substrate requirements for protein synthesis. Maintenance of protein synthesis depends on many factors, including the nature and degree of the insult, the source and amount of exogenous protein, and previous nutritional status. Consequently, no single nutritional formulation is appropriate for all patients. An appropriate calorie-nitrogen ratio (150 to 200:1) should be maintained, but evidence suggests that increased protein intake (and a lower calorie-nitrogen ratio) may be efficient in selected hypermetabolic patients. In the absence of severe renal or hepatic dysfunction precluding the use of standard nutritional regimens, approximately 0.25 to 0.35 g of nitrogen/kg of body weight should be provided daily. Specialized nutritional formulations designed to improve nitrogen use in organ dysfunction such as acute renal and hepatic failure are targeted either to supplement deficiencies associated with the disease process or to correct characteristic amino acid abnormalities.

The requirements for vitamins and essential trace minerals can be easily met in the typical patient with an uncomplicated postoperative course. Vitamins usually are not given in the absence of preoperative deficiencies. Patients maintained on elemental diets or parenteral hyperalimentation require complete vitamin and mineral supplementation. The commercial defined-formula enteral diets contain varying amounts of essential minerals and vitamins (Table 1-11). It is necessary to ensure that adequate replacement is available in the diet or by supplementation. Numerous commercial vitamin preparations are available for intravenous or intramuscular use, although most do not contain vitamin K and some do not contain vitamin B₁₂ or folic acid. Supplemental trace minerals may be given intravenously. Essential fatty acid supplementation also may be necessary, especially in patients with depletion of adipose stores. Patients receiving intravenous feeding require all the above micronutrients to prevent the development of deficiencies.

Indications and Methods for Nutritional Support

The selection of patients who require partial or complete nutritional support has become increasingly important as constraints on hospitalization and resource management escalate. The ability to provide nutritional support to stressed patients and to attenuate nitrogen losses in catabolic states is an important adjunct to surgical care. The need for nutritional support should be assessed during the preoperative and postoperative courses of all but the most routine cases. Most surgical patients, however, do not require special nutritional regimens. The reasonably well-nourished and otherwise healthy individual who undergoes an uncomplicated major operative procedure has sufficient body fuel reserves to withstand the catabolic insult and partial starvation for at least 1 week. Adequate quantities of parenteral fluids with appropriate electrolyte composition and a minimum of 100 g glucose daily to minimize protein catabolism will be all that is necessary in most patients. Assuming that the patient has a relatively uncomplicated postoperative course and resumes normal oral intake at the end of this period, defined-formula diets or parenteral alimentation are unnecessary and inadvisable because of the associated risks. During the early anabolic phase, the patient needs an adequate caloric intake of proper composition to meet the energy needs of the body and to allow protein synthesis. A high calorie-to-nitrogen ratio (optimally approximately 150 kcal/g nitrogen) and an adequate supply of vitamins and minerals are necessary for maximum anabolism during this period. In contrast to this group, there are populations of surgical patients for whom an adequate nutritional regimen can be of critical importance for a successful outcome. These include some patients who are chronically debilitated preoperatively from their diseases or from malnutrition and patients who have suffered trauma, sepsis, or surgical complications and cannot maintain an adequate caloric intake. In many cases the need for nutritional therapy during the early catabolic phase is apparent. This most certainly includes patients for whom there is a high expectation of prolonged hospitalization and diminished capacity for voluntary nutrient intake, such as patients with extensive burns or those with other severe injuries and incipient or overt organ failure. Despite the intuitively obvious decision to initiate nutritional support in such populations, documentation of nutrition-specific benefits or improvements in outcome are generally lacking. Nevertheless, such highly stressed and at-risk patients should receive consideration of nutritional support early. The dilemma more commonly presented to the clinician is the identification of other patients in whom a reasonable expectation of benefit from nutritional intervention can be met. Prospective, randomized trials have significantly narrowed the populations in whom this expectation might be met. In general, the indications for preoperative nutritional support, at least in hospitalized patients, appear largely confined to patients with evidence of more severe erosion of lean body mass and adipose tissue stores. This does not preclude the possibility that nutritional support in the ambulatory setting or those with evidence of organ failure or immunosuppression might achieve benefit from specialized nutritional support before elective surgery.

Specialized nutritional support can be given enterally, or enterally with supplements via peripheral vein, or by central venous routes. The enteral route should always be used when possible because it is considered to be more economical and well tolerated in many patients, including those having undergone recent abdominal surgery. Nasopharyngeal, gastrostomy, and jejunostomy tube feedings may be considered for alimentation in patients who have a relatively normal gastrointestinal tract but cannot or will not eat. Elemental diets may be administered by similar routes when bulk and fat-free nutrients requiring minimal digestion are indicated. Parenteral alimentation may be used for supplementation in the patient with limited oral intake or, more commonly, for complete nutritional management in the absence of oral intake. Clinical studies demonstrate that parenteral feeding potentially enhances the magnitude of macroendocrine (stress hormones) and microendocrine (cytokine) mediator responses to an antigenic challenge (Fig. 1-37). While the mechanisms for amplification of counterregulatory hormone and proinflammatory mediator levels in parenterally fed subjects remain to be fully elucidated, a loss of intestinal barrier function permitting acute or chronic host exposure to luminal toxins has been proposed. In human beings, it has not been clearly determined whether parenteral nutrition significantly alters intestinal barrier function instead of intracellular and intercellular anatomy. The incidence of systemic immune compromise resulting from parenteral nutrition has proved difficult to document. While several studies suggest a higher incidence of infectious complications in parenterally fed subjects compared with an enterally fed cohort, this observation is largely confined to traumatically injured populations (Table 1-12).

Despite the failure to document clinical differences between the enteral and parenteral feeding routes for exogenous nutrients, the gastrointestinal tract serves a number of synthetic and immunologic functions that bear consideration in the design of nutritional support regimens. A number of approaches for preserving gastrointestinal mucosal integrity and gut mass, including luminal stimulation by digestible or nondigestible substrates, and infusion of critical intestinal fuel sources such as glutamine or short-chain fatty acids, are undergoing clinical trials. To date, these products have not been clearly documented to improve outcome in the majority of populations studied.

The patient's ability to tolerate and absorb enteral feedings is determined by the rate of infusion, the osmolality, and the chemical nature of the product. Enteral feedings often are begun at a rate of 30 to 50 mL/h and are increased by 10 to 25 mL/h per day until the optimal volume is delivered. After full volume is attained, the concentration of the solution is increased slowly to the desired strength. If esophageal or gastric feedings are given, residual gastric volume should be monitored to reduce the risk of a major aspiration episode. If abdominal cramping or diarrhea occurs, the rate of administration or the concentration of the solution should be decreased. All feeding tubes should be thoroughly irrigated clear of solutions if feedings are interrupted or medications are given by this route.

Enteral Feeding Nasoenteric Tube Feeding

The use of feeding tubes that traverse the gastroesophageal junction should normally be used only in alert patients. While some exceptions might transiently exist, prolonged use of such feeding tubes should be discouraged. The foremost contraindication for nasoesophageal or gastric tube feeding is unconsciousness or lack of protective laryngeal reflexes, which may result in life-threatening pulmonary complications from aspiration. Even with a tracheostomy, it is inadvisable to feed mentally obtunded patients via such route, since feedings often can be recovered from tracheostomy suction, indicating continued aspiration of gastric contents. Esophageal feedings are seldom permissible.

The nasojejunal tube may allow feeding beyond dysfunctional gastric stomas and high gastrointestinal fistulas. In such cases it may be possible to maintain nutrition without a jejunostomy tube until stomal dysfunction relents or the fistula heals. Such tubes may be positioned in the upper small intestine by positioning the patient in a manner that promotes passage of the mercury-weighted tube into the desired intestinal segment. If this technique is unsuccessful, placement may be accomplished with fluoroscopic guidance or by an experienced endoscopist. Proper position of the tube must be confirmed radiographically.

Whenever dietary preparations are administered into the gastrointestinal tract via tubes, it is advisable to use bedside infusion pumps to ensure a constant rate of delivery over each 24-h period. The use of such pumps decreases the incidence of gastrointestinal side effects induced by overly rapid delivery of hyperosmolar solutions, and it allows safer administration of larger daily volumes of nutrients, because gastric distention is minimized. Investigation is required for all abdominal complaints in such patients in view of reports of intussusception around feeding tubes placed more distally in the small intestine.

Gastrostomy Tube Feeding

The administration of blended food through a gastrostomy tube is a good method for feeding patients with a variety of chronic gastrointestinal lesions arising at or above the cardioesophageal junction. Gastrostomy tube feeding is contraindicated for mentally obtunded patients with inadequate laryngeal reflexes. This feeding method should be used only in alert patients or in patients with total obstruction of the distal esophagus.

Surgically constructed gastrostomies of the Stamm (serosa-lined, temporary) or the modified Glassman (mucosa-lined, permanent) type are an acceptable means of providing enteral feedings, although percutaneous endoscopic gastrostomies (PEGs) have proved to be safe and equally effective. The feeding mixture may be ordinarily prepared food converted by a blender into a semiliquid consistency. Hyperosmolality of the feeding formula is not generally a problem as long as the pylorus is intact.

Jejunostomy Tube Feeding

Jejunostomy tube feedings usually are required for patients in whom nasoesophageal or gastrostomy tube feedings are contraindicated. This includes comatose patients, patients with high gastrointestinal fistulas or obstructions, and patients in whom a nasojeunal feeding tube cannot be placed. The jejunostomy may be of the Roux-en-Y (permanent) or the Witzel (temporary) type. The latter is constructed by inserting a number 18 French rubber catheter into the proximal jejunum approximately 30 cm distal to the ligament of Treitz.

The wall of the jejunum is inverted over the tube for about 3 cm as it emerges from the bowel to create a serosa-lined tunnel that allows rapid sealing of the jejunal opening when the tube is removed. An alternative procedure is the placement of a smaller-bore polyethylene or Silastic catheter. The tube is brought out through a stab incision in the left upper quadrant of the abdomen. The jejunum is sutured to the anterior abdominal wall at the point of tube entry to seal it from the peritoneal cavity. It is acceptable to place jejunostomy tubes concomitantly with major or trauma-related abdominal operations if prolonged nutritional support is anticipated in such patients.

Under some circumstances, when the need for postoperative enteral feedings is evident or likely, the placement of a needle-catheter feeding tube may obviate the need for more extensive procedures. The ability to secure jejunal feeding tubes endoscopically makes this a reasonable alternative to surgically constructed jejunostomies. In a large series, Maurer and colleagues reported the feasibility, safety, and cost-effectiveness of fluoroscopically guided percutaneous insertion of jejunostomy tubes in a diverse population of patients who would otherwise have required intraoperative or endoscopic feeding-tube placement.

If the jejunostomy tube is inadvertently removed, blind attempts at reinsertion should not be attempted. If discovered within a few hours, the tube may be reinserted under fluoroscopic guidance to be certain that it is in the bowel before feedings are resumed. The patient is observed for signs of peritonitis for 12 to 18 h after feedings are restarted. If there is any doubt about the position of the tube, it should be replaced surgically.

Feedings are safely begun 12 to 18 h after jejunostomy construction, even though peristalsis is not audible. Jejunostomy tube feedings usually are initiated with one of the many commercially available defined-formula diets (see Table [1-11](#)). When provided by continuous infusion, such formulas usually are well tolerated, but all patients must be serially evaluated to assure efficacy.

With proper care, about 85 percent of jejunostomy patients tolerate their feedings. When diarrhea occurs it usually can be controlled by temporarily reducing the concentration and volume of formula. Failing this, feeding is halted for a day, then resumed from the beginning of the feeding regimen, progressing more slowly than before. In many cases symptoms are relieved if the rate and volume of infusion are reduced and cold formula avoided. Failing control of diarrhea by these means, or as an alternative method to opiates, the periodic administration of bulk-forming agents might be helpful.

If the patient with a jejunostomy has a proximal bowel or biliary fistula draining more than 300 mL daily for a prolonged period, the fistular drainage may be collected by sump suction, cooled in an ice basin at bedside, and promptly re-fed in small increments throughout the day. To avoid jejunal overloading, the fistular fluid is re-fed between formula feedings. Aspirated gastric juice should not be re-fed, because it may cause jejunal irritation and profuse diarrhea. If the fistular drainage is profuse, it usually is not possible to re-feed more than 2 L/day, and fluid and electrolyte losses must be replaced with appropriate intravenous supplements. Additional water may be given with the feedings or administered between the feedings as indicated. Occasionally an elemental diet is indicated when other jejunostomy formulas are not tolerated.

Defined-Formula Diets

Commercial production of nutritionally complete liquid diets, derived in purified form from natural foods or from foods prepared synthetically are widely used in acute and chronic nutritional support efforts. These diets may be used for complete nutritional support or as dietary supplements for patients who are unable to eat or digest enough food to meet their energy requirements. They may be preferable to high-calorie parenteral feedings for patients who have part of the small bowel available for the absorption of simple sugars and amino acids. Elemental diets have been found useful for patients with depleted protein reserves secondary to gastrointestinal tract disease, such as ulcerative or granulomatous colitis and malabsorption syndrome, and for patients with only partial function of the gastrointestinal tract, such as the short bowel syndrome or gastric or small-bowel fistulas with feeding distal to the fistula. These diets also have been used during preoperative bowel preparation.

The commercially prepared diets also contain baseline electrolytes, water, fat-soluble vitamins (except vitamin K in some cases), and trace minerals. They contain no bulk and therefore produce a minimum of residue. They do not contain lactose and are more readily tolerated in such lactase-deficiency states as gastroenteritis, intestinal resection, radiation, or genetic predisposition. There are several products whose protein content is partially hydrolyzed or completely hydrolyzed to amino acids or dipeptides. When digestion and absorption are normal, there appears to be little therapeutic advantage to the use of crystalline amino acid formulas. A listing of the basic constituents for several commercial preparations as well as the volume necessary to achieve minimal daily requirements is given in Table [1-11](#). The practitioner should consult product information to ascertain further details regarding the precise composition of a prescribed formula.

Special products designed for use in the presence of organ dysfunction also are available (see Table [1-11](#)). Fat may contribute less than 1 percent or as much as 47 percent of the calories in these commercial formulas. Most contain long-chain fats as corn oil, soy oil, or safflower oil. Some include medium-chain triglycerides. Because the high caloric density of fat does not increase the osmolality of the formula when significant maldigestion or malabsorption is present, a diet low in fat or one supplemented with medium-chain triglycerides may be useful. To prevent the development of essential fatty acid deficiency, the clinician must be mindful of the possible need for additional lipids when providing such specialized diets to patients.

Specific products are limited in their overall clinical usefulness by virtue of the fixed content of nutrients. There has been a trend toward preparing enteral diets in modular form whereby certain critical items, such as sodium, potassium, and fat, can be modified in concentration as needed.

The amount of elemental diet required to maintain weight and nitrogen balance varies with the individual patient. In severe catabolic states, the standard diet often fails to achieve positive nitrogen balance. Careful attention to water and electrolyte balance is mandatory, particularly when large quantities of fluid are being lost through fistulas or other routes. Additional sodium and potassium may be added to the mixture (not to exceed a total of 100 mEq), although they should be given in intravenous fluids when larger quantities are needed. Water may be added to the mixture in the face of excessive pure water losses.

Complications include nausea, vomiting, and diarrhea that develop because of the high osmolality of the diets. This generally can be controlled by decreasing the rate and/or concentration of the mixture. Hypertonic nonketotic coma may occur in the presence of excessive water losses or if the diets are administered at concentrations above those recommended. Hyperglycemia and glycosuria can occur in any severely ill patient, particularly latent diabetics, and insulin may be indicated.

A number of prospective trials have suggested that one or more enteral nutritional regimens may reduce complications and improve outcome. These formulations are promoted as enhancing various aspects of immune or solid organ function. There is no evidence to suggest that this is uniformly the case given that other prospective randomized trials failed to document any benefits.

Parenteral Alimentation

Parenteral alimentation involves the continuous infusion of a hyperosmolar solution containing carbohydrates, proteins, fat, and other necessary nutrients through an indwelling catheter inserted into the superior vena cava. In order to obtain the maximum benefit, the ratio of calories to nitrogen must be adequate (at least 100 to 150 kcal/g nitrogen) and the two materials must be infused simultaneously. When the sources of calories and nitrogen are given at different times, there is a significant decrease in nitrogen use. These nutrients can be given in quantities considerably greater than the basic caloric and nitrogen requirements, and this method has proved highly successful in achieving growth and development, positive nitrogen balance, and weight gain in a variety of clinical situations.

Indications for the Use of Intravenous Hyperalimentation

It is difficult to demonstrate that parenteral feeding significantly alters the clinical course or outcome in most nonsurgical patient populations. Clinical trials and metaanalysis of parenteral feeding in the perioperative period have, however, suggested that preoperative nutritional support may benefit some surgical patients, particularly those with extensive malnutrition. By contrast, definitive evidence of benefit accruing from use of nutritional support in the postoperative setting is lacking. The routine use of parenteral alimentation in the critical-care environment has yet to be adequately assessed, and so it is currently used intuitively. The evidence underlying the application of parenteral nutrition in situations of surgical relevance was reviewed before the formulation of clinical practice guidelines published by a recent Georgetown University panel. The principal indications for parenteral alimentation are found in seriously ill patients suffering from malnutrition, sepsis, or surgical or accidental trauma when use of the gastrointestinal tract for feedings is not possible. It has been used in many instances in which it is not needed or in which the use of the gastrointestinal tract is more appropriate. In some instances intravenous nutrition may be used to supplement inadequate oral intake. The safe and successful use of this regimen requires proper selection of patients with specific nutritional needs, experience with the technique, and an awareness of the associated complications. The fundamental goals are to provide sufficient calories and nitrogen substrate to promote tissue repair and to maintain the integrity or growth of lean tissue mass. Listed below are situations in which parenteral nutrition has been used in an effort to achieve these goals. Indications 1 and 2 below usually are exclusively used for intravenous nutrition. Indications 3 to 13 might be appropriate for enteral or parenteral nutrition.

(1) Newborn infants with catastrophic gastrointestinal anomalies, such as tracheoesophageal fistula, gastroschisis, omphalocele, or massive intestinal atresia.

(2) Infants who fail to thrive nonspecifically or secondarily to gastrointestinal insufficiency associated with the short bowel syndrome, malabsorption, enzyme deficiency, meconium ileus, or idiopathic diarrhea.

(3) Adult patients with short bowel syndrome secondary to massive small-bowel resection or enteroenteric, enterocolic, enterovesical, or enterocutaneous fistulas.

(4) Patients with high alimentary tract obstructions without vascular compromise, secondary to achalasia, stricture, or neoplasia of the esophagus, gastric carcinoma, or pyloric obstruction.

(5) Surgical patients with prolonged paralytic ileus after major operations, multiple injuries, or blunt or open abdominal trauma, or patients with reflex ileus complicating various medical diseases.

(6) Patients with normal bowel length but with malabsorption secondary to sprue, hypoproteinemia, enzyme or pancreatic insufficiency, regional enteritis, or ulcerative colitis.

(7) Adult patients with functional gastrointestinal disorders such as esophageal dyskinesia after cerebrovascular accident, idiopathic diarrhea, psychogenic vomiting, or anorexia nervosa.

(8) Patients who cannot ingest food or who regurgitate and aspirate oral or tube feedings because of depressed or obtunded sensorium after severe metabolic derangements,

neurologic disorders, intracranial surgery, or central nervous system trauma.

- (9) Patients with excessive metabolic requirements secondary to severe trauma, such as extensive full-thickness burns, major fractures, or soft- tissue injuries.
- (10) Patients with granulomatous colitis, ulcerative colitis, and tuberculous enteritis, in which major portions of the absorptive mucosa are diseased.
- (11) Paraplegics, quadriplegics, or debilitated patients with indolent decubitus ulcers in the pelvic areas, particularly when soilage and fecal contamination are a problem.
- (12) Patients with malignancy, with or without cachexia, in whom malnutrition might jeopardize successful delivery of a therapeutic option.
- (13) Patients with potentially reversible acute renal failure, in whom marked catabolism results in the liberation of intracellular anions and cations, inducing hyperkalemia, hypermagnesemia, and hyperphosphatemia.

Contraindications to hyperalimentation include the following:

- (1) Lack of a specific goal for patient management, or when instead of extending a meaningful life, inevitable dying is prolonged.
- (2) Periods of cardiovascular instability or severe metabolic derangement requiring control or correction before attempting hypertonic intravenous feeding.
- (3) Feasible gastrointestinal tract feeding; in the vast majority of instances, this is the best route by which to provide nutrition.
- (4) Patients in good nutritional status, in whom only short-term parenteral nutrition support is required or anticipated.
- (5) Infants with less than 8 cm of small bowel, since virtually all have been unable to adapt sufficiently despite prolonged periods of parenteral nutrition.
- (6) Patients who are irreversibly decerebrate or otherwise dehumanized.

Insertion of Central Venous Infusion Catheter

The successful use of intravenous hyperalimentation generally depends on the proper placement and management of the central venous feeding catheter. A 16-gauge, 8- or 12-inch radiopaque catheter is introduced percutaneously through the subclavian or internal jugular vein and threaded into the superior vena cava. Although the technique for subclavian vein puncture (Fig. 1-38) has been the preferable and more widely used technique, the internal jugular approach also may be useful (Fig. 1-39). For insertion of the intravenous catheter through the subclavian vein, the patient is placed supine in a 15-degree head-down position with a small pad placed between the shoulder blades to allow the shoulders to drop posteriorly. This allows expansion of the subclavian vein and easier penetration. The skin may be scrubbed with acetone to defat the surface and then with an iodophor compound. Drapes are carefully placed, and *scrupulous* aseptic precautions are observed. Local anesthetic is infiltrated into the skin, forming a wheal, as well as into the subcutaneous tissue and periosteum at the inferior border of the midpoint of the clavicle. Most commercially prepared kits for central venous catheter insertion are equipped with a 2- to 2½-inch long, 16-gauge needle. This needle attaches to a 5 to 10 mL syringe and is inserted, beveled down through the wheal, and advanced toward the tip of the operator's finger, which is pressed well into the patient's suprasternal notch. The needle should hug the inferior clavicular surface and go over the first rib into the subclavian vein. With slight negative pressure applied to the syringe, entrance into the vein will be noted by the appearance of blood. The needle is advanced a few millimeters further to be sure that it is entirely within the lumen of the vein. The thumb is held over the needle hub as the syringe is removed to avoid air embolism. A flexible guide-wire is then introduced into the vein through the bore of the needle, leaving at least half the length of the guide-wire visible above the skin to prevent losing the wire in the vein or inducing arrhythmias. With control of the guide-wire, the needle is then withdrawn and removed over the guide-wire. The puncture site can be slightly extended with a number 11 blade, and a dilator forms a tract in the soft tissue by being passed in and out over the guide-wire. A 16-gauge, 8- or 12-inch radiopaque catheter is then introduced over the guide-wire until the catheter tip reaches the superior vena cava. The guide-wire is then withdrawn and venous blood return is ascertained by syringe aspiration. The catheter hub is then connected to a sterile intravenous administration tubing, and a slow infusion is begun while the catheter is sewn to the skin with a small suture. Antibiotic ointment is routinely applied around the entrance of the catheter into the skin, and an occlusive dressing is applied over it, including the junction of the intravenous tubing with the catheter. A chest film is immediately obtained to confirm the position of the radiopaque catheter in the vena cava and to check for a possible pneumothorax. Every 2 or 3 days, the intravenous tubing is changed at the catheter entry site over a guide-wire. The catheter site is scrubbed as for an operative procedure, and antibiotic ointment and a new occlusive dressing are applied. Withdrawal or administration of blood through the catheter or the use of the catheter for central venous pressure measurements should be avoided, since the risk of contamination and catheter occlusion are significantly increased. The use of the internal jugular approach is satisfactory but more prone to developing local or systemic infection. It is unwise, unless absolutely necessary, to place catheters into the inferior vena cava from the lower extremities because of the greater likelihood of sepsis and thromboembolic phenomena. Long catheters inserted through the antecubital cephalic or basilic veins may be advanced into the superior vena cava. Initial experience with polyvinyl chloride catheters was disappointing because of a high incidence of thrombophlebitis. The use of polyurethane catheters has decreased the incidence of such complications. Other vascular access methods may be achieved by surgical cutdowns and passing the catheters through the subcutaneous tissue of the anterior chest wall or the neck (Fig. 1-40).

Preparation and Administration of Solutions

The basic solution contains a final concentration of 20 to 25% dextrose and 3 to 5% crystalline amino acids. The solutions are usually prepared sterily in the pharmacy from commercially available kits containing the component solutions and transfer apparatus. Preparation in the pharmacy under laminar flow reduces the incidence of bacterial contamination of the solution. Proper preparation with suitable quality control is essential to avoid septic complications. Because of the considerable variability in amino acid and electrolyte concentrations among commercially available alimentation formulations, physicians must become familiar with the solutions used in their institutions. Only in this manner may additives, in the form of additional electrolytes, be rationally planned to meet the specific metabolic needs of the patient. Electrolyte requirements may vary considerably from patient to patient, depending on routes of fluid and electrolyte loss, renal function, metabolic rate, cardiac function, and underlying disease state. Intravenous vitamin preparations also should be added to parenteral formulations. Vitamin deficiencies are rare occurrences if such preparations are used. In addition, phytonadione (vitamin K₁) 10 mg and folic acid 5 mg should be administered intramuscularly once a week, since these are unstable in the hyperalimentation solution. Cyanocobalamin (vitamin B₁₂) 1 mg is given by intramuscular injection once a month. Intramuscular administration of iron may be required for patients with iron deficiency anemia, although adequate mobilization of iron stores may occur once the patient is anabolic. During prolonged fat-free parenteral nutrition essential fatty acid deficiency may become apparent, manifested by a dry, scaly dermatitis and loss of hair. The syndrome may be prevented by periodic infusion of a fat emulsion at a rate equivalent to 10 to 15 percent of total calories (Table 1-13). Essential trace minerals may be required after prolonged total parenteral nutrition and can be supplied by direct addition of commercial preparations of dextrose amino acids solutions. The most frequent presentation of trace mineral deficiencies is the eczematoid rash that develops diffusely and at intertriginous areas in zinc-deficient patients. Other rare trace mineral deficiencies include a microcytic anemia associated with copper deficiency and glucose intolerance presumably related to chromium deficiency. These complications are seldom seen except in patients receiving parenteral nutrition for extended periods. The daily administration of commercially available trace mineral supplements obviates most such problems. Depending on fluid and nitrogen tolerance, parenteral nutrition solutions usually can be increased over 2 to 3 days to achieve the desired infusion rate. Insulin may be supplemented as necessary to ensure glucose tolerance. Wolf and Elwyn demonstrated that maximum efficiency of glucose use occurs at an infusion rate of 7 mg/kg body weight per min. Dextrose infusions above this level result in increased fat synthesis and provide no additional suppression of amino acid gluconeogenesis. Rarely, additional intravenous fluids and electrolytes might be necessary with continued abnormal large losses of fluids. The patient should be carefully monitored for development of electrolyte, volume, acid-base, and septic complications. Vital signs and urinary output are regularly observed, and the patient should be weighed daily. Frequent adjustments of the volume and composition of the solutions are necessary during the course of therapy. Electrolyte determinations are made daily until stable and every 2 or 3 days thereafter, and the hemogram, liver function chemistries, and levels of blood urea nitrogen, phosphate, and magnesium are determined weekly. The urine or capillary blood glucose level is checked every 6 h and serum glucose concentration checked at least once daily during the first few days of the infusion and at frequent intervals thereafter. Relative glucose intolerance may occur after initiation of parenteral alimentation. Insulin may be supplemented as necessary to improve carbohydrate tolerance. The response of blood glucose to exogenous insulin is evaluated by frequent capillary blood determinations, rather than reliance on glycosuria. If the blood glucose levels remain elevated or glycosuria persists, the dextrose concentration may be decreased, the infusion rate slowed, or regular insulin added to each bottle. The rise in blood glucose concentration observed after initiating an intravenous alimentation program may be temporary, as the normal pancreas increases its output of insulin in response to the continuous carbohydrate infusion. In patients with diabetes mellitus, additional crystalline or human insulin may be required. The administration of adequate amounts of potassium is essential to achieve positive nitrogen balance and to replace depleted intracellular stores. In addition, a significant shift of potassium ion from the extracellular to the intracellular space can take place because of the large glucose infusion, with resultant hypokalemia, metabolic alkalosis, and poor glucose utilization. In some cases as much as 240 mEq of potassium ion daily may be required. Hypokalemia may cause glycosuria, which would be treated with potassium, not insulin. Before giving insulin, the serum potassium level must be checked to avoid compounding the hypokalemia. Patients with insulin-dependent diabetes mellitus may exhibit wide fluctuations in blood glucose levels during parenteral nutrition. Partial replacement of lipid emulsions for dextrose calories may alleviate these problems in selected patients.

Fat Emulsions

Lipid emulsions derived from soybean or safflower oils are widely used as an adjunctive nutrient to prevent the development of essential fatty acid deficiency. They have been used as a major energy source in parenteral alimentation, but there is no evidence of enhanced metabolic efficacy if greater than 10 to 15 percent of calories is provided as lipid emulsions. Fat emulsion, dextrose, and amino acid combinations are as effective as carbohydrate and amino acid solutions in the repletion of nonstressed patients. The efficiency of fat as a caloric source in the traumatized, hypermetabolic patient is not well documented. There is a theoretic advantage to the use of lipid emulsions in some septic and trauma patients when nonsuppressible fat oxidation and increased norepinephrine excretion accompany glucose infusion. Patients with abnormal fat transport or metabolism, lipid nephrosis, coagulopathy, or serious pulmonary disease should not receive fat emulsions. Most investigators advise limitation of administered fat emulsions to between 2.0 and 2.5 g/kg of body weight per day.

Special Formulations

Numerous studies have documented the safety of parenteral alimentation in patients with renal failure. In these patients special formulations of essential amino acids may be indicated. Selection of the appropriate calorie and nitrogen concentration must be judged by fluid tolerance, associated illnesses, and the frequency of dialysis. Appropriate use of

dialysis is additive to nutritional support in improving survival of these patients. Solutions for patients with acute, oliguric renal failure contain a final dextrose concentration of 40 to 45 percent and only essential l-amino acids. In patients with nonoliguric renal failure, it may be possible to use essential and nonessential amino acids to promote protein synthesis. Solutions designed for patients with hepatic failure contain increased levels of branched-chain amino acids and decreased concentrations of aromatic amino acids. Such solutions improve encephalopathy but may not improve survival, which is dictated by the underlying hepatic pathology. Patients with moderate hepatic reserve and alcoholic hepatitis also may be treated with standard parenteral formulas to control encephalopathy and ascites. Cachexia related to severe cardiac disease may be judiciously treated with highly concentrated dextrose and amino acid formulas that are low in sodium content. Given the rather modest benefits demonstrable with nutritional support during the catabolic phase, there has been much recent investigation into possible adjunctive therapies. Efforts to enhance anabolism via growth factor (growth hormone, IGF-1) or anabolic steroid administration generally do not appear to be of additional benefit under full-calorie feeding conditions. Some benefit might be achieved in patients who exhibit more chronic disease conditions in which weaning from nutritional support might be indicated.

Complications

Problems may arise in the placement and maintenance of venous access or in the formulation and delivery of parenteral solutions. One of the more common and serious complications associated with long-term parenteral feeding is sepsis secondary to contamination of the central venous catheter. Contamination of solutions should be considered but is rare when proper pharmacy protocols have been followed. This problem occurs more frequently in patients with systemic sepsis and in many cases is a consequence of hematogenous seeding of the catheter with bacteria. Usually it is a result of failure to observe strict aseptic precautions during preparation and administration of the solutions. One of the earliest signs of systemic sepsis may be the sudden development of glucose intolerance (with or without temperature increase) in a patient who previously has been maintained on parenteral alimentation without difficulty. When this occurs or if fever develops without obvious cause, a diligent search for a potential septic focus is indicated. Other causes of fever also should be investigated. If fever persists, the infusion catheter should be removed and cultured. Some centers are now replacing catheters considered at low risk for infection over a J-wire. Should evidence of infection persist over 24 to 48 h without a definable source, the catheter should be replaced in the opposite subclavian vein or into one of the internal jugular veins and the infusion restarted. It may be advisable to wait a short period before reinserting the catheter, especially if bacteremia or hemodynamic instability are present.

Other complications related to catheter placement include the development of pneumothorax, hemothorax, or hydrothorax; subclavian artery injury; cardiac arrhythmia if the catheter is placed into the atrium or the ventricle; air embolism or catheter embolism; and, rarely, cardiac perforation with tamponade. Clinically evident thrombophlebitis or thrombosis of the superior vena cava has been rare, but radiographically proved thrombophlebitis has been noted in up to 25 percent of selected patients.

Although the use of multiple-lumen catheters for infusion therapy and monitoring critically ill patients is occasionally indicated, the risks (particularly of sepsis and of venous thrombosis) attending the prolonged use of such catheters may be increased. Efforts should be directed toward replacing these catheters with standard single-lumen intravenous feeding catheters as early as possible. The acute nutritional management of surgical patients seldom requires the use of permanently implanted catheters (see Fig. 1-38). Use of these catheters should be restricted to nonseptic or high-risk patients requiring prolonged periods of nutritional or fluid therapy or for selected patients requiring frequent blood sampling.

Hyperosmolar nonketotic hyperglycemia may develop with normal rates of infusion in patients with impaired glucose tolerance or in any patient if the hypertonic solutions are administered too rapidly. This is a particularly common complication in latent diabetics and in patients who have had severe surgical stress or trauma. Treatment of the condition consists of volume replacement with correction of electrolyte abnormalities and the administration of insulin. This serious complication can be avoided with careful attention to daily fluid balance and frequent determinations of urine and blood glucose levels and serum electrolyte levels.

A number of volume, concentration, and compositional abnormalities also may develop, but these are largely avoided by careful attention to the details of patient management. This is particularly important for elderly patients and for patients with significant cardiovascular, renal, or hepatic disorders. It is important not to “overfeed” the parenterally nourished patient. This is particularly true of the depleted patient in whom excess calorie infusion may result in carbon dioxide retention and respiratory insufficiency. Excess feeding also has been related to the development of hepatic steatosis or marked glycogen deposition in certain patients. Mild abnormalities of serum transaminase, alkaline phosphatase, and bilirubin levels may occur in many parenterally nourished patients. Failure of the tests to plateau or return toward normal over 7 to 14 days should suggest another cause.

Home Parenteral Nutrition

Patients who do not require a hospital environment for management of their primary disease, yet cannot tolerate adequate enteral or oral feeding, may be candidates for home parenteral nutrition. As opposed to the temporary methods of vascular access, Silastic catheters have proved to be durable portals for long-term parenteral nutrition (see Fig. 1-40). Alternatives to this technique include the placement of subcutaneous infusion ports. An absolute catheter-related infection rate of 0.3 per year per patient is still encountered. While home parenteral nutrition is more cost-effective than similar inpatient methods, criteria for selection of patients must be more stringent than those listed above for hospitalized patients. Patients with terminal illnesses, lack of self-care ability, or lack of a supportive home environment are candidates for this method. Inflammatory bowel disease, motility disorders, and ischemic bowel infarction are also indications.

A period of inpatient training is necessary to acquaint the patient and family with appropriate methods of solution preparation and delivery. This is best done in a multidisciplinary setting in which professionals are thoroughly familiar with the acute and chronic complications of home parenteral nutrition. There is interest in new technologies that might promote the transition of parenteral nutrition–dependent patients to partial or complete enteral nutrition. Such methods have demonstrated some promise in initial trials but will most likely prove inadequate for most parenteral nutrition–dependent patients.

CHAPTER 2 - Fluid and Electrolyte Management of the Surgical Patient

G. Tom Shires III
Annabel Barber
G. Tom Shires

ANATOMY OF BODY FLUIDS

One of the most critical aspects of patient care is management of the composition of body fluids and electrolytes. Most diseases, many injuries, and even operative trauma have a great impact on the physiology of fluids and electrolytes in the body. These changes often exceed those brought about by acute lack of alimentation. A thorough understanding of the metabolism of salt, water, and electrolytes and of certain metabolic responses is essential to the care of surgical patients.

In the sections that follow, the anatomy of body fluids and the physiologic principles that maintain normal fluid and electrolytes are defined, and a classification of derangements is outlined to allow an organized therapeutic approach.

A prerequisite to the understanding of fluid and electrolyte management is knowledge of the extent and composition of the various body fluid compartments. Early attempts to define these compartments were relatively accurate, but a more precise definition has been obtained by many investigators through the use of isotope tracer techniques. The wide range of normal values is a function of body size, weight, and sex, but these compartments are relatively constant in the individual patient in the normal steady state. The figures used in this section are approximate and presented as a percentage of body weight.

Total Body Water

Water constitutes 50 to 70 percent of total body weight. Using deuterium oxide or tritiated water for measurement of total body water, the average normal value is 60 percent of body weight for young adult males and 50 percent for young adult females. A normal variation of ± 15 percent applies to both groups. The actual figure for each healthy individual is remarkably constant and is a function of several variables, including age and lean body mass. Because fat contains little water, the lean individual has a greater proportion of water to total body weight than the obese person. The lower percentage of total body water in females correlates well with a relatively large amount of subcutaneous adipose tissue and small muscle mass. Moore and associates demonstrated that total body water as a percentage of total body weight decreases steadily and significantly with age to a low of 52 and 47 percent in males and females, respectively. Conversely, the highest proportion of total body water to body weight is found in newborns, with a maximum of 75 to 80 percent. During the first several months after birth, there is a gradual "physiologic" loss of body water as infants adjust to their environment. At 1 year of age, the total body water averages approximately 65 percent of the body weight and remains relatively constant throughout the remainder of infancy and childhood.

The water of the body is divided into three functional compartments (Fig. 2-1). The fluid within the body's diverse cell population represents 30 to 40 percent of the body weight. The extracellular water represents 20 percent of the body weight and is divided between the intravascular fluid, or plasma (5 percent of body weight), and the interstitial, or extravascular, extracellular fluid (15 percent of body weight).

Intracellular Fluid

Measurement of intracellular fluid is determined indirectly by subtraction of the measured extracellular fluid from the measured total body water. The intracellular water is 30 to 40 percent of the body weight, with the largest proportion in the skeletal muscle mass. Because of the smaller muscle mass in females, the percentage of intracellular water is lower than in males.

The chemical composition of the intracellular fluid is shown in Fig. 2-2; potassium and magnesium are the principal cations, and phosphates and proteins the principal anions. This is an approximation, because few data concerning the intracellular fluid are available.

Extracellular Fluid

The total extracellular fluid volume represents approximately 20 percent of the body weight. The extracellular fluid compartment has two major subdivisions. The plasma volume comprises approximately 5 percent of the body weight in the normal adult. The interstitial, or extravascular, extracellular fluid volume comprises approximately 15 percent of the body weight.

The interstitial fluid is further complicated by having a rapidly equilibrating functional component as well as several more slowly equilibrating nonfunctioning components. The nonfunctioning components include connective tissue water and water that has been termed transcellular, which includes cerebrospinal and joint fluids. This nonfunctional component normally represents only 10 percent of the interstitial fluid volume (1 to 2 percent of body weight) and should not be confused with the relatively nonfunctional extracellular fluid, often called a "third space," found in burns and soft-tissue injuries.

The normal constituents of the extracellular fluid are shown in Fig. 2-2; sodium is the principal cation, and chloride and bicarbonate the principal anions. Plasma and interstitial fluid differ slightly in ionic composition. Because plasma has a higher protein content (organic anions), its total concentration of cations is higher and its concentration of inorganic anions somewhat lower than those of interstitial fluid, as explained by the Gibbs-Donnan equilibrium equation (i.e., the product of the concentrations of any pair of diffusible cations and anions on one side of a semipermeable membrane is equal to the product of the same pair of ions on the other side). For practical considerations, however, they may be considered equal. The total concentration of intracellular ions exceeds that of the extracellular compartment and seems to violate the concept of osmolar equilibrium between the two compartments. This apparent discrepancy is due to the fact that the concentration of ions is expressed in milliequivalents (mEq), without regard to osmotic activity. In addition, some of the intracellular cations probably exist in undissociated form.

Osmotic Pressure

The physiologic and chemical activity of electrolytes depend on three factors: (1) the number of particles present per unit volume (moles or millimoles [mmol] per liter); (2) the number of electric charges per unit volume (equivalents or milliequivalents per liter); and (3) the number of osmotically active particles or ions per unit volume (osmoles or milliosmoles [mOsm] per liter). Measurements in grams or milligrams per 100 milliliters express the weight of the electrolytes per unit volume but do not allow a physiologic comparison of the solutes in a solution.

A mole of a substance is the molecular weight of that substance in grams, and a millimole is that figure expressed in milligrams. For example, a mole of sodium chloride is 58 g (Na-23, Cl-35), and a millimole is 58 mg. The expression, however, gives no direct information about the number of osmotically active ions in solution or the electric charges that they carry.

The electrolytes of the body fluids can be expressed in terms of chemical combining activity, or "equivalents." An equivalent of an ion is its atomic weight expressed in grams divided by the valence, and 1 mEq of an ion is that figure expressed in milligrams. In the case of univalent ions, 1 mEq is the same as a millimole. In the case of divalent ions, such as calcium or magnesium, 1 mmol equals 2 mEq. The importance of this expression is that 1 mEq of any substance will combine chemically with 1 mEq of any other substance; in any given solution, the number of milliequivalents of cations present is balanced by precisely the same number of milliequivalents of anions.

When the osmotic pressure of a solution is considered, it is more descriptive to use the units osmole and milliosmole. These units refer to the actual number of osmotically active particles present in solution but are not dependent on the chemical combining capacities of the substances. Thus a millimole of sodium chloride, which dissociates nearly completely into sodium and chloride, contributes 2 mOsm, and 1 mmol of sodium sulfate (Na_2SO_4), which dissociates into three particles, contributes 3 mOsm. One millimole of non-ionized substance, such as glucose, is equal to 1 mOsm of the substance.

The differences in ionic composition between intracellular and extracellular fluid are maintained by the semipermeable cell membrane. The total number of osmotically active particles is 290 to 310 mOsm in each compartment. Although the total osmotic pressure of a fluid is the sum of the partial pressures contributed by each of the solutes in that fluid, the effective osmotic pressure is dependent on those substances that fail to pass through the pores of the semipermeable membrane. The dissolved proteins in the plasma, therefore, are primarily responsible for effective osmotic pressure between the plasma and the interstitial fluid compartments. This is frequently referred to as the colloid oncotic pressure. The effective osmotic pressure between the extracellular and intracellular fluid compartments would be contributed to by any substance that does not traverse the cell membranes freely. While sodium, as the principal cation of the extracellular fluid, contributes a major portion of the osmotic pressure, other substances that fail to penetrate the cell membrane freely, such as glucose, also increase the effective osmotic pressure.

Because the cell membranes are completely permeable to water, the effective osmotic pressures in the two compartments are considered to be equal. Any condition that alters the effective osmotic pressure in either compartment results in redistribution of water between the compartments. Thus an increase in effective osmotic pressure in the extracellular fluid, which would occur typically as a result of increased sodium concentration, would cause a net transfer of water from the intracellular to the extracellular fluid compartment. This transfer of water would continue until the effective osmotic pressures in the two compartments were equal. Conversely, a decrease in the sodium concentration in the extracellular fluid will cause a transfer of water from the extracellular to the intracellular fluid compartment. Depletion of the extracellular fluid volume without a change in the concentration of ions will not result in transfer of free water from the intracellular space.

The intracellular fluid shares in losses that involve a change in concentration or composition of the extracellular fluid, but shares only slowly in changes involving loss of isotonic volume alone. For practical considerations, most losses and gains of body fluid are directly from the extracellular compartment.

NORMAL EXCHANGE OF FLUID AND ELECTROLYTES

Knowledge of the basic principles governing the internal and external exchanges of water and salt is mandatory for care of the patient undergoing major operative surgery. The stable internal fluid environment, which is maintained by the kidneys, brain, lungs, skin, and gastrointestinal tract, may be compromised by surgical stress or by direct damage to any of these organs.

Water Exchange

The normal individual consumes an average of 2000 to 2500 mL water per day; approximately 1500 mL water is taken by mouth, and the rest is extracted from solid food, either from the contents of the food or as the product of oxidation (Table 2-1). The daily water losses include 250 mL in stools, 800 to 1500 mL in urine, and approximately 600 mL as insensible loss. A patient deprived of all external access to water must still excrete a minimum of 500 to 800 mL urine per day in order to excrete the products of catabolism, in

addition to the mandatory insensible loss through the skin and lungs.

Insensible loss of water occurs through the skin (75 percent) and the lungs (25 percent) and is increased by hypermetabolism, hyperventilation, and fever. The insensible water loss through the skin is not from evaporation of water from sweat glands but from water vapor formed within the body and lost through the skin. With excessive heat production (or excessive environmental heat), the capacity for insensible loss through the skin is exceeded and sweating occurs. These losses may, but seldom do, exceed 250 mL/day per degree of fever. An unhumidified tracheostomy with hyperventilation increases the loss through the lungs and results in a total insensible loss up to 1.5 L/day.

A frequently overlooked source of gain is the water of solution, which is the water that holds carbohydrates and proteins in solution in the cell. Normally, gain of water from this source is zero, but after 4 to 5 days without food intake, the postoperative patient may begin to gain significant quantities of water (up to 500 mL/day) from excessive cellular catabolism.

Salt Gain and Losses

In the normal individual, daily salt intake varies from 50 to 90 mEq (3 to 5 g) as sodium chloride (Table 2-2). Balance is maintained primarily by the kidneys, which excrete the excess salt. Under conditions of reduced intake or extrarenal losses, the normal kidney can reduce sodium excretion to less than 1 mEq/day within 24 h after restriction. In the patient with salt- wasting kidneys, however, the loss may exceed 200 mEq/L of urine. Sweat represents a hypotonic loss of fluids with an average sodium concentration of 15 mEq/L in the acclimatized person. In the unacclimatized person, the sodium concentration in sweat may be 60 mEq/L or more. Insensible fluid lost from the skin and lungs, by definition, is pure water. For practical considerations, normal losses may be relatively free of salt in the healthy individual with normal renal function.

The volume and composition of various types of gastrointestinal secretions are shown in Table 2-3. Gastrointestinal losses usually are isotonic or slightly hypotonic, although there is considerable variation in the composition. These should be replaced by an essentially isotonic salt solution. It is also important to reiterate that distributional or sequestration losses of extracellular fluid at any point in the operative or postoperative course also represent isotonic losses of salt and water.

CLASSIFICATION OF BODY FLUID CHANGES

The disorders in fluid balance may be classified in three general categories: disturbances of (1) volume, (2) concentration, and (3) composition. Of primary importance is the concept that although these disturbances are interrelated, each is a separate entity.

If an isotonic salt solution is added to or lost from the body fluids, only the volume of the extracellular fluid is changed. The acute loss of an isotonic extracellular solution, such as intestinal juice, is followed by a significant decrease in the extracellular fluid volume and little, if any, change in the intracellular fluid volume. Fluid will not be transferred from the intracellular space to refill the depleted extracellular space as long as the osmolarity remains the same in the two compartments.

If water alone is added to or lost from the extracellular fluid, the concentration of osmotically active particles changes. Sodium ions account for 90 percent of the osmotically active particles in the extracellular fluid and generally reflect the tonicity of body fluid compartments. If the extracellular fluid is depleted of sodium, water will pass into the intracellular space until osmolarity is again equal in the two compartments.

The concentration of most other ions within the extracellular fluid compartment can be altered without significant change in the total number of osmotically active particles, thus producing only a compositional change. For instance, a rise of the serum potassium concentration from 4 to 8 mEq/L would have a significant effect on the myocardium, but it would not significantly change the effective osmotic pressure of the extracellular fluid compartment. Normally functioning kidneys minimize these changes considerably, particularly if the addition or loss of solute or water is gradual. An internal loss of extracellular fluid into a nonfunctional space, such as the sequestration of isotonic fluid in a burn, peritonitis, ascites, or muscle trauma, is termed a distributional change. This transfer or functional loss of extracellular fluid internally may be extracellular (e.g., peritonitis), or intracellular (e.g., hemorrhagic shock), or both (e.g., major burns). In any event, all distributional shifts or losses result in a contraction of the functional extracellular fluid space.

Volume Changes

Volume deficit or excess usually is diagnosed by clinical examination of the patient. There are no readily available, useful laboratory tests in the acute phase except measurement of the plasma volume. Direct measurement of the extracellular fluid volume using radioisotopic tracers is feasible only in a research setting. There are several laboratory tests, however, that indirectly reflect changes in extracellular fluid volume. The blood urea nitrogen (BUN) level rises with an extracellular fluid deficit of sufficient magnitude to reduce glomerular filtration. The serum creatinine level may not increase proportionally in young people with healthy kidneys, and this discrepancy often is used as one test to differentiate prerenal and renal azotemia. The concentration of formed elements in the blood, such as the hematocrit, increases with an extracellular fluid deficit and decreases with an extracellular fluid excess. The concentration of serum sodium is not related to the volume status of extracellular fluid; a severe volume deficit may exist with a normal, low, or high serum level.

Volume Deficit

Extracellular fluid volume deficit is the most common fluid disorder in the surgical patient. The lost fluid is not water alone, but water and electrolytes in approximately the same proportion as they exist in normal extracellular fluid. The most common causes of extracellular fluid volume deficit are losses of gastrointestinal fluids from vomiting, nasogastric suction, diarrhea, and fistular drainage. Other common causes include sequestration of fluid in soft-tissue injuries and infections, intraabdominal and retroperitoneal inflammatory processes, peritonitis, intestinal obstruction, and burns. The signs and symptoms of volume deficit are easily recognized and are listed in Table 2-4. The central nervous system and cardiovascular signs occur early with acute rapid losses, but tissue signs may be absent until the deficit has existed for at least 24 h. The central nervous system signs are similar to barbiturate intoxication and may be missed if the volume deficit is mild. The cardiovascular signs are secondary to a decrease in plasma volume and may be associated with varying degrees of hypotension in the patient with a severe extracellular fluid volume deficit. Skin turgor may be difficult to assess in the elderly patient or in the patient with recent weight loss and is not diagnostic in the absence of other confirmatory signs. The body temperature tends to vary with the environmental temperature. In a cool room, the patient may be slightly hypothermic and the febrile response to illness may be suppressed. This occurs frequently and can be very misleading during clinical evaluation of the septic patient. After partial correction of the volume deficit, the temperature generally will rise to the appropriate level. Severe volume depletion depresses all body systems and interferes with the clinical evaluation of a patient. For example, a volume-depleted patient with severe sepsis from peritonitis may have a normal temperature and white blood cell count, complain of little pain, and have unremarkable findings on abdominal examination. The clinical picture may change dramatically, however, when the extracellular fluid volume is restored.

Volume Excess

Extracellular fluid volume excess may be generally iatrogenic or secondary to renal insufficiency, cirrhosis, or congestive heart failure. Plasma and interstitial fluid volumes are increased. In the healthy young adult the signs are generally those of circulatory overload, manifested primarily in the pulmonary circulation, and of excessive fluid in other tissue (see Table 2-4). In the elderly patient, congestive heart failure with pulmonary edema may develop quickly with a moderate volume excess.

Concentration Changes

Sodium is primarily responsible for the osmolarity of the extracellular fluid space: determination of the serum concentration of sodium generally indicates the tonicity of body fluids. Hyponatremia and hypernatremia can be diagnosed on clinical grounds (Table 2-5), but signs and symptoms generally are not present until the changes are severe. Clinical signs of hyponatremia or hypernatremia occur early and with greater severity when the rate of change in extracellular sodium concentration is very rapid. Changes in concentration should be noted early by laboratory tests and corrected promptly.

Hyponatremia

Acute symptomatic hyponatremia (sodium less than 130 mEq/L) clinically is characterized by central nervous system signs of increased intracranial pressure and tissue signs of excessive intracellular water. The hypertension probably is induced by the rise in intracranial pressure, and the blood pressure usually returns to normal with the administration of hypertonic solutions of sodium salts. Of importance with severe hyponatremia is the relatively rapid development of oliguric renal failure, which may not be reversible if therapy is delayed.

Many chronic hyponatremic states are asymptomatic until the serum sodium level falls below 120 mEq/L. One important exception is the patient with increased intracranial pressure after closed head injury, in whom mild hyponatremia may be fatal, because of the progressive increase in intracellular water as the extracellular fluid osmolarity falls.

Hypernatremia

Central nervous system and tissue signs characterize acute symptomatic hypernatremia. This is the only state in which dry, sticky mucous membranes are characteristic. This sign does not occur with pure extracellular fluid volume deficit alone and may be misleading in the patient who breathes through the mouth. Body temperature generally is elevated and may approach a lethal level, as in the patient with heatstroke.

While volume changes occur frequently without any change in serum sodium concentration, the reverse is not true. The disease states that cause a significant acute alteration in the serum sodium level frequently produce a concomitant change in the extracellular fluid volume.

Mixed Volume and Concentration Abnormalities

Mixed volume and concentration abnormalities may develop as a consequence of the disease state or occasionally as a result of inappropriate parenteral fluid therapy. Moyer noted that the clinical picture associated with a combination of fluid abnormalities will be an algebraic composite of the signs and symptoms of each state. Like signs produced by both abnormalities will be additive, and opposing signs will nullify one another. For example, the tendency for the body temperature to fall with an extracellular volume deficit may be counteracted by the tendency for it to rise with severe hypernatremia.

One of the more common mixed abnormalities is an extracellular fluid deficit and hyponatremia. This state is readily produced in the patient who continues to drink water while losing large volumes of gastrointestinal fluids. It may also occur in the postoperative period when gastrointestinal losses are replaced with inadequate volumes of only 5% dextrose in water or a hypotonic sodium solution. An extracellular volume deficit accompanied by hypernatremia may be produced by the loss of a large amount of hypotonic salt solution, such as sweat, in the absence of fluid intake.

The prolonged administration of excessive quantities of sodium salts with restricted water intake may result in an extracellular volume excess and hypernatremia. This may also occur when pure water losses (such as insensible loss of water from the skin and lungs) are replaced with sodium- containing solutions only. Similarly, the excessive administration of water or hypotonic salt solutions to the patient with oliguric renal failure may rapidly produce an extracellular volume excess and hyponatremia.

Normally functioning kidneys may minimize these changes to some extent and compensate for many of the imprecise replacements associated with parenteral fluid administration. In contrast, the patient in anuric or oliguric renal failure is particularly prone to develop these mixed volume and osmolar concentration abnormalities. Fluid and electrolyte management in these patients, therefore, must be precise. Unfortunately, the fact that a patient with normal kidneys who develops a significant volume deficit may be in a state of "functional" renal failure often is not appreciated. As the volume deficit progresses, the glomerular filtration rate falls precipitously, and the kidneys' unique functions for maintaining fluid homeostasis are lost. These changes may occur with only a mild volume deficit in the elderly patient with borderline renal function. In these elderly patients, the blood urea nitrogen level may rise higher than 100 mg/dL in response to the fluid deficit with a concomitant rise in the serum creatinine level. Fortunately, these changes usually are reversible with early and adequate correction of the extracellular fluid volume deficit.

Composition Changes

Compositional abnormalities of importance include changes in acid-base balance and changes in the concentration of potassium, calcium, and magnesium.

Acid-Base Balance

The pH of the body fluids is normally maintained within narrow limits in spite of the large load of acid produced endogenously as a by-product of body metabolism. The acids are neutralized efficiently by several buffer systems and subsequently excreted by the lungs and kidneys.

The important buffers include proteins and phosphates, which play a primary role in maintaining intracellular pH, and the bicarbonate–carbonic acid system, which operates principally in the extracellular fluid space. The proteins and hemoglobin have only minor influence in the extracellular fluid space, but the latter is of prime significance as an intracellular buffer in the red blood cell.

A buffer system consists of a weak acid or base and the salt of that acid or base. The buffering effect is the result of the formation of an amount of weak acid or base equivalent to the amount of strong acid or base added to the system. The resultant change in pH is considerably less than if the substance were added to water alone. Thus inorganic acids (e.g., hydrochloric, sulfuric, phosphoric) and organic acids (e.g., lactic, pyruvic, keto acids) combine with base bicarbonate, producing the sodium salt of the acid and carbonic acid:

The carbonic acid formed is then excreted via the lungs as CO_2 . The inorganic acid anions are excreted by the kidneys with hydrogen or as ammonium salts. The organic acid anions generally are metabolized as the underlying disorder is corrected, although some renal excretion may occur with high levels.

The functions of the buffer systems are expressed in the Henderson- Hasselbalch equation, which defines the pH in terms of the ratio of the salt and acid. The pH of the extracellular fluid is defined primarily by the ratio of the amount of base bicarbonate (the majority as sodium bicarbonate) to the amount of carbonic acid (related to the CO_2 content of alveolar air) present in the blood:

$$\text{pH} = \text{pK} + \log \frac{\text{HCO}_3^-}{\text{H}_2\text{CO}_3} = 7.38 + \log \frac{27 \text{ mEq/L}}{1.33 \text{ mEq/L}} = 7.38 + 1 = 8.38$$

The term pK represents the dissociation constant of carbonic acid in the presence of base bicarbonate, which by measurement is 6.1. At a body pH of 7.4, the ratio must be 20:1, as depicted. From a chemical standpoint, this is an inefficient buffer system, but the unusual property of CO_2 of behaving as an acid or changing to a neutral gas subsequently excreted by the lungs makes it quite efficient biologically.

As long as the 20:1 ratio is maintained, regardless of the absolute values, the pH will remain at 7.4. When an acid is added to the system, the concentration of bicarbonate (the numerator in the Henderson-Hasselbalch equation) decreases. Ventilation immediately increases to eliminate larger quantities of CO_2 , with a subsequent decrease in the carbonic acid (the denominator in the Henderson-Hasselbalch equation) until the 20:1 ratio is reestablished. Slower, more complete compensation is effected by the kidneys with increased excretion of acid salts and retention of bicarbonate. The reverse occurs if an alkali is added to the system. Respiratory acidosis and alkalosis are produced by disturbances of ventilation, with an increase or decrease in the denominator and hence a change from the 20:1 ratio. Compensation is primarily renal, with retention of bicarbonate and increased excretion of acid salts in respiratory acidosis and the reverse process in respiratory alkalosis.

The four types of acid-base disturbances are listed in Table 2-6. Use of the CO_2 combining power (approximates the plasma bicarbonate) or CO_2 content (includes bicarbonate, carbonic acid, and dissolved CO_2) and knowledge of the patient's disease may allow an accurate diagnosis in the uncomplicated case. Use of the serum CO_2 content or CO_2 combining power alone is generally inadequate as an index of acid-base balance. This test principally reflects the level of plasma bicarbonate, dissolved CO_2 and carbonic acid contribute no more than a few millimoles under most circumstances. In the acute phase, therefore, respiratory acidosis or alkalosis may exist without any change in the serum CO_2 content; determinations of the pH and P_{CO_2} from a freshly drawn arterial blood sample are necessary for diagnosis.

More complex acid-base disturbances are encountered frequently. Combinations of respiratory and metabolic changes may represent compensation for the initial acid-base disturbance or may indicate two or more coexisting primary disorders (Table 2-7).

A knowledge of the pH, bicarbonate concentration, and Pa_{CO_2} allows an accurate diagnosis of most acid-base disturbances. However, the clinical interpretation of these measurements is associated with some inherent problems. Although the Pa_{CO_2} is considered an accurate index of primary respiratory disturbances, changes in the level may represent compensation for a primary metabolic alteration. Thus a depressed Pa_{CO_2} (below 40 mmHg) is characteristic of respiratory alkalosis but also represents the normal compensatory response to a metabolic acidosis. Similarly, the level of plasma bicarbonate cannot be regarded exclusively as an index of metabolic disturbances. An elevated plasma bicarbonate level may indicate a primary metabolic alkalosis or a compensatory response to chronic respiratory acidosis. Astrup and colleagues proposed the use of the standard bicarbonate and base excess values. Base excess (or deficit) directly expresses, in mEq/L, the amount of fixed base (or acid) added to each liter of blood. This defines the metabolic component of acid-base disorders.

One useful approach to defining pure, combined, or compensated disturbances relates measured changes in Pa_{CO_2} and pH to calculated changes that would be expected from pure etiologies. Within reasonable physiologic ranges, a 10-mmHg change in Pa_{CO_2} yields a 0.08 change in pH from the normal values of Pa_{CO_2} (40 mmHg) and pH (7.4).

Respiratory Acidosis

This condition is associated with retention of CO_2 secondary to decreased alveolar ventilation. The more common causes are listed in Table 2-6. Initially the Pa_{CO_2} is elevated (usually above 50 mmHg), and the serum bicarbonate concentration (measured as CO_2 content) is normal. In the chronic form, the Pa_{CO_2} remains elevated, and the bicarbonate concentration rises as renal compensation occurs.

This problem may be particularly serious in the patient with chronic pulmonary disease, in whom preexisting respiratory acidosis may be accentuated in the postoperative period. A number of conditions resulting in inadequate ventilation (e.g., airway obstruction, atelectasis, pneumonia, pleural effusion, pain from an upper abdominal incision, or abdominal distention limiting diaphragmatic excursion) may exist singly or in combination to produce respiratory acidosis. Although restlessness, hypertension, and tachycardia in the immediate postoperative period may be caused by pain, similar signs indicate inadequate ventilation with hypercapnia. The use of narcotics in this situation compounds the problem by depressing respiration.

Management involves prompt correction of the pulmonary defect, when feasible, and measures to ensure adequate ventilation. Endotracheal intubation and mechanical ventilation occasionally are necessary. Strict attention to tracheobronchial hygiene during the postoperative period is an important preventive measure in all patients, and particularly in those with chronic pulmonary disease. Encouraging deep breathing and coughing, using humidified air to prevent inspissation of secretions, and avoiding oversedation are all indicated.

Respiratory Alkalosis

Respiratory alkalosis is a more common problem in the surgical patient than previously recognized. Hyperventilation because of apprehension, pain, hypoxia, central nervous system injury, and assisted ventilation are all common causes. Any of these conditions may cause a rapid decrease in the Pa_{CO_2} and increase in serum pH. The serum bicarbonate concentration is normal in the acute phase but falls with compensation if the condition persists.

The majority of patients who require ventilatory support in the postoperative period develop varying degrees of respiratory alkalosis. This may be the inadvertent result of improper use of the mechanical respirator, or it may occur during attempts to raise the P_{O_2} in a hypoxic patient. Proper management of the patient on a mechanical ventilator requires frequent measurements of blood gases and appropriate corrections of the ventilatory pattern when indicated. The Pa_{CO_2} should not be allowed to fall below 30 mmHg, as serious complications may occur, particularly in the presence of a complicating hypokalemia or metabolic alkalosis. Generally the Pa_{CO_2} can be maintained at an acceptable level by proper adjustments of the ventilatory rate and volume.

The dangers of a severe respiratory alkalosis are those related to potassium depletion and include the development of ventricular arrhythmias and fibrillation, particularly in patients who are digitalized or have preexisting hypokalemia. Other complications include a shift of the oxyhemoglobin dissociation curve to the left, which limits the ability of hemoglobin to unload oxygen at the tissue level except at low tissue oxygen tensions, and the development of tetany and convulsions if the level of ionized calcium is significantly depressed. The development of hypokalemia may be quite sudden and is related to entry of potassium ions into the cells in exchange for hydrogen and an excessive urinary potassium loss in exchange for sodium. Severe and persistent respiratory alkalosis often is difficult to correct and may be associated with a poor prognosis because of the underlying cause of hyperventilation. The treatment of alkalosis is directed primarily toward preventing the condition by the proper use of mechanical ventilation and correcting preexisting potassium deficits.

Metabolic Acidosis

Metabolic acidosis results from the retention or gain of fixed acids (diabetic ketoacidosis, lactic acidosis, azotemia) or the loss of base bicarbonate (diarrhea, small-bowel fistula, renal insufficiency with inability to resorb bicarbonate). The excess of hydrogen ions results in lower pH and serum bicarbonate concentration. The initial compensation is pulmonary, with an increase in the rate and depth of breathing and depression of the Pa_{CO_2} .

Renal damage may interfere with the important role of the kidneys in the regulation of acid-base balance. The kidneys serve a vital function in this regard through the excretion of nitrogenous waste products and acid metabolites and the resorption of bicarbonates. If renal damage occurs and these functions are lost, metabolic acidosis develops rapidly and may be difficult to control.

With normal kidneys, metabolic acidosis may develop when the capacity of the kidneys for handling a large chloride load is exceeded. This is particularly common in patients who have excessive losses of alkaline gastrointestinal fluids (biliary, pancreatic, small-bowel secretions) and are maintained on parenteral fluids for an extended period. Continued replacement of these losses with fluids that have an inappropriate chloride- bicarbonate ratio, such as isotonic sodium chloride solution, will not correct the pH change; the use of a balanced salt solution, such as lactated Ringer's solution, is indicated. Anion gap has become a useful tool in the management of acid-base disorders. This value can be determined routinely when evaluating serum electrolytes. The gap is calculated from the sum of serum chloride and bicarbonate levels subtracted from the serum sodium concentration. The normal value is 10 to 15 mEq/L. The anion gap is a laboratory anomaly because routine clinical laboratory tests measure the cations sodium and potassium and the anions chloride and bicarbonate. The unmeasured anions that account for the "gap" are sulfate and phosphate plus lactate and other organic anions. If the acidosis is a result of loss of bicarbonate (e.g., diarrhea) or gain of a chloride acid (e.g., administration of ammonium chloride), the anion gap will be normal. Conversely, if the acidosis is a result of increased production of an organic acid (e.g., lactic acid in circulatory shock) or the retention of sulfuric or phosphoric acid (e.g., renal failure), the concentration of unmeasured anions (anion gap) will be increased.

Conditions associated with an elevated anion gap are listed in Table 2-8. The most common cause of an elevated anion gap is shock or inadequate tissue perfusion from any number of causes, resulting in accumulation of large quantities of lactic acid. Diabetic ketoacidosis, starvation, and ethanol intoxication cause elevation of the anion gap by the formation of keto acids; renal failure and uremia cause the elevation by the retention of sulfuric and phosphoric acids. Poisoning by methanol, ethylene glycol, and aspirin produce increased anion gaps by elevation of their organic acid counterparts (formic, oxalic, and salicylic acids). These causes should be considered, singly or in combination, in a patient with an elevated anion gap.

One of the most common causes of severe metabolic acidosis in surgical patients is acute circulatory failure with accumulation of lactic acid. This is a reflection of tissue hypoxia from inadequate perfusion, although it is only one of the manifestations of cellular dysfunction. Acute hemorrhagic shock may result in a rapid and profound drop in the pH, and attempts to raise the blood pressure with vasopressors will compound the problem by further compromising tissue perfusion. Similarly, attempts to correct the acidosis by the infusion of large quantities of sodium bicarbonate without restoration of flow are futile. After restoration of adequate tissue perfusion by proper volume replacement, the lactic acid is quickly metabolized and the pH returned to normal. The use of lactated Ringer's solution to replace the extracellular fluid deficit incurred with hemorrhagic shock concomitant with administration of whole blood does not accentuate the lactic acidosis. Instead there is a rapid decrease in the serum lactate and return of pH toward normal, which is not the case when whole blood alone is used (see Table 2-8).

The indiscriminate use of sodium bicarbonate during the resuscitation of patients in hypovolemic shock is discouraged for several reasons. A mild metabolic alkalosis is a common finding after resuscitation, in part because of the alkalizing effects of blood transfusions and the administration of lactated Ringer's solution. After infusion (and partial restoration of hepatic blood flow), the citrate contained in the transfused blood and the lactate in lactated Ringer's solution are metabolized and bicarbonate is formed. The organic acidosis (lactic acid) that developed during the shock episode is rapidly cleared once adequate tissue perfusion is restored. Lactic acid production ceases, the hydrogen ion load is buffered and excreted via the lungs as CO₂, and the organic anion, lactate, is metabolized to bicarbonate by the liver. If excessive quantities of sodium bicarbonate are administered simultaneously, severe metabolic alkalosis can result. An alkaline pH may be highly undesirable in this situation, particularly in patients with hypoxia or a low fixed cardiac output, because it shifts the oxyhemoglobin dissociation curve to the left. Other factors that shift the oxygen dissociation curve to the left in this situation include the depressed level of erythrocyte 2,3- diphosphoglycerate in the transfused blood and the development of hypothermia. If the curve shifts far enough to the left, significant interference with oxygen unloading at the tissue level may occur.

The treatment of metabolic acidosis should be directed toward correction of the underlying disorder when possible. Bicarbonate therapy properly may be reserved for the treatment of severe metabolic acidosis, particularly after cardiac arrest, when partial correction of the pH may be essential to restore myocardial function. Studies indicate that the acidosis accompanying cardiac arrest is well compensated for a significant period of time if the patient is well ventilated and not previously acidotic. In addition, the administration of bicarbonate in the usual recommended doses may induce an acute and severe hyponatremia and hyperosmolarity. Bicarbonate should be used judiciously during cardiac arrest; the initial dose should not exceed 50 mL of 7.5% solution (45 mEq NaHCO₃ containing 90 mOsm), and the decision for additional doses should be based on measurements of pH and PaCO₂ when possible.

Similarly, pH correction of more protracted states of metabolic acidosis may be indicated, but it should be accomplished slowly. Since no satisfactory formula for estimating the amount of alkali needed has been devised, frequent measurements of serum electrolyte levels and blood pH are the best guide to therapy.

Metabolic Alkalosis

Metabolic alkalosis results from the loss of fixed acids or the gain of bicarbonate and is aggravated by any preexisting potassium depletion. The pH and plasma bicarbonate concentration are elevated. Compensation for metabolic alkalosis is primarily by renal mechanisms; respiratory compensation generally is small and cannot be detected in most patients. Rarely, hypercapnia may represent a compensatory response to metabolic alkalosis in patients without chronic pulmonary disease. When this is suspected, rapid reduction in PaCO₂ by mechanical ventilation should be avoided. Rather, the PaCO₂ will fall as the metabolic alkalosis is corrected.

The majority of patients with metabolic alkalosis have some degree of hypokalemia, a result in part of the influx of potassium ions into the cells as hydrogen ions efflux into the serum. The dangers of metabolic alkalosis are the same as those discussed for respiratory alkalosis.

A problem commonly encountered in the surgical patient is hypochloremic, hypokalemic metabolic alkalosis resulting from persistent vomiting or gastric suction in the patient with pyloric obstruction. Unlike vomiting with an open pylorus, which involves a combined loss of gastric, pancreatic, biliary, and intestinal secretions, vomiting with an obstructed pylorus results in loss of fluid with high chloride and hydrogen ion concentrations in relation to sodium. Initially the urinary excretion of bicarbonate increases to compensate for the alkalosis. This increase in urinary bicarbonate excretion results from net hydrogen ion resorption by the renal tubular cells, with accompanying potassium ion excretion. As the volume deficit progresses, aldosterone-mediated sodium resorption is accompanied by potassium excretion. The resulting hypokalemia leads to excretion of hydrogen ions in place of potassium ions by this mechanism, producing paradoxical aciduria. The net result is a self-perpetuating alkalosis with hypokalemia. Proper management includes replacement of the extracellular fluid volume deficit with isotonic sodium chloride solution in addition to replacement of potassium. Volume repletion should be started and a good urine output obtained before potassium is administered.

Rarely, severe hypokalemic metabolic alkalosis in a patient with pyloric outlet obstruction may be refractory to standard therapy. This occurs most often in patients who also have severe hypochloremia and several liters of nasogastric drainage daily. In the past, the infusion of ammonium chloride or arginine hydrochloride was the usual method for increasing the level of nonvolatile acids. However, infusion of ammonium chloride may produce ammonia toxicity, and arginine hydrochloride is no longer available commercially. The use of 0.1 N to 0.2 N hydrochloric acid is a safe and effective therapy for correction of severe, resistant metabolic alkalosis. The infusion should be administered over a period of 6 to 24 h, with measurements of pH, PaCO₂, and serum electrolytes every 4 h. Generally, 1 or 2 L of solution over a period of 24 h is sufficient, but additional hydrochloric acid should be infused when indicated by appropriate clinical and laboratory evidence. Temporary control of the alkalosis with this method usually is successful, but the underlying cause should be controlled as soon as possible.

Potassium Abnormalities

The normal dietary intake of potassium is approximately 50 to 100 mEq daily, and in the absence of hypokalemia, the majority of this is excreted in the urine. Ninety-eight percent of the potassium in the body is located within the intracellular compartment at a concentration of approximately 150 mEq/L, and it is the major cation of intracellular water. Although the total extracellular potassium in a 70-kg male would amount approximately to only 63 mEq (4.5 mEq/L × 14 L), this small amount is critical to cardiac and neuromuscular function. In addition, the turnover rate in the extracellular fluid compartment may be extremely rapid.

The intracellular and extracellular distribution of potassium is influenced by many factors. Significant quantities of intracellular potassium are released into the extracellular space in response to severe injury or surgical stress, acidosis, and the catabolic state. A significant rise in serum potassium concentration may occur in these states in the presence of oliguric or anuric renal failure, but dangerous hyperkalemia (greater than 6mEq/L) rarely is encountered when renal function is normal. After severe trauma normal or excessive urinary volumes may not reflect the kidney's ability to clear solutes or to excrete potassium.

Hyperkalemia

The signs of a significant hyperkalemia are limited to the cardiovascular and gastrointestinal systems. The gastrointestinal symptoms include nausea, vomiting, intermittent intestinal colic, and diarrhea. The cardiovascular signs are apparent on the electrocardiogram (ECG) initially, with high, peaked T waves, widened QRS complex, and depressed ST segments. Disappearance of T waves, heart block, and diastolic cardiac arrest may develop with increasing levels of potassium.

Treatment of hyperkalemia consists of immediate measures to reduce the serum potassium level, withholding of exogenous potassium, and correction of the underlying cause if possible. Temporary suppression of the myocardial effects of a sudden rapid rise of potassium level can be accomplished by the intravenous administration of 1 g of 10% calcium gluconate under ECG monitoring. Serum potassium levels may be transiently decreased by administration of bicarbonate and glucose with insulin (45 mEq NaHCO₃ in 1000 mL/D₁₀W with 20 units regular insulin), which promote cellular uptake of potassium. However, the definitive treatment of hyperkalemia requires the enteral administration of cation exchange resins (Kayexalate) or dialysis.

Hypokalemia

The more common problem in the surgical patient is hypokalemia, which may occur as a result of: (1) excessive renal excretion; (2) movement of potassium into cells; (3) prolonged administration of potassium-free parenteral fluids with continued obligatory renal loss of potassium (20 mEq/day or more); (4) total parenteral hyperalimentation with inadequate potassium replacement; and (5) loss in gastrointestinal secretions.

Potassium has an important role in the regulation of acid-base balance. Increased renal excretion occurs with respiratory and metabolic alkalosis. Potassium is in competition with hydrogen ions for renal tubular excretion in exchange for sodium ions. Thus, in alkalosis, the increased potassium ion excretion in exchange for sodium ions permits hydrogen ion conservation. Hypokalemia may produce a metabolic alkalosis, because an increase in excretion of hydrogen ions occurs when the concentration of potassium in the tubular cell is low. In addition, movement of hydrogen ions into the cells as a consequence of potassium loss is partly responsible for the alkalosis. In metabolic acidosis the reverse process occurs, and the excess hydrogen ion is exchanged for sodium, with retention of greater amounts of potassium.

Renal tubular excretion of potassium ions is increased when large quantities of sodium are available for excretion. The more sodium ions available for resorption, the more potassium is exchanged for sodium in the lumen. Potassium requirements for prolonged or massive isotonic fluid volume replacement are increased, probably on this basis.

The renal excretion of potassium may be small in comparison with the amount of potassium that may be lost in gastrointestinal secretions. The amount per liter in various types of

gastrointestinal fluids is shown in Table [2-3](#). Although the average potassium concentration of some of these fluids is relatively low, significant hypokalemia will result if potassium-free fluids are used for replacement.

Hypokalemia also may be a serious problem in the patient who is maintained on intravenous nutrition. Large quantities of supplemental potassium generally are necessary to restore depleted intracellular stores and to meet the requirements for tissue synthesis during the anabolic phase.

Most of the factors that influence potassium metabolism result in excess excretion, and a tendency toward hypokalemia occurs frequently in the surgical patient, except when shock or acidosis interferes with the normal renal handling of potassium.

The signs of potassium deficit are related to failure of normal contractility of skeletal, smooth, and cardiac muscle and include weakness that may progress to flaccid paralysis, diminished to absent tendon reflexes, and paralytic ileus. Sensitivity to digitalis, with cardiac arrhythmias and ECG signs of low voltage, flattening of T waves, and depression of ST segments, are characteristic. Signs of potassium deficit may be masked by those of a severe extracellular fluid volume deficit. Repletion of the volume deficit may further aggravate the situation by lowering the serum potassium level through dilution.

Hypokalemia is best dealt with through prevention. In the replacement of gastrointestinal fluids, it is safe to replace the upper limits of loss, because an excess is readily handled by the patient with normal renal function. No more than 40 mEq should be added to a liter of intravenous fluid, and the rate of administration should not exceed 40 mEq/h unless the ECG is being monitored. In the absence of specific indications, potassium should not be given to the oliguric patient or to patients during the first 24 h after severe surgical stress or trauma.

Calcium Abnormalities

The majority of the 1000 to 1200 g of body calcium in the average-sized adult is found in the bone in the form of phosphate and carbonate. Normal daily intake of calcium is 1 to 3 g. Most of this is excreted via the gastrointestinal tract, and 200 mg or less is excreted in the urine daily. The normal serum level is 8.5 to 10.5 mg/dL, about half of which is non-ionized and bound to plasma protein. An additional non-ionized fraction (5 percent) is bound to other substances in the plasma and interstitial fluid, and the remaining 45 percent is the ionized portion that is responsible for neuromuscular stability. Determination of the plasma protein level, therefore, is essential for proper analysis of the serum calcium level. The ratio of ionized to non-ionized calcium is also related to the pH; acidosis causes an increase in the ionized fraction, and alkalosis causes a decrease.

Disturbances of calcium metabolism generally are not a problem in the postoperative patient without complications, with the exception of skeletal loss during prolonged immobilization. Routine administration of calcium to the surgical patient, therefore, is not needed in the absence of specific indications.

Hypocalcemia

The symptoms of hypocalcemia, which may be seen when serum levels are below 8 mg/dL, include numbness and tingling of the circumoral region and the tips of the fingers and toes. The signs are of neuromuscular origin and include hyperactive tendon reflexes, positive Chvostek's sign, muscle and abdominal cramps, tetany with carpopedal spasm, convulsions (with severe deficit), and prolongation of the Q-T interval on the ECG.

The common causes include acute pancreatitis, massive soft-tissue infections (necrotizing fasciitis), acute and chronic renal failure, pancreatic and small-bowel fistulas, and hypoparathyroidism. Transient hypocalcemia is a frequent occurrence in the hyperparathyroid patient after removal of a parathyroid adenoma, owing to atrophy of the remaining glands and avid bone uptake. Asymptomatic hypocalcemia may occur with hypoproteinemia (normal ionized fraction), but symptoms may appear with a normal serum calcium level in a patient with severe alkalosis. In this case there is a decrease in the physiologically active or ionized fraction of total serum calcium. Calcium levels also may fall with a severe depletion of magnesium.

Treatment is directed toward correction of the underlying cause and repletion of the deficit. Acute symptoms may be relieved by the intravenous administration of calcium gluconate or calcium chloride. Calcium lactate may be given orally, with or without supplemental vitamin D, in the patient requiring prolonged replacement. The routine administration of calcium during massive transfusions of blood is controversial and reflects the paucity of studies in which calcium ion levels have been measured. In the majority of studies, calcium ion concentrations have been estimated from measured total serum calcium levels. Available data indicate that the majority of patients receiving blood transfusions do not require calcium supplementation. The binding of ionized calcium by citrate generally is compensated for by the mobilization of calcium from body stores. For patients receiving blood as rapidly as 500 mL every 5 to 10 min, calcium administration is recommended. An appropriate dose, according to Moore's data, is 0.2 g calcium chloride (2 mL 10% calcium chloride solution), administered intravenously in a separate line, for every 500 mL of blood transfused. To avoid dangerous levels of hypercalcemia, this dose of calcium is recommended only while blood is being transfused at the rate noted above. The total dose of calcium generally should not exceed 3 g unless there is objective evidence of hypocalcemia. Larger doses rarely are indicated because there is some mobilization of calcium and citrate breakdown with release of calcium ions even with shock and inadequate peripheral perfusion. During massive transfusions, some attempt should be made to monitor the calcium level. An approximation of calcium ion concentration can be obtained by monitoring the Q-T interval on the ECG, although techniques for the rapid measurement of calcium ion concentration are available.

Hypercalcemia

The symptoms of hypercalcemia are vague and of gastrointestinal, renal, musculoskeletal, and central nervous system origin. The early manifestations of hypercalcemia include easy fatigue, lassitude, weakness of varying degree, anorexia, nausea, vomiting, and weight loss. With higher serum calcium levels, lassitude gives way to somnambulism, stupor, and, finally, coma. Other symptoms include severe headaches, pains in the back and extremities, thirst, polydipsia, and polyuria. The critical level for serum calcium is 15 mg/dL or higher, and unless treatment is instituted promptly, the symptoms may rapidly progress to death. The two major causes of hypercalcemia are hyperparathyroidism and cancer with bony metastasis. The latter is seen most frequently in the patient with metastatic breast cancer who is receiving estrogen therapy.

A serum calcium concentration of 15 mg/dL or higher requires emergency treatment. Most patients have an extracellular fluid volume deficit because of the effects of hypercalcemia (vomiting, polyuria), and vigorous volume repletion with salt solutions lowers the calcium level by dilution and increased urinary calcium excretion. Rapid correction of the associated extracellular fluid volume deficit immediately lowers the serum calcium level by dilution and by increased renal clearance, which may be augmented by furosemide administration.

Oral or intravenous inorganic phosphates effectively lower serum calcium by inhibiting bone resorption and forming calcium-phosphate complexes that are deposited in soft tissues and bone. Intravenous use may cause an abrupt fall in calcium, and tetany, hypotension, and acute renal failure have been reported with this form of therapy. If intravenous phosphorus is used, it should be given slowly over a period of approximately 12 h once daily for no more than 2 or 3 days. Inorganic phosphates are contraindicated in patients with hyperphosphatemia or renal failure. Intravenous sodium sulfate also lowers serum calcium by increasing urinary excretion of calcium. It is less effective than phosphate salts, however, and probably is no more effective than normal saline.

Corticosteroids decrease resorption of calcium from bone and reduce the intestinal absorption of vitamin D. They have been useful in treating hypercalcemic patients with sarcoidosis, myelomas, lymphomas, and leukemias, although the reduction in serum calcium may not be apparent for 1 or 2 weeks. Mithramycin, a cytotoxic drug, effectively lowers serum calcium in 24 to 48 h by direct action on the bones. The drug is relatively safe in the small doses used, and the calcium level may remain normal for several days to weeks after a single dose. Calcitonin induces a moderate decrease in serum calcium, but the effect is diminished with repeated administration. The definitive treatment of acute hypercalcemic crisis in patients with hyperparathyroidism is immediate surgery.

In the patient with metastatic cancer, a preventive approach to hypercalcemia should be taken. The serum calcium level is checked frequently; if it is elevated, the patient is placed on a low-calcium diet and measures to ensure adequate hydration are instituted.

Magnesium Abnormalities

The total body content of magnesium in the average adult is approximately 2000 mEq, about half of which is incorporated in bone and only slowly exchangeable. The distribution of magnesium is similar to that of potassium, the major portion being intracellular. Serum magnesium concentration normally ranges from 1.5 to 2.5 mEq/L. The normal dietary intake of magnesium is approximately 20 mEq (240 mg) daily. The larger part is excreted in the feces and the remainder in the urine. The kidneys show a remarkable ability to conserve magnesium; on a magnesium-free diet, renal excretion of this ion may be less than 1mEq/day.

Magnesium Deficiency

Magnesium deficiency is known to occur with starvation, malabsorption syndromes, protracted losses of gastrointestinal fluid, prolonged intravenous fluid therapy with magnesium-free solutions, and during total parenteral nutrition when inadequate quantities of magnesium have been added to the solutions. Other causes include acute pancreatitis, treatment of diabetic ketoacidosis, primary aldosteronism, chronic alcoholism, amphotericin B therapy, and a protracted course after thermal injury.

The magnesium ion is essential for proper function of most enzyme systems, and depletion is characterized by neuromuscular and central nervous system hyperactivity. The signs and symptoms are similar to those of calcium deficiency, including hyperactive tendon reflexes, muscle tremors, and tetany with a positive Chvostek's sign. Progression to delirium and convulsions may occur with a severe deficit. A concomitant calcium deficiency occasionally is noted and is refractory to treatment in the absence of magnesium repletion.

The diagnosis of magnesium deficiency depends on an awareness of the syndrome and clinical recognition of the symptoms. Laboratory confirmation is available, but it is not reliable because the syndrome may exist in the presence of a normal serum magnesium level. The possibility of magnesium deficiency should always be considered in the surgical patient who exhibits disturbed neuromuscular or cerebral activity in the postoperative period. This is particularly important in patients who have had protracted dysfunction of the gastrointestinal tract with long-term maintenance on parenteral fluids and in patients on parenteral hyperalimentation. Routine magnesium administration is always indicated in the management of these patients.

Treatment of magnesium deficiency is by the parenteral administration of magnesium sulfate or magnesium chloride solution. If renal function is normal, as much as 2 mEq of magnesium per kg of body weight per day can be administered intravenously or intramuscularly daily in the face of severe depletion. The intravenous route is preferable for the initial treatment of a severe symptomatic deficit. The solution is prepared by the addition of 80 mEq of magnesium sulfate (20 mL 50% solution containing 4 mEq/mL magnesium) to 1 L of intravenous fluid and is administered over a 4-h period. If the patient is not symptomatic, the infusion should be given over a longer period. The possibility of acute magnesium toxicity should be kept in mind when giving magnesium intravenously. When large doses are given, the heart rate, blood pressure, respiration, and ECG should be monitored closely for signs of magnesium toxicity, which could lead to cardiac arrest. It is advisable to have calcium chloride or calcium gluconate available to counteract any adverse effects of a rapidly rising serum magnesium level.

Partial or complete relief of symptoms may follow this infusion as a result of increased concentration of magnesium ion in the extracellular fluid compartment, although continued

replacement over a period of 1 to 3 weeks is necessary to replenish the intracellular compartment. For this purpose and for the asymptomatic patient who may have significant magnesium depletion, 10 to 20 mEq of 50% magnesium sulfate solution per day may be given intramuscularly or in intravenous fluids; alternatively, 800 mg magnesium oxide per day may be given orally. When intramuscular magnesium sulfate is used, it should be given in divided doses or at multiple sites because the intramuscular injection of this salt is painful. After complete repletion of intracellular magnesium, and in the absence of abnormal loss, balance may be maintained by the administration of as little as 4 mEq of magnesium ion daily. The amount of magnesium supplementation required for patients on parenteral hyperalimentation varies but 12 to 24 mEq daily is effective for the average patient.

Magnesium should not be given to the oliguric patient or in the presence of a severe volume deficit unless actual magnesium depletion has been demonstrated. If given to a patient with renal insufficiency, considerably smaller doses are used and the patient is carefully observed for signs or symptoms of toxicity.

Magnesium Excess

Symptomatic hypermagnesemia, although rare, is most commonly seen with severe renal insufficiency. Retention and accumulation of magnesium may occur in any patient with impaired glomerular or renal tubular function, and the presence of acidosis may rapidly compound the problem. Serum magnesium levels tend to parallel changes in potassium concentration in these cases. In patients on ordinary dietary intakes of magnesium, increased serum concentrations do not occur until the glomerular filtration rate falls below 30 mL/min. Magnesium-containing antacids and laxatives (milk of magnesia, epsom salts, Gelusil, Maalox) are commonly administered in quantities that are sufficient to produce toxic serum levels of magnesium in patients with impaired renal function. Other conditions that may be associated with symptomatic hypermagnesemia include early thermal injury, massive trauma or surgical stress, severe extracellular volume deficit, and severe acidosis.

The early signs and symptoms of magnesium excess include lethargy and weakness with progressive loss of deep tendon reflexes. Interference with cardiac conduction occurs with increasing levels of magnesium, and changes in the ECG (increased P-R interval, widened QRS complex, and elevated T waves) resemble those seen in hyperkalemia. Somnolence leading to coma and muscular paralysis occur in the later stages, and death is usually caused by respiratory or cardiac arrest.

Treatment consists of immediate measures to lower the serum magnesium level by correcting coexisting acidosis, replenishing preexisting extracellular volume deficit, and withholding exogenous magnesium. Acute symptoms may be temporarily controlled by the slow intravenous administration of 5 to 10 mEq of calcium chloride or calcium gluconate. If elevated levels or symptoms persist, peritoneal dialysis or hemodialysis is indicated.

FLUID AND ELECTROLYTE THERAPY

Parenteral Solutions

Many different electrolyte solutions, with various compositions, are available for parenteral administration (Table 2-9). Several of the more commonly used solutions are discussed below. The choice of a particular fluid depends on the patient's volume status and the type of concentration or compositional abnormality present.

A cost-effective extracellular "mimic" of isotonic salt solution for replacing gastrointestinal losses and extracellular fluid volume deficits, in the absence of gross abnormalities of concentration and composition, is lactated Ringer's solution. This solution is physiologic and contains 130 mEq of sodium balanced by 109 mEq of chloride and 28 mEq of lactate. Lactate is used instead of bicarbonate because it is more stable in intravenous fluids during storage. The lactate is converted readily to bicarbonate by the liver after infusion. Concern about the ability of the liver to metabolize lactate is unwarranted even when infusing large quantities of lactated Ringer's solution to patients in hemorrhagic shock. This fluid has minimal effects on normal body fluid composition and pH even when infused in large quantities. There are other balanced salt solutions available, some with sodium acetate or bicarbonate instead of lactate; all are considered interchangeable.

Isotonic sodium chloride contains 154 mEq of sodium and 154 mEq of chloride per liter. The high concentration of chloride above the normal serum concentration of 103 mEq/L imposes on the kidneys an appreciable load of excess chloride that cannot be rapidly excreted. A dilutional acidosis may develop by reducing base bicarbonate relative to carbonic acid. This solution is ideal, however, for the initial correction of an extracellular fluid volume deficit in the presence of hyponatremia, hypochloremia, and metabolic alkalosis. In a similar situation with moderate metabolic acidosis, M/6 sodium lactate (167 mEq/L each of sodium and lactate) may be given.

For maintenance fluid in the postoperative period, 0.45% sodium chloride in 5% dextrose solution is used often to provide free water for insensible losses and some sodium for renal adjustment of serum concentration. With added potassium, this is a reasonable solution to use for maintenance requirements in a patient with no complications who requires only a short period of parenteral fluids.

Preoperative Fluid Therapy

Preoperative evaluation and correction of existing fluid disorders is an integral part of surgical care. An orderly approach to these problems requires an understanding of the common fluid disturbances associated with surgical illness and adherence to a few simple guidelines.

The analysis of a particular fluid disorder may be facilitated by categorizing the abnormalities as volume, concentration, and compositional changes. Although some disease states produce characteristic changes in fluid balance, much confusion may be avoided by regarding each disturbance as a separate entity. There are no shortcuts; close observation of the patient and frequent reevaluation of the clinical situation is the most rewarding approach. For example, volume changes cannot be accurately predicted from a knowledge of the level of serum sodium because an extracellular fluid volume deficit or excess may exist with a normal, low, or high sodium concentration. Similarly, any of the four primary acid-base disturbances may be associated with any combination of volume and concentration abnormalities.

Correction of Volume Changes

Changes in the volume of extracellular fluid are the most frequent and important abnormalities encountered in the surgical patient. Depletion of the extracellular fluid compartment without changes in concentration or composition is a common problem. The diagnosis of volume changes is made almost entirely on clinical grounds. The signs that will be present in an individual patient depend not only on the relative or absolute quantity of extracellular fluid that has been lost but also on the rapidity with which it is lost and the presence or absence of signs of associated disease.

Volume deficits in the surgical patient may result from external loss of fluids or from an internal redistribution of extracellular fluid into a nonfunctional compartment. It usually involves a combination of the two, but the internal redistribution frequently is overlooked.

The phenomenon of internal redistribution or translocation of extracellular fluid is peculiar to many surgical diseases; in the individual patient, the loss may be quite large. Although the concept of a "third space" is not new, it usually is considered only in relation to patients with massive ascites, burns, or crush injuries. Of more importance is the third-space loss into the peritoneum, the bowel wall, and other tissues with inflammatory lesions of the intraabdominal organs. The magnitude of these losses may not be fully appreciated without realization that the peritoneum alone has approximately 1.8 m² of surface area. A slight increase in thickness from sequestration of fluid, which would not be appreciated on casual observation, may result in a functional loss of several liters of fluid. Swelling of the bowel wall and mesentery and secretion of fluid into the lumen of the bowel cause even larger losses. Similar deficits may occur with massive infection of the subcutaneous tissues (necrotizing fasciitis) or with severe crush injury.

These "parasitic" losses remain a part of the extracellular fluid space and may be measured as a slowly equilibrating volume. The term *nonfunctional* is used because the fluid is no longer able to participate in the normal functions of the extracellular compartment and may just as well have been lost externally. Any transfer of intracellular fluid to the extracellular compartment for replenishment of the loss is insignificant in the acute phase. The patient with ascites may have an enormous total extracellular fluid volume, but the functional component is severely depleted. The same is true of extensive inflammatory or obstructive lesions of the gastrointestinal tract, although the loss is not as obvious. These losses evoke the signs and symptoms of an extracellular fluid volume deficit with or without the concomitant external loss of fluids.

Exact quantification of these deficits is impossible and probably unnecessary. The defect can be estimated on the basis of the severity of the clinical signs. A mild deficit represents a loss of approximately 4 percent of body weight; a moderate loss is 6 to 8 percent of body weight; and a severe deficit is approximately 10 percent of body weight. Cardiovascular signs predominate when there is acute rapid loss of fluid from the extracellular fluid compartment with few or no tissue signs. In addition to the estimated deficit, fluids lost during treatment must be replaced.

Immediately after diagnosis of a volume deficit, prompt fluid replacement with a balanced salt solution should be started. Continuing therapy is tailored to the response of the patient, based on frequent clinical examination. Reliance on a formula or a single clinical sign to determine the adequacy of resuscitation is perilous. Rather, reversal of the signs of the volume deficit, combined with stabilization of the blood pressure and pulse and an hourly urine volume of 30 to 50 mL are used as general guidelines. An adequate hourly urine output, although usually a reliable index of volume replacement, may be totally misleading. The excessive administration of glucose (over 50 g in a 2- to 3-h period) may result in osmotic diuresis, while an osmotic agent such as mannitol tends to produce urine at the expense of the vascular volume. Patients with chronic renal disease or incipient acute renal damage from shock and injury also may have inappropriately high urinary volumes. In addition, the rapid administration of salt solutions may transiently expand the intravascular volume, increase the glomerular filtration rate, and result in an immediate outpouring of urine, although the total extracellular fluid space remains quite depleted.

The choice of the proper fluid for replacement depends on concomitant concentration or compositional abnormalities. With pure extracellular fluid volume loss or when only minimal concentration or compositional abnormalities are present, the use of a balanced salt solution, such as lactated Ringer's, is desirable.

Rate of Fluid Administration

The rate of fluid administration varies considerably, depending on the severity and type of fluid disturbance, the presence of continuing losses, and the cardiac status. The most severe volume deficits may be safely replaced initially with isotonic solutions at rates up to 2000 mL/h, with the rate reduced as the fluid status improves. Constant observation by a physician is mandatory when the administration exceeds 1000 mL/h. At these rates a significant portion may be lost as urinary output because of a transient overexpansion of the plasma volume.

In elderly patients, associated cardiovascular disorders do not preclude correction of existing volume deficits, but they do necessitate slower, more careful correction with constant monitoring of the cardiopulmonary system. If urinary output is not promptly restored, measurements of central filling pressures and cardiac output may be required in order to prevent renal injury from insufficient volume restoration.

Correction of Concentration Changes

If severe symptomatic hyponatremia or hypernatremia complicates the volume loss, prompt correction of the concentration abnormality to the extent that symptoms are relieved is

necessary. Volume replenishment should be accomplished with slower correction of the remaining concentration abnormality. For immediate correction of severe hyponatremia, 5% sodium chloride solution or molar sodium lactate solution is used, depending on the patient's acid-base status. In any case, the sodium deficit can be estimated by multiplying the decrease in serum sodium concentration below normal (in mEq/L) by the total body water (in L). Initially, up to one-half of the calculated amount of sodium may be administered slowly, followed by clinical and chemical reevaluation of the patient before any additional infusion of sodium salts.

This estimate is based on total body water, because the effective osmotic pressure in the extracellular compartment cannot be increased without increasing this function proportionally in the intracellular compartment. Although absolute reliance on any formula is undesirable, proper use of this estimate allows a safe quantitative approximation of the sodium deficit. Only a portion of the total deficit is replaced initially to relieve acute symptoms. Further correction is facilitated when renal function is restored by correction of the volume deficit. If the total calculated deficit were given rapidly, severe hypervolemia might occur, particularly in patients with limited cardiac reserve. The infusion of small, successive increments of hypertonic saline solution with frequent evaluation of the clinical response and serum sodium concentration is recommended.

In the treatment of moderate hyponatremia with an associated volume deficit, volume replacement can be started immediately with concomitant correction of the serum sodium deficit. Isotonic sodium chloride solution (normal saline) is used initially in the presence of metabolic alkalosis, and M/6 sodium lactate (167 mEq/L each of sodium and lactate) is used to correct an associated acidosis. Correction of the serum sodium concentration may require only a few liters of these solutions; the remainder of the volume deficit may be replaced with lactated Ringer's solution.

Treatment of hyponatremia associated with volume excess is by restriction of water. In the presence of severe symptomatic hyponatremia, a small amount of hypertonic salt solution may be infused cautiously to alleviate symptoms. Because this will cause additional volume expansion, it is contraindicated in patients with limited cardiac reserve; peritoneal dialysis or hemodialysis is preferred in this situation.

For the correction of severe, symptomatic hypernatremia with an associated volume deficit, 5% dextrose in water may be infused slowly until symptoms are relieved. If the extracellular osmolality is reduced too rapidly, however, convulsions and coma may result. For this reason, correction of hypernatremia concomitant with repletion of the volume deficit by half-strength sodium chloride or half-strength lactated Ringer's solution is safer in most cases. In the absence of a significant volume deficit, water should be administered cautiously since dangerous hypervolemia may result; constant observation and frequent determinations of the serum sodium concentration are indicated. The problem is simplified when a sufficient quantity of fluid has been given to permit renal excretion of the solute load.

Composition and Miscellaneous Considerations

Correction of existing potassium deficits should be started after an adequate urine output is obtained, particularly in the patient with metabolic alkalosis because this may be secondary to or aggravated by potassium depletion. Calcium and magnesium rarely are needed during preoperative resuscitation but should be given as indicated, particularly to patients with massive subcutaneous infections, acute pancreatitis, or chronic starvation.

Fluid abnormalities also must be suspected in the patient for whom an elective procedure is planned. Chronic illnesses frequently are associated with extracellular fluid volume deficits, and concentration and compositional changes are not uncommon. Correction of anemia and recognition of the fact that a concentrated blood volume may exist in the chronically debilitated patient is of obvious importance. The hematocrit level increases approximately 3 percent after the infusion of one unit of packed red blood cells into the adult of average size. The increase may be significantly greater in the patient with a contracted intravascular volume, indicating the need for concurrent volume replacement.

The prevention of volume depletion during the preoperative period is important. Prolonged periods of fluid restriction in preparation for various diagnostic procedures, and the use of cathartics and enemas for preparation of the bowel may cause a significant acute loss of extracellular fluid. Prompt recognition and treatment of these losses is necessary to prevent complications during the operative period.

Intraoperative Fluid Management

If preoperative replacement of extracellular fluid volume has been incomplete, hypotension may develop promptly with the induction of anesthesia. This can be insidious because the ability of the awake patient to compensate for a mild volume deficit is revealed only when the compensatory mechanisms are abolished with anesthesia. This problem is prevented by maintaining baseline requirements and replacing abnormal losses of fluids and electrolytes by intravenous infusions in the preoperative period.

In addition to blood losses during operation, there appear to be extracellular fluid losses during major operative procedures. Some of these, including edema from extensive dissection, collections within the lumen and wall of the small bowel, and accumulations of fluid in the peritoneal cavity, are clinically discernible and well recognized. They are believed to represent distributional shifts, in that the functional volume of extracellular fluid is reduced, but not externally lost from the body. These functional losses often are referred to as "parasitic losses," "third space edema," or "sequestration" of extracellular fluid. Another source of extracellular fluid loss during major operative trauma is the wound, though this is a smaller loss and difficult to quantify except in extensive and major operative procedures.

At the beginning of the twentieth century surgeons became aware that many changes occurred in urinary output, blood volume, and fluid and electrolyte composition during and after surgery. Assessment of these changes awaited the development of analytic techniques and their application to patient studies. In the following 25 years, saline solutions in varying combinations were given to patients undergoing operation, often in excessive amounts. Work in the late 1930s and early 1940s by Moyer and others indicated that during and after operative procedures, saline and water solutions should be withheld entirely because most of the fluid administered is retained.

The possibility was recognized that the operative and postoperative retention of salt and water administered in relatively small amounts might be physiologic retention to replace a deficit of salt and water incurred by the operative procedure. Subsequent studies revealed that functional extracellular fluid decreases with major abdominal operations, largely as sequestered loss into the operative site. This extracellular fluid volume deficit can be replaced during the operative procedure. These data led to the conclusion that the need for an extracellular "mimic" in the form of balanced salt solution can be clinically estimated. Intraoperative correction of the volume deficit with salt solution markedly reduces postoperative oliguria but is not intended to substitute for blood replacement. It is believed to be a physiologic supplement, or an adjunct, to replace sequestered losses.

The pendulum thus swung from the indiscriminate use of salt solutions in the first quarter of the twentieth century to almost total withholding of fluid and electrolytes from surgical patients in the second quarter of the century; today indications are that proper management lies between these two extremes. Some guidelines are necessary for the intraoperative administration of saline solutions as a "mimic" for the sequestered extracellular fluid. Because this varies from an almost imperceptible minimum to a high of approximately 3 L during an uncomplicated procedure, quantification is extremely difficult with available means of measuring functional extracellular fluid. Consequently, no accurate formula for intraoperative fluid administration can be derived. Some arbitrary but clinically useful guidelines are as follows: (1) Blood should be replaced to maintain an acceptable red blood cell mass irrespective of any additional fluid and electrolyte therapy. (2) The replacement of extracellular fluid should begin during the operative procedure. (3) Balanced salt solution needed during operation is approximately 0.5 to 1 L/h, but only to a maximum of 2 to 3 L during a 4-h major abdominal procedure, unless there are other measurable losses.

Using a similar fluid regimen, Thompson and associates reported experiences in a series of 670 patients undergoing major aortoiliac reconstructive procedures. In this group of patients, the average amount of lactated Ringer's solution administered was 3555 mL, giving an average intraoperative replacement of salt solution of 677 mL/h of operative procedure. In the last 6 years of this study there were only two deaths in 298 operations, an operative mortality of 0.67 percent. Among all 670 patients, only two patients died of renal failure, an incidence of 0.3 percent. No patient died of pulmonary insufficiency. This extremely low incidence of renal failure, even in the presence of extensive operative trauma, is similar to the authors' data for major abdominal operative procedures.

Data reported by Virgilio and others indicate that in the previously healthy surgical patient, the addition of albumin to intraoperative blood and extracellular fluid replacement is not only unnecessary but also potentially harmful. Data by Shires on operative measurements of cardiac function and extravascular lung water indicate that optimal function is obtained with replacement of blood and an extracellular "mimic" without the addition of extra albumin.

The addition of crystalloid fluid resuscitation, in appropriate volume, to blood replacement in the past quarter century has markedly improved the ability to maintain intraoperative homeostasis and avoid organ injury associated with inadequate volume replacement.

Postoperative Fluid Management

Immediate Postoperative Period

Orders for postoperative fluids are not written until the patient is in the recovery room and the fluid status has been assessed. Evaluation at this point should include a review of preoperative fluid status, the amount of fluid loss and gain during operation, and clinical examination of the patient with assessment of the vital signs and urinary output. Initial fluid orders are written to correct any *existing* deficit, followed by maintenance fluids for the remainder of the day. For the patient with complications who has received or lost large amounts of fluid, it is frequently difficult to estimate what the fluid requirements will be for the first 24 h after operation; hence intravenous fluids are ordered 1 L at a time, and the patient is checked frequently until the situation is clarified. Proper replacement of fluids during this relatively short period facilitates subsequent fluid management.

Immediately after operation, extracellular fluid volume depletion may occur as a result of continued losses of fluid at the site of injury or operative trauma, e.g., into the wall or lumen of the small intestine. Several liters of extracellular fluid may be slowly deposited in such areas within a few hours or over the first postoperative day or so. Unrecognized deficits of extracellular fluid volume during the early postoperative period are manifested primarily as circulatory instability. The signs of volume deficiency in other organ systems may be delayed for several hours with this type of fluid loss. Postoperative hypotension and tachycardia require prompt investigation and appropriate therapy. The usually accepted adequate blood pressure of 90/60 mmHg and a pulse of less than 120 in postoperative patients may not be sufficient to prevent renal ischemia unless, in addition to lack of signs of shock, urine flow is adequate (30 to 50 mL/hour). Evaluation of the level of consciousness, pupillary size, airway patency, breathing patterns, pulse rate and volume, skin warmth and color, body temperature, urine output, and a critical review of the operative procedure and the operative fluid management, are recommended. Because operative trauma frequently involves loss or transfer of significant quantities of whole blood, plasma, or extracellular fluid that can be only grossly estimated, circulatory instability is most commonly caused by underestimated initial losses or insidious, concealed continued losses. Operative blood loss usually is estimated by the operating surgeon to be 15 to 40 percent less than the isotopically measured blood loss from that patient. For a patient with circulatory instability, further volume replacement of an additional 1000 mL isotonic salt solution, while determining whether continuing losses or other causes are present, often resolves the problem.

It is unnecessary and probably unwise to administer potassium during the first 24 h after operation unless a definite potassium deficit exists. This is particularly important for the patient subjected to prolonged operative trauma involving one or more episodes of hypotension and for the posttraumatic patient with hemorrhagic hypotension. Oliguric renal failure or the more insidious high-output renal failure may develop, and the administration of even a small quantity of potassium may be detrimental.

Later Postoperative Period

The problem of volume management during the postoperative convalescent phase is one of accurate measurement and replacement of all losses. In the otherwise healthy individual, this involves the replacement of measured sensible losses, which usually are of gastrointestinal origin, and the estimation and replacement of insensible losses.

The insensible loss usually is relatively constant and averages 600 mL/day. This may be increased by hypermetabolism, hyperventilation, and fever to a maximum of approximately 1500 mL/day. The estimated insensible loss is replaced with 5% dextrose in water. This loss may be partially offset by an insensible gain of water from excessive tissue catabolism in the postoperative patient with complications, particularly if associated with oliguric renal failure.

Approximately 1 L of fluid should be given to replace that volume of urine required to excrete the catabolic end products of metabolism (800 to 1000 mL/day). In the individual with normal renal function, this may be given as 5% dextrose in water because the kidneys are able to conserve sodium with excretion of less than 1 mEq daily. It is probably unnecessary to stress the kidneys to this degree, however, and a small amount of salt solution may be given in addition to water to cover urinary loss. In elderly patients with salt-losing kidneys or in patients with head injuries, an insidious hyponatremia may develop if urinary losses are replaced with water. Urinary sodium in these circumstances may exceed 100 mEq/L and result in a daily loss of significant amounts of sodium. Measurement of urinary sodium facilitates accurate replacement.

Urine volume is not replaced on a milliliter-for-milliliter basis. A urinary output of 2000 to 3000 mL on a given day may represent diuresis of fluids given during surgery or may represent excessive fluid administration. If these large losses are completely replaced, the urine output progressively increases, and this may proceed to a situation resembling diabetes insipidus, with urinary outputs in excess of 10 L/day.

Sensible losses, by definition, can be measured or, as in the case of sweating, estimated. Gastrointestinal losses usually are isotonic or slightly hypotonic, and they are replaced with an essentially isotonic salt solution. When the estimated loss is slightly above or below isotonicity, appropriate corrections can be made in the daily water administration, while isotonic salt solutions are used to replace these losses volume for volume. Sweating usually is not a problem except with the febrile patient, in whom losses may, but seldom do, exceed 250 mL/day per degree of fever. Excessive sweating may represent a considerable loss of sodium in the unacclimatized individual.

Determination of serum electrolyte levels usually is unnecessary in the patient with an uncomplicated postoperative course maintained on parenteral fluids for 2 to 3 days. A more prolonged period of parenteral replacement or one complicated by excessive fluid losses requires frequent determinations of the serum sodium, potassium, and chloride levels and of carbon dioxide combining power. Adjustments then can be made with intravenous fluids of appropriate composition.

Daily maintenance fluid should be administered at a steady rate while the losses are incurred. If given over a shorter period, renal excretion of the excess salt and water may occur while the normal losses continue over the full 24-h period. For the same reason, fluids of different composition are alternated, and additives to intravenous fluids (e.g., potassium chloride and antibiotics) are evenly distributed in the total volume of fluid given.

Daily fluid orders should begin with an assessment of the patient's volume status and a check for possible concentration of compositional disorders as reflected by proper laboratory determinations. All measured and insensible losses are replaced with fluids of appropriate composition, with allowances made for any preexisting deficit or excess. The amount of potassium replacement is 40 mEq daily for renal excretion of potassium in addition to approximately 20 mEq/L for replacement of gastrointestinal losses. Inadequate replacement may prolong the usual postoperative ileus and contribute to the insidious development of a resistant metabolic alkalosis. Calcium and magnesium are replaced when needed.

Special Considerations in the Postoperative Patient Volume Excesses

The administration of isotonic salt solutions in excess of volume losses (external or internal) may result in overexpansion of the extracellular fluid space. The otherwise normal person in a postoperative state tolerates an acute overexpansion extremely well. Excesses administered over several days, however, will soon exceed the kidneys' ability to excrete sodium. It is important to determine accurately, from intake and output records and serum sodium concentrations, the actual needs of the patient managed over several postoperative days. Attention to the signs and symptoms of overload usually prevents volume excess. It occurs most frequently with attempts to meet excessive volume losses that are not measurable, such as those resulting from incompletely controlled fistula drainage.

The earliest sign of volume overload is weight gain during the catabolic period, when the patient should be losing $\frac{1}{4}$ to $\frac{1}{2}$ lb/day. Heavy eyelids, hoarseness, or dyspnea on exertion may appear rapidly. Circulatory and pulmonary signs of overload appear late and represent a massive overload. Peripheral edema may be a sign, but it does not necessarily indicate volume excess. In the absence of additional evidence for volume overload, other causes for peripheral edema should be considered. Overexpansion of the *total* extracellular fluid may coexist with *depletion* of the functional extracellular fluid compartment, along with decreased effective circulating plasma volume.

Hyponatremia

Significant postoperative alterations in serum sodium concentration are infrequent when the fluid resuscitation during operation has included adequate volumes of isotonic salt solutions. The kidneys retain the ability to excrete moderate excesses of salt water administered in the early postoperative period if functional extracellular fluid has been adequately replaced during the operative or immediate postoperative period. Previous studies of sodium balance revealed that patients do excrete sodium after the functional deficit incurred by the shift of extracellular fluid has been replaced. Wright and Gann demonstrated normal capacity to excrete water postoperatively when isotonic salt solutions are administered before a challenge with a water load. The commonly described hyponatremia associated with surgical procedures and traumatic injury is prevented by the replacement of extracellular fluid deficits. The daily maintenance of normal osmolarity is simplified by the replacement of observable losses of sodium content.

Hyponatremia may occur easily when water is given to replace losses of sodium-containing fluids or when water administration consistently exceeds water losses. The latter may occur with oliguria or in association with decreased water loss through the skin and lungs, intracellular shifts of sodium, or the cellular release of excessive amounts of endogenous water. Severe or refractory hyponatremia is unlikely to occur when renal function remains normal.

In the presence of hyperglycemia, determination of the glucose concentration is necessary to evaluate the significance of a depressed serum sodium level. Because glucose does not enter cells by passive diffusion, it exerts an osmotic force in the extracellular compartment. This contribution to osmotic pressure is normally small, but with an elevated glucose concentration the increased osmotic pressure causes the transfer of cellular water into the extracellular compartment, resulting in a dilutional hyponatremia. Hence hyponatremia may be observed when the total effective osmotic pressure in the extracellular compartment is normal or even above normal. Each 100-mg/dL rise above normal in the blood glucose level results in a decrease in the serum sodium concentration of 1.6 to 3 mEq/L.

Endogenous Water Release

The patient maintained on intravenous fluids without adequate caloric intake will, between the fifth and tenth days, gain significant quantities of water (maximum 500 mL/day) from excessive cellular catabolism, thereby decreasing the quantity of exogenous water required per day.

Intracellular Shifts

Systemic bacterial sepsis often is accompanied by a precipitous drop in serum sodium concentration. This sudden change is poorly understood, but it usually accompanies loss of extracellular fluid as interstitial or intracellular sequestrations. The condition can be treated by withholding free water, restoring extracellular fluid volume, and initiating treatment of the sepsis.

Hypernatremia

Hypernatremia (serum sodium concentration above 150 mEq/L), although uncommon, is a dangerous abnormality. Unlike decreased serum sodium concentration, hypernatremia is produced easily when renal function is normal. The extracellular fluid hyperosmolarity results in a shift of intracellular water from within the cell to the extracellular fluid compartment; in this situation, a high serum sodium level may indicate a significant deficit of total body water. In surgical patients hypernatremia is most often the result of excessive or unexpected water losses, but it may result from use of salt-containing solutions to replace water losses. Classification of water losses may be helpful in preventing and treating this abnormality.

Excessive Extrarenal Water Losses

With increased metabolism from any cause, but particularly when it is associated with fever, the water loss through evaporation of sweat may reach a level of several liters daily. Patients with a tracheostomy in a dry environment can (with high minute volumes) lose as much as 1 to 1.5 L of water/day by this route. Increased water evaporation from a granulating surface is of significant magnitude in the thermally injured patient, with losses as great as 3 to 5 L/day.

Increased Renal Water Losses

Extremely large volumes of solute-poor urine may result from hypoxic damage to the distal tubules and collecting ducts or loss of antidiuretic hormone stimulation from damage to the central nervous system. In both instances, facultative water resorption is impaired. The former occurs in high-output renal failure; this is the most common type of renal failure after severe injury or operative trauma. The latter occurs with extensive head injuries accompanied by temporary diabetes insipidus.

Solute Loading

High protein intake may produce an increased osmotic load of urea that necessitates the excretion of large volumes of water. Hypernatremia, azotemia, and extracellular fluid volume deficits follow. These can be prevented by an intake of 7 mL of water per gram of dietary protein.

Excessive glucose administration results in the need for a large volume of water for excretion. Osmotic diuretics, such as mannitol and urea, also result in the obligatory excretion of a large volume of water and increased urinary sodium losses. In addition, isotonic salt solutions, if used to replace pure water losses, rapidly produce hypernatremia.

Acute Renal Failure

Acute renal insufficiency after trauma or surgical stress is a lethal complication. The diagnosis is based on persistent oliguria and chemical evidence of uremia after stabilization of the circulation. The clinical course is characterized by oliguria lasting from several days to several weeks followed by a progressive rise in daily urine volume until the excretory and concentrating functions of the kidney are gradually restored.

Acute renal failure is classified according to its cause as prerenal, renal, or postrenal (Table 2-10). The most common cause is sequestered or third-space loss in the area of the surgical procedure. Shock from blood loss and occlusion of small arteries (e.g., renal artery emboli) also may cause prerenal failure. Renal artery occlusions are less common causes than volume depletion or hypotensive shock. The common intrarenal causes of renal failure in the postoperative patient include endotoxemia, trauma, drugs (such as aminoglycosides), or the generation of pigment delivery to the kidneys (as with myoglobin), or destabilized hemoglobin (as with a cardiac bypass machine). Postrenal causes are

almost always because of obstruction of the ureter, the bladder, or the urethra.

Therapy of acute renal failure after surgery begins with removal of the cause. With prerenal azotemia, for example, correction of the extracellular fluid volume deficit with an extracellular fluid volume mimic, such as lactated Ringer's solution, will correct the oliguria and increase retention of nitrogenous products such as creatinine. With intrarenal causes, correction of sepsis or removal of nephrotoxic drugs such as aminoglycosides is mandatory. Postrenal obstruction is generally the result of stone, tumor, or surgical misadventures resulting in ureteral occlusion, or perhaps benign prostatic hypertrophy. One of the more common causes of postoperative oliguria is a blocked Foley catheter.

Therapy is directed not only at the cause of the renal failure but also at maintaining homeostasis within the biochemical abnormalities that ensue. The significant biochemical abnormalities are as follows:

(1) Metabolic acidosis results from failure of renal excretion of fixed acids and the inability to maintain respiratory compensation.

(2) Hyperkalemia is a result of large amounts of intracellular potassium released in acute renal failure. Serum potassium level is elevated by the systemic acidosis and must be corrected early.

(3) Hyponatremia is a commonly observed electrolyte disturbance in patients with acute renal failure. Production of metabolic water from metabolism of nutrients and liberation of water from intracellular breakdown contribute to the excess of free water.

(4) Hyperphosphatemia and hypocalcemia usually evolve in patients with posttraumatic acute renal failure because of inadequate excretion and excessive release from injured tissue.

(5) Hypermagnesemia occurs regularly because the kidney is the major organ for regulating magnesium balance. Magnesium levels can rise rapidly in patients with acute renal failure, particularly if magnesium-containing preparations such as antacids are administered.

Predisposing Factors

A number of specific factors may contribute to the development of postoperative renal failure, including the following:

Trauma

Trauma generally contributes to acute renal failure in the surgical patient as a result of the hypovolemic shock caused by blood loss. In addition, myoglobinuria may accompany severe trauma if there has been significant crush injury with rhabdomyolysis. Similarly, if the patient has received blood transfusions after trauma, small amounts of incompatible blood will produce intravascular hemolysis and hemoglobinuria, leading to acute renal failure. Extracellular fluid volume depletion is a common complicating factor in the trauma patient because of the development of prolonged ileus, peritonitis, or sequestration of fluid at a site of injury producing hypovolemia. The development of sepsis is a further contributing factor in these patients.

Sepsis

The onset of sepsis from any cause, including specific infections, such as urinary, biliary, or intraperitoneal sepsis and contamination from colon procedures or from severe trauma, causes acute renal failure. Endotoxin from any source is the priming agent for the release of endogenously produced cytokines, such as tumor necrosis factor (TNF), that have been shown clearly to produce acute renal failure. It must be remembered that nephrotoxic antibiotics that are used to treat sepsis may themselves cause or worsen acute renal failure.

Cardiopulmonary bypass

As many as 5 to 25 percent of patients who have had prolonged cardiopulmonary bypass have oliguric renal failure or the less frequently lethal nonoliguric renal failure. This is most likely from hypoperfusion of the kidneys.

Renal transplantation

Failure of a transplanted kidney to function in the early postoperative period should raise questions concerning technical problems with the renal artery, obstruction of urinary flow, or intravascular volume problems because of continued bleeding in the patient. Hyperacute rejection, which is uncommon, also should be considered.

Urologic surgery

Urologic procedures pose additional and specific problems for development of acute renal failure after surgery. These problems usually are caused by obstruction in one form or another. Obstruction may occur at the level of the kidney, ureter, bladder, or urethra as a result of urologic procedures. Removal of the obstruction or cause of obstruction should relieve the acute renal failure. The presence of obstruction can be determined by radiographic, tomographic, and computed tomography studies.

Vascular disease

If the blood flow to the kidney is interrupted for a prolonged period, as in operations on the abdominal aorta or the renal artery, acute renal failure may result. Acute renal failure may be delayed because of an obstruction from an organizing hematoma around a vascular anastomosis or ureteral strictures at the site of the ureteral devascularization. Similarly, immediate postoperative hemorrhage may cause hypovolemia and acute renal failure.

Preexisting renal disease

This can contribute to postoperative renal failure. When the kidney is diseased because of nephrosclerosis, diabetes, chronic glomerulonephritis, or chronic tubular interstitial nephritis, the organ is predisposed to the development of acute renal failure.

Radiographic contrast agents

When used preoperatively, contrast agents can be a predisposing factor; a transient reduction in renal function might have occurred preoperatively.

Drugs

A number of drugs can lead to postoperative renal toxicity and acute renal failure. The most prominent are the aminoglycosides, for which renal toxicity has been reported, even with careful monitoring and maintenance of recommended drug levels. Cyclosporine, amphotericin B, and nonsteroidal anti-inflammatory drugs also may contribute to postoperative acute renal failure. The commonly used chlorinated inhalation anesthetic agents have been responsible for primary acute renal failure after operation as well.

Laboratory Studies

Urinalysis

Examination of the urine is an essential diagnostic test in patients with postoperative renal failure. The presence of blood or myoglobin is a positive diagnostic test, and red cell casts may be present in the urine of patients with urinary obstruction. Sodium, creatinine, urea, and osmolality levels should be measured in the urine.

Urine Osmolality

Patients with acute renal failure are isosthenuric; that is, the urine osmolality is close to that of plasma, typically near 300 mOsm/L. Patients with prerenal azotemia have osmolalities of 500 mOsm/L or more (Table 2-11). The ratio of urine-to-plasma osmolality has been shown to be more discriminating than urinary values alone. Urine-to-plasma osmolality ratios of less than 1:10 are consistent with acute renal failure, but prerenal azotemia usually produces ratios of 1:25 or higher.

Urine Urea and Creatinine

The urine-to-plasma urea and urine-to-plasma creatinine ratios are the most useful in diagnosing acute renal failure postoperatively. A urine-to-plasma creatinine ratio below 20 is indicative of acute renal failure, and a ratio above 40 indicates prerenal azotemia. A urine-to-plasma urea ratio of less than 3 indicates tubular injury, and a ratio above 8 usually indicates prerenal azotemia.

Urine Sodium

The underperfused kidney is sodium retaining, and a low urine sodium concentration is characteristic of prerenal azotemia. However, when acute renal failure has occurred, there is diminished sodium reabsorption by the kidney. Patients with acute renal failure usually have a higher urine sodium level (above 40 mEq/L). Values of urine sodium concentration between 20 and 40 mEq/L are nondiscriminatory. Consequently, urine sodium concentration is not as sensitive in providing diagnostic accuracy as is the urine-to-plasma urea ratio.

Management of the Patient with Established Acute Renal Failure

When the diagnosis of acute renal failure is made with rising levels of blood urea nitrogen and creatinine and low urine volume, initial efforts should be directed toward correcting reversible causes. Attention then is turned to fluid and electrolyte balance problems occurring because of acute renal failure and adjusting the dosage of any administered drug to compensate for impaired elimination.

Fluid and Electrolyte Management

Hyperkalemia

Of all the electrolyte abnormalities that are encountered in acute renal failure, hyperkalemia is the most serious, and it must be treated early. Untreated hyperkalemia leads to cardiac arrest. The severity of the hyperkalemia can be estimated by the ECG changes, including peaked T waves, prolonged PR intervals, loss of P waves, and widening of the QRS complex.

When significant ECG changes are apparent, calcium infusion with 1 to 2 g 10% calcium gluconate should be administered over 10 to 15 min to stabilize the cardiac membranes and neutralize the toxic effects of hyperkalemia. This therapy frequently is lifesaving, but the serum potassium level must be lowered quickly. This may include the administration of insulin, concentrated glucose, and intravenous sodium bicarbonate. Enteric cation-exchange resins or dialysis therapy must be used fairly soon to remove the potassium from the body.

Fluid Volume

In a patient with renal failure and little or no urine output, excessive intake of salt and water will be retained, eventually causing pulmonary edema and congestive heart failure. Fluid intake should be restricted to replacing measured fluid losses plus 500 to 600 mL per day of insensible loss. Careful balance studies of intake and output are mandatory. Once any extracellular fluid volume deficits have been corrected, the quantity of maintenance fluids amount only to measurable losses and insensible loss.

Hyponatremia

Hyponatremia evolves early, usually because of excessive free water availability from breakdown of protein, carbohydrate, and fat as well as administered free water. If serum sodium concentration falls below 120 mEq/L, dialysis is the only therapeutic endeavor that corrects hyponatremia.

Metabolic Acidosis

Metabolic acidosis is almost inevitable when the kidney fails to remove acid by-products from the body. Treatment involves the use of sodium bicarbonate, but dialysis is often required as well. Excessive restriction of protein in the catabolic injured patient in order to delay the need for dialysis is not advisable.

Other Electrolyte Abnormalities

Hypocalcemia and hyperphosphatemia may occur in the patient who has experienced a crush injury or a burn covering a significant proportion of body surface area. Severe hyperphosphatemia may require dialysis. Hypocalcemia can be managed with careful replacement of calcium.

Use of Dialysis in Acute Renal Failure

The indications for dialysis are listed in Table [2-12](#). Dialysis is best initiated before the occurrence of the life-threatening complications of acute renal failure such as hyperkalemia, severe acidosis, uremic encephalopathy, or uremic pericarditis. There are four forms of dialysis for acute renal failure: hemodialysis, peritoneal dialysis, continuous arterial-venous dialysis, and continuous venovenous ultrafiltration.

Hemodialysis is the most effective and is the treatment of choice in the very hypercatabolic patient. Hemodialysis may require 4 to 5 h of daily dialysis to counteract the effects of the hypercatabolism. In others, dialysis may be done three to four times per week, depending on the rate of hypercatabolism. A major advantage of hemodialysis is that removal of fluid by ultrafiltration is easily controlled.

Peritoneal dialysis frequently is used for the patient with severe heart disease, including coronary artery disease and myocardial infarction. For these patients peritoneal dialysis may be safer than hemodialysis, with more gradual changes in volume, particularly after surgery.

Continuous therapy, such as arterial-venous and venovenous dialysis, have virtually replaced the use of hemodialysis in most postoperative patients with acute renal failure. The advantage of venovenous continuous therapy is that an arterial line is not required. A blood pump is used to maintain extracorporeal blood flow. An additional advantage of this system is that the flow is not blood pressure dependent.

High-Output Renal Failure

Uremia occurring without a period of oliguria and accompanied by a daily urine volume greater than 1000 to 1500 mL/day is a more frequent but less well recognized disorder than acute renal insufficiency. Clinical experience and laboratory experiments suggest that high-output renal failure represents the renal response to a less severe or a modified episode of renal injury than that required to produce classic oliguric renal failure; it is thus a milder form of renal insufficiency. Through serial measurement of blood urea nitrogen and serum electrolytes, informed chemical and fluid volume management of high-output renal failure can be carried out with a much greater latitude because of the daily urine volume excretion. Normal extracellular fluid volume and normal serum sodium concentration are easily maintained when accurate daily outputs of each are obtained and replaced accordingly. The sodium-containing fluids may be administered with lactate to control the mild metabolic acidosis that occurs. Severe acidosis may develop if isotonic losses from the gastrointestinal tract or renal excretion of sodium are replaced with sodium chloride.

The primary danger of high-output renal failure is the delay in recognition because of normal urine output. The inappropriate administration of intravenous potassium in this setting can result in hyperkalemia. Good urinary output and gastrointestinal involvement requiring suction usually indicate the need for daily potassium replacement. With this type of renal failure, potassium intoxication may be produced. As little as 20 mEq potassium chloride given intravenously may rapidly produce myocardial potassium intoxication requiring exchange resin or hemodialysis treatment.

The typical course of high-output renal failure begins without a period of oliguria. The daily urine volumes are normal or higher than normal, often reaching levels of 3 to 5 L/day while blood urea nitrogen is increasing. An attempt to decrease urine output by water restriction rapidly results in hypernatremia without a change in urine volume. On the average, urea nitrogen continues to increase for 8 to 12 days before a downward trend occurs. The blood-to-urine urea ratio is about 1:10 until a decrease occurs in the blood urea concentration.

Functionally, the disorder is characterized by a glomerular filtration rate of less than 20 percent of normal and complete resistance to vasopressin for 1 to 3 weeks after the blood urea nitrogen has declined. During the next 6 to 8 weeks, the glomerular filtration rate gradually rises, and the response to vasopressin becomes normal.

CHAPTER 3 - Hemostasis, Surgical Bleeding, and Transfusion

Seymour I. Schwartz

BIOLOGY OF HEMOSTASIS

Hemostasis is a complex process that prevents or terminates blood loss from a disrupted intravascular space, provides a fibrin network for tissue repair, and, ultimately, removes the fibrin when it is no longer needed (Fig. 3-1). Endothelial cells functionally act to prevent clotting. They interfere with platelet recruitment by inactivating *adenosine diphosphate (ADP)*. They provide an environment in which thrombin is also inactivated by complexing with antithrombin III. Endothelial cells release thrombomodulin, which down- modulates the coagulation process. Four major physiologic events participate, both in sequence and interdependently, in the hemostatic process. Vascular constriction, platelet plug formation, fibrin formation, and fibrinolysis occur in that general order, but the products of each of these four processes are interrelated in such a way that there is a continuum and multiple reinforcements (Fig. 3-2).

Vascular Constriction

Vasoconstriction is the initial vascular response to injury, even at the capillary level. It is dependent upon local contraction of smooth muscle that has a reflex response to various stimuli. The initial vascular constriction occurs before any platelet adherence at the site of injury. Adherence of endothelial cells to adjacent endothelial cells may be sufficient to cause cessation of blood loss from the intravascular space. Vasoconstriction is subsequently linked to platelet plug and fibrin formation. *Thromboxane A₂ (TXA₂)*, which results from the release of arachidonic acid from platelet membranes during aggregation, is a powerful vasoconstrictor. By contrast, prostacyclin, which is also secreted during the platelet release reaction, is a potent vasodilator. Serotonin, 5-hydroxytryptamine (5-HT), released during platelet aggregation, is another vasoconstrictor, but it has been shown that when platelets have been depleted of serotonin in vivo, constriction is not inhibited. Bradykinin and fibrinopeptides in the coagulation schema are also capable of contracting smooth muscle. Some patients with mild bleeding disorders and a prolonged bleeding time have, as their only abnormality, capillary loops that fail to constrict in response to injury.

A lateral incision in a small artery may remain open because of physical forces, whereas complete transection of a similarly sized vessel contracts to the extent that bleeding may cease spontaneously. The vascular response factor should also include the contribution of pressure provided by surrounding tissues. Bleeding from a small venule ruptured by trauma, in the thigh of an athlete, may be negligible because of the compressive effect of surrounding muscle. In the same individual, bleeding from a similar vessel in the nasal mucosa may be significant. When there is low perivascular pressure, as seen in patients with muscle atrophy accompanying aging, in patients on prolonged steroid therapy, and in patients with the Ehlers-Danlos syndrome, bleeding tends to be more persistent. Vascular abnormalities, such as hereditary hemorrhagic telangiectasia, may predispose the patient to bleeding from the involved region.

Platelet Function

Platelets are 2-mm diameter fragments of megakaryocytes and number 200,000 to 400,000/mm³ in circulating blood with a life span of 7 to 9 days. They play an integral role in hemostasis along two pathways. Platelets, which normally do not adhere to each other or to the normal vessel wall, form a plug that stops bleeding when vascular disruption occurs. Injury to the intima exposes subendothelial collagen to which platelets adhere within 15 s of the traumatic event. This requires von Willebrand factor (vWF), a protein that is lacking in patients with von Willebrand's disease. The platelets then expand and develop pseudopodal processes and also initiate a release reaction that recruits other platelets from the circulating blood. As a consequence, a loose platelet aggregate forms, sealing the disrupted blood vessel. The aggregation up to this point is reversible and is not associated with secretion. This process is known as *primary hemostasis*. The administration of heparin does not interfere with this reaction, which is why hemostasis can occur in the heparinized patient. *ADP* and serotonin are principal mediators in this process of adhesion and aggregation. Various prostaglandins have opposing activities. Arachidonic acid, released from platelet membranes, is converted by cyclooxygenase to prostaglandin G₂ (PGG₂) and PGH₂, which in turn are converted to *TXA₂*, a potent platelet aggregator and vasoconstrictor. By contrast, PGI₂ (prostacyclin) and PGE₂ inhibit aggregation and act as vasodilators.

ADP, released from damaged tissues and platelets, plus platelet factor 4 and trace thrombin on the platelet surface in the face of Ca²⁺ and Mg²⁺, stimulate a platelet release reaction by which the content of the platelet and its granules is discharged.

Fibrinogen is required for this process. Thrombin plays a central role in this process by stimulating platelet degranulation and activating the generation of thromboxane A₂. During this process, platelet factor 4, b- thromboglobulin, platelet-derived growth factor, *ADP*, serotonin, and calcium are introduced into the plasma. The release reaction results in compaction of the platelets and the formation of an “amorphous” plug, which is no longer reversible. This process is inhibited by cyclic adenosine monophosphate (cAMP). As a consequence of the release reaction, platelet factor 3 is made available and contributes phospholipid to several stages of the coagulation cascade.

The lipoprotein surface provided by platelets catalyzes reactions that are involved in the conversion of prothrombin (factor II) into thrombin (Fig. 3-3). Platelet factor 3 is involved in the reaction by which activated factor IX (IXa), factor VIII, and calcium activate factor X. It is also involved in the reaction by which factor Xa, factor V, and Ca²⁺ activate factor II. Platelets may also play a role in the initial activation of factors XI and XII. Platelet factor 4 and b-thromboglobulin are also made available during the release reaction, and they may inhibit the activity of heparin and modify fibrin formation. The platelets also play a role in the fibrinolytic process by releasing an inhibitor of plasminogen activation.

Coagulation

Coagulation is the process by which prothrombin is converted into the proteolytic enzyme thrombin, which in turn cleaves the fibrinogen molecule to form insoluble fibrin in order to stabilize and add to the platelet plug. Coagulation consists of a series of zymogen activation stages in which circulating proenzymes are converted in sequence to activated proteases (Fig. 3-4). The traditional concept of the clotting system evolved from test tube analysis and follows two pathways: the *intrinsic* pathway involves components normally present in blood, and the *extrinsic* pathway is initiated by the tissue lipoprotein (Fig. 3-5). In the intrinsic pathway factor XII is activated by binding to subendothelial collagen. Prekallikrein and high- molecular-weight kininogen amplify this contact phase. Activated factor XII (XIIa) proteolytically cleaves factor XI and also prekallikrein to form factor XIa and kallikrein. In the presence of Ca²⁺, factor XIa activates factor IX (IXa). This in turn complexes with factor VIII, which can be activated to a more potent form by thrombin, and, in the presence of Ca²⁺ and the phospholipid platelet factor 3, activates factor X. In the extrinsic pathway, the tissue phospholipid, thromboplastin, reacts with factor VII and Ca²⁺ to activate factor X.

Activated factor X (Xa), produced by the two pathways, proteolyses prothrombin (factor II) to form thrombin. The effects of thrombin are limited to the area of endothelial disruption by several processes. Thrombin activates the fibrin stabilizing factor (XIII) and cleaves fibrinopeptides A and B from fibrinogen (factor I) to form fibrin, a monomer that is cross-linked with factor XIIIa, to form a stable clot (Fig. 3-6). The escape of thrombin into the circulation is prevented from complexing with antithrombin locally by the binding of the thrombin to thrombomodulin on the endothelium, creating a complex that cannot cleave fibrinogen and also activating protein C, which in turn inactivates factors V and VIII. Additionally, circulating thrombin is inactivated by plasma protease inhibitors. This process is accelerated by factor V, tissue lipoproteins, platelet surface phospholipids, and Ca²⁺.

All the coagulation factors except thromboplastin, Ca²⁺, and most of factor VIII are synthesized in the liver. Factors II, VII, IX, and X require vitamin K for their production (Table 3-1).

Fibrinolysis

Fibrinolysis is a natural process directed at maintaining the patency of blood vessels by lysis of fibrin deposits. Also involved in the maintenance of vascular patency is circulating antithrombin III (ATIII) which neutralizes the action of thrombin and other proteases in the coagulation cascade.

Fibrinolysis is initiated at the same time as the clotting mechanism under the influence of circulating kinases, tissue activators, and kallikrein that are present in many organs, including venous endothelium. Fibrinolysis is dependent on the enzyme plasmin, which is derived from a precursor plasma protein (plasminogen) (Fig. 3-7). Plasminogen levels are known to rise as a consequence of exercise, venous occlusion, and anoxia. Plasminogen activation is also initiated by the activation of factor XII. The plasminogen is preferentially absorbed on fibrin deposits. The enzyme plasmin lyses fibrin and acts on other coagulant proteins as well, including fibrinogen, factor V, and factor VIII. The smaller fragments of polypeptide products of fibrin that are produced interfere with normal platelet aggregation; the larger fragments are incorporated into the clot in lieu of normal fibrin monomers and result in an unstable clot. Human blood also contains an antiplasmin that inhibits plasminogen activation, and platelets are believed to possess antifibrinolytic activity.

CONGENITAL HEMOSTATIC DEFECTS

Inheritance

The modes of inheritance of hemostatic disorders, with only rare exceptions, are of three types: (1) autosomal dominant, (2) autosomal recessive, and (3) sex-linked recessive. The most common hemostatic disorder transmitted by the autosomal dominant mode is von Willebrand's disease. Hereditary hemorrhagic telangiectasia and factor XI deficiency also appear to be transmitted in this fashion.

Occasionally, in a pedigree with an autosomal dominant gene, an *apparently* normal person may transmit disease to his or her child. The parent clearly carried the gene, which clinically expressed no defect.

In inherited hemostatic disorders, the difference in clinical expression between dominant and recessive genes is a graded one rather than an “all- or-none” phenomenon. The heterozygous individual with an autosomal recessive trait may have a measurable deficiency of the factor governed by that gene, but no clinical disease. In order to demonstrate clinical expression of disease, the individual must be homozygous. This appears to be the case, for example, in factor X deficiency. Other hemostatic disorders probably inherited in this mode are deficiencies in factor V, factor VII, and factor I.

Sex-linked recessive inheritance governs true hemophilia (factor VIII deficiency) and factor IX deficiency (Christmas disease). The genes for these diseases are recessive in expression and are carried on the female (X) chromosome. When paired with the normal X chromosome (the female carrier state), clinical disease is not present. When the affected X chromosome is paired with the normal male (Y) chromosome, clinical disease is expressed.

Platelet Deficiencies

Hereditary quantitative disorders include disorders of platelet production (hereditary thrombocytopenia) and platelet destruction (Wiskott-Aldrich syndrome). The most common congenital platelet deficiency is the abnormality seen in *von Willebrand's disease*, in which the von Willebrand factor (vWF) is missing; vWF has been shown to be required for platelet adhesion to subendothelial collagen (see section below). Also, platelets from patients with von Willebrand's disease, unlike those of normal patients, fail to aggregate in vitro with the addition of ristocetin. Another inherited disorder affecting platelets is the rare *Bernard-Soulier syndrome*. Patients with Bernard-Soulier syndrome have normal levels of vWF, and the addition of vWF does not affect aggregation of platelets in the presence of ristocetin. In Bernard-Soulier syndrome, the platelet membrane receptor for vWF, a portion

of the glycoprotein I complex, is missing.

Glanzmann's thrombasthenia is a rare congenital disorder in which platelets fail to aggregate in the presence of *ADP* and mediation of factors involved in clot retention is impaired. Patients with *congenital afibrinogenemia* also have impairment of platelet aggregation because fibrinogen is required for this process to occur. Patients with congenital afibrinogenemia have disturbed platelet function, manifested by a prolonged bleeding time correctable by fibrinogen administration.

Congenital disorders of platelet secretion include *storage pool disease*, in which the platelets lack the storage capability of *ADP* required for aggregation. The Hermansky-Pudlak syndrome (oculocutaneous albinism, ceroidlike deposits in macrophages, and bleeding diathesis) is classified in this category. Congenital *primary release defects* have also been described and are responsible for prolonged bleeding time.

Congenital Defects of Coagulation Factors

Factor VIII Deficiency (Classical Hemophilia)

Classical hemophilia (hemophilia A) is a disease of males. The failure to synthesize factor VIII in normal proportions is inherited as a sex-linked recessive trait. Spontaneous mutations account for almost 20 percent of cases. The incidence of the disease is approximately 1:10,000 to 1:15,000 population, and the clinical manifestations can be extremely variable.

Clinical Manifestations

Characteristically, the severity of clinical manifestations is related to the degree of deficiency of factor VIII. Spontaneous bleeding and severe complications are the rule when virtually no factor VIII can be detected in the plasma. When plasma factor VIII concentrations are in the range of 5 percent of normal, the patient may have no spontaneous bleeding yet may bleed severely with trauma or surgical treatment. Patients with levels greater than 5 percent of normal (greater than 0.05 units/mL) are considered mild hemophiliacs. Patients whose factor VIII levels fall between 1 and 5 percent of normal are considered moderately severe hemophiliacs. Typically, members of the same pedigree with true hemophilia have approximately the same degree of clinical manifestations.

While the severely affected patient may bleed during early infancy, significant bleeding typically is noted first when the child is a toddler. At that time, in addition to the classic bleeding into joints, epistaxis and hematuria may be noted. Bleeding that is life-threatening may follow injury to the tongue or lingual frenulum. Tracheal compression and retropharyngeal bleeding may follow tonsillar infection. Intracranial bleeding, associated with trauma in half the cases, accounts for 25 percent of deaths. Vascular and neural compromise may occur in relation to pressure secondary to bleeding into a soft-tissue closed space. Talipes equinus contracture deformity may be seen in severely hemophilic patients secondary to bleeding into the calf. Volkmann's contracture of the forearm and flexion contractures of the knees and elbows are also disabling sequelae of deep soft-tissue bleeding.

Hemarthrosis is the most characteristic orthopaedic problem. Bleeding into the joint may cause few symptoms until distention of the joint capsule occurs. A large hemarthrosis generally is manifested by a tender, swollen, warm, and painful joint. Muscle spasm and pain around the joint arise from involvement of periarticular structures. These signs may mimic infection. The same orthopaedic problems are noted in association with severe factor IX deficiency (Christmas disease).

Retroperitoneal bleeding may follow lifting of a heavy object or strenuous exercise. Signs of posterior peritoneal irritation and spasm of the iliopsoas suggest the diagnosis. Hypovolemic shock may occur, since the amount of blood loss that can take place in this setting is enormous. The clinical manifestations of intramural intestinal hematoma are nausea and vomiting, crampy abdominal pain, and signs of peritoneal irritation that mimic those of appendicitis. Fever and leukocytosis may be noted. Radiographs of the abdomen may fail to reveal any abnormality or may display a modest amount of ileus. Upper gastrointestinal examination may demonstrate a uniform thickening of mucosal folds that has been described as a "picket fence" or "stack of coins" appearance (Fig. 3-8). Intramural hematomas of the intestine occur in other hemostatic disorders and therefore should be considered when any patient with a hemostatic problem presents with findings suggesting an acute intraabdominal process.

Treatment

Replacement Therapy

The plasma concentration of factor VIII necessary for maintenance of hemostatic integrity is normally quite small. Patients with as little as 2 to 3 percent of factor VIII activity usually do not bleed spontaneously. Once serious bleeding begins, however, a much higher level of factor VIII activity, probably approaching 30 percent, is necessary to achieve hemostasis.

The half-life of factor VIII is 8 to 12 h. After administration of a given dose of factor VIII, approximately one-half of the initial posttransfusion activity disappears from the plasma in 4 h. This early disappearance is thought to be due in large part to diffusion from the intravascular space. The period of equilibration may extend for as long as 8 h, at which time only about one-quarter of the initial level remains in the circulating blood. From that time on, the slope of disappearance is less steep. Twenty-four hours after a given dose, no more than 7 to 8 percent of administered factor VIII activity remains within the circulation.

One unit of factor VIII activity is considered that amount present in 1 mL of normal plasma. Actually, fresh frozen plasma contains 0.60 unit/mL. Theoretically, in a patient with 0 percent activity, to achieve an initial posttransfusion level of 60 percent of normal, using fresh plasma, a volume of plasma equal to 60 percent of the patient's estimated plasma volume would have to be administered. Table 3-2 shows approximate levels of factor VIII required for hemostasis in different disorders. The minimum hemostatic level of factor VIII for mild hemorrhages is 30 percent; for joint and muscle bleeding and major hemorrhages, it is 50 percent. For major surgery and life-threatening bleeding, levels of 80 to 100 percent should be reached preoperatively and maintained above 30 percent for 2 weeks. Remembering the loss from the circulation, one-half the initial dose would need to be supplied every 12 h. The use of fresh plasma in such circumstances would require a volume that is excessive. Factor VIII concentrates are available that circumvent this problem. Cryoprecipitate concentrates of factor VIII can be regarded as containing 9.6 units/mL. The amount of material to be given can be computed from the formula

Patient's weight (kg) × desired rise of factor VIII (% average normal) / Total units of factor VIII in dose = *R*

where *R* is a factor that is fairly constant for any given type of material and represents the rise of factor VIII obtained in the patient's plasma for every unit of transfused factor VIII per kilogram of the patient's body weight. Half that amount is subsequently administered every 4 to 6 h to maintain a safe level.

A variety of factor VIII concentrates are available. Regardless of the preparation employed, continued laboratory assessment of circulating factor VIII level is an important element in the control of these patients. Wet-frozen cryoprecipitate is preferred for replacement in patients with mild hemophilia since the risk of hepatitis is less than it is with factor VIII concentrates. The latter are preferred for major replacement problems. In mild hemophilia A and in mild von Willebrand's disease, DDAVP (1-desamino- 8-d-arginine vasopressin), a synthetic derivative of vasopressin, has been used to effect a dose-dependent increase of all factor VIII activities and to effect release of plasminogen activator. DDAVP reduces blood loss associated with major surgical procedures by 40 percent. Patients undergoing orthopaedic or neurosurgical procedures should also receive a fibrinolytic inhibitor.

After major surgical treatment of the hemophiliac, transfusion replacement of factor VIII should be continued for at least 10 days. Wounds should be well healed and all drains removed before termination of therapy. If sutures remain, transfusion should be reinstituted before they are removed. Many recent reports document the safety of major surgical procedures in hemophilic patients receiving replacement therapy. But in one large series the incidence of postoperative hemorrhage did not improve over a 16-year period despite a threefold increase in dosage of factor VIII, suggesting that circulating factor VIII levels are not the sole determinant of bleeding in these patients.

The viruses of homologous serum hepatitis and HIV have been transmitted by various plasma concentrates. Other complications of replacement therapy include the appearance of inhibitors of factor VIII, which may arise in the hemophiliacs who have had transfusion. These inhibitors have been characterized as antibodies of the gG variety. They tend to diminish in several weeks if further transfusion is not employed. Laboratory search for these factors should be carried out in every hemophilic patient who is considered a candidate for elective surgical treatment, as their presence complicates transfusion management. Paradoxical bleeding may occur in patients transfused to an appropriate factor VIII level as a result of the development of abnormal platelet function.

Adjunctive Management

Treatment of soft tissue bleeding is directed at the prevention of airway obstruction and vascular and neural damage. These are accomplished best by the administration of sufficient factor VIII. Bed rest and cold packs can be of some assistance. In general, results of fasciotomy to relieve pressure have varied from disappointing to disastrous. The occasional development of large cysts has resulted in sufficient deformity and disability to require amputation.

The primary treatment of hemophilic hemarthrosis is directed at maintaining full range of motion and minimal destruction of the cartilage. Aspiration of blood from the hemophilic joint is not uniformly endorsed, and when regarded as necessary it should be considered a major surgical event. Elevation of factor VIII level by transfusion is necessary. The procedure should be carried out in the operating room under strict sterile precautions. In most instances aspiration is not required, and the combination of factor VIII replacement and local cold packing proves sufficient. Physiotherapy plays a critical role and should consist of *active* exercises, since the patient is unlikely to move the extremity to a point where bleeding will recur. Passive exercises often result in recurrence of bleeding. The reader is referred to the review by Curtiss for details of orthopaedic management.

The management of intramural intestinal hematoma and retroperitoneal bleeding is based on appropriate transfusion therapy and avoidance of surgical treatment. Even when a relatively minor procedure, such as tracheostomy, is performed, the plasma level of factor VIII should be raised above 25 to 30 percent. Since dental hygiene usually is poor in hemophilic patients, dental and oral surgical treatment frequently are necessary.

Factor IX Deficiency (Christmas Disease)

Factor IX deficiency clinically is indistinguishable from factor VIII deficiency and also has an X-linked recessive mode of inheritance. These two entities were considered a single disease until 1952, when their unique deficiencies were documented. Factor IX deficiency accounts for 20 percent of hemophiliacs. Like classical hemophilia (hemophilia A), Christmas disease (hemophilia B), can occur in severe, moderate, or mild forms according to the level of factor IX activity in the plasma. One-half of afflicted patients have the severe form, which has a factor IX level of less than 1 percent. Patients have a prolonged *partial thromboplastin time (PTT)*.

Treatment

Most patients with severe factor IX deficiency require substitution therapy on a regular basis. All patients require substitution therapy whenever minor or major surgery is performed. Therapy is generally based on the administration of fresh frozen plasma or, rarely, factor IX concentrates. Initially the rate of disappearance of factor IX from the circulation is more rapid than that of factor VIII; subsequently factor IX, with a half-life of 18 to 40 h, has a slower disappearance rate. During severe hemorrhage, treatment should be directed at achieving plasma factor IX levels of 20 to 50 percent of normal for the first 3 to 5 days, and then maintaining the plasma level at 10 to 20 percent of normal for approximately 10

days. The usual daily dose is 30 to 50 units/kg of body weight, followed by 20 units/kg of body weight/24 h. When an operation is required, the plasma level of approximately 50 to 70 percent of normal should be achieved. During the operation and the first postoperative day, 60 units/kg of body weight/24 h is recommended, followed by 30 to 40 units/kg every 24 h for the next 2 to 3 days, and 20 units/kg every 24 h for 3 to 4 days. In all instances, the levels should be monitored by laboratory determinations. The development of antibodies against factor IX represents a serious complication that is difficult to deal with. This occurs in about 10 percent of patients with Christmas disease. These patients are managed by withholding all infusion therapy with blood or plasma. High doses of factor IX concentrates combined with cyclophosphamide have been effective.

von Willebrand's Disease

von Willebrand's disease occurs as commonly as true hemophilia. The increasing recognition of this disease is related to more reliable factor VIII assays. This hereditary disorder of hemostasis is usually transmitted as an autosomal dominant trait, but recessive inheritance may occur. The disease is characterized by a diminution of the level of factor VIII:C (procoagulant) activity that corrects the clotting abnormality in hemophilia A plasma. The reduction of factor VIII:C activity usually is not as great as that seen in classical hemophilia. Also unlike classical hemophilia, in which factor VIII:C activity remains constant, in the patient with von Willebrand's disease, variation in the level of circulating factor VIII:C activity may be noted. Characteristically, these patients also have a prolonged bleeding time, but this is less constant than the factor VIII:C reduction. A given patient may have an abnormal bleeding time on one occasion and a normal bleeding time on another. The level of factor VIII-related antigen (factor VIII:Ag) is disproportionately lower than that of factor VIII:C, and ristocetin fails to cause platelet aggregation in about 70 percent of patients with the disease. The vast majority of patients have a prolonged activated partial thromboplastin time (aPTT).

Clinical Manifestations

The manifestations of bleeding usually are mild and often are overlooked until trauma or the stress of surgical treatment makes them apparent. A careful clinical history is therefore of great importance in these patients. Spontaneous manifestations often are limited to bleeding into the skin or mild mucous membrane bleeding. Epistaxis and menorrhagia have been relatively common in the author's experience. Serious bleeding after dental extractions and tonsillectomy also are not uncommon. Fatal bleeding from the gastrointestinal tract has been described.

Treatment

Treatment is directed at correcting the bleeding time and factor VIII R:vWF (the von Willebrand factor). Only cryoprecipitate is reliably effective. Lyophilized concentrates of factor VIII:C lack the required factor VIII R:vWF. Newer factor VIII concentrates have a full complement of vWF. Bleeding time is corrected with cryoprecipitate 10 to 40 units/kg of body weight/12 h. Replacement therapy should be begun 1 day before a surgical procedure. Aspirin *must* be avoided for 10 days before an elective operation. Duration of treatment should be the same as that described for the patient with classical hemophilia. Intravenous high-dose g-globulin has been used successfully to treat an acquired type of von Willebrand's disease associated with myeloproliferative disorders, leukemias, and lymphomas.

An analogue of the antidiuretic hormone vasopressin, DDAVP (desmopressin acetate), administered intravenously temporarily (for 1 to 2 h) increases vWF:Ag, ristocetin cofactor, and VIII:C and shortens the bleeding time. Desmopressin may induce thrombocytopenia and release tissue plasminogen activator.

Rare Deficiencies of Coagulation Factors

Factor XI (plasma thromboplastin antecedent [PTA]) deficiency (Rosenthal's syndrome) is a mild disorder occurring mainly in patients of Jewish ancestry. Patients may undergo major procedures without significant bleeding. Fresh frozen plasma is therapeutic. *Factor V (proaccelerin) deficiency (parahemophilia)* is rare; significant bleeding usually occurs in homozygotes. Excessive bleeding is characteristically associated with factor levels lower than 1 percent of normal. Administration of fresh frozen plasma to raise the level to 25 percent of normal is sufficient. *Factor VII (proconvertin) deficiency* also is associated with excessive operative bleeding in homozygous patients. Administration of banked plasma to raise the factor level above 10 percent of normal provides adequate hemostasis. *Factor X (Stuart-Prower) deficiency* is associated with amyloidosis and with familial carotid body tumors. Frozen or normal plasma is therapeutic. *Factor II (prothrombin) deficiency* is rare and can be corrected with plasma infusion to achieve levels greater than 30 percent of normal.

Although the *prothrombin time (PT)* will reveal factor VII deficiency, it cannot be used as a guide to therapy because it remains abnormal when adequate levels of factor VII are achieved. Patients with factor VII deficiency have normal *PTT* and *thrombin time (TT)*. Specific assays can define any of these deficiencies. Vitamin K therapy is ineffective in raising levels of factors II, V, VII, X, and XI.

When the transfusion programs outlined earlier for deficiency of the prothrombin group of factors (factors II, V, VII, and X) are employed, the one-stage prothrombin time does not return to normal. Rather, a one-stage *PT* slightly less than twice the control value is achieved. This is sufficient to result in normal hemostasis. Of the four "prothrombin" factors, only factor V must be provided as fresh or freshly frozen plasma. Stored plasma is equally effective as therapy for factors II, VII, and X.

Inherited Fibrinogen Abnormalities

Included in this category are patients with congenital afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia. Fewer than 200 cases of afibrinogenemia have been reported. This disorder is ascribed to an autosomal recessive mode of inheritance. The affected individuals are presumably homozygous for the trait. Bleeding time may be markedly prolonged in some patients because fibrinogen is required for platelet aggregation. Conventional methods for measuring fibrinogen in the plasma give a zero value, but immunologic techniques may detect trace amounts of a fibrinogen-like protein. Patients have an indefinitely prolonged whole-blood coagulation time, which can be corrected by the addition of fibrinogen. The deficiency usually is less a clinical problem than is classical hemophilia, however. Bleeding usually begins early in life, and bleeding from the umbilical cord is a characteristic symptom. Bleeding may follow operations, dental extraction, and trauma, but the most feared complication is intracranial bleeding after minor injury to the head.

Less profound inherited deficiencies of fibrinogen have been observed and categorized as congenital hypofibrinogenemia. Two groups of hypofibrinogenemic patients have been differentiated: those with fibrinogen values below 50 mg/dL and those with higher levels. The clinical manifestations depend on the fibrinogen concentration. Another congenital disorder is dysfibrinogenemia, in which there are structural defects in the fibrinogen molecule. Both hypofibrinogenemia and dysfibrinogenemia have a dominant mode of inheritance. Dysfibrinogenemic patients are frequently asymptomatic but may have moderate or severe bleeding associated with an operation. They have a propensity for thromboembolic disorders and have a higher incidence of wound dehiscence after operative intervention. The thrombin clotting time is diagnostic for this general category of abnormalities, but definition of the precise abnormality requires a series of complex laboratory studies.

Treatment

Although the hemostatically optimal level of fibrinogen is not known, a level greater than 100 mg/dL is generally required during an operation. The patient's fibrinogen level should be raised above this before the procedure. Substitution therapy may be effected by the infusion of fresh frozen plasma or cryoprecipitate. In order to achieve a fibrinogen level near 100 mg/dL for 24 h, an initial dose of 20 to 25 mg fibrinogen/kg of body weight should be administered, followed by one-third the initial amount given on a daily basis throughout the postoperative period. But appropriate corrections must be based on actual fibrinogen measurements. Normal fibrinogen concentration should be maintained until wound healing is shown to be adequate.

Congenital Factor XIII Deficiency

This rare autosomal recessive disorder is manifest by umbilical bleeding in the newborn and slow wound healing after an operation. In general, most of the bleeding manifestations are mild, but intracranial bleeding may occur as a consequence of minor trauma. Immunologic assays have demonstrated deficiency of the protein. Therapy is accomplished with fresh frozen plasma, cryoprecipitate, or factor XIII concentrates. With major bleeding, or accompanying surgical intervention, the desired concentration of the recipient's plasma is 0.3 to 0.5 mmol/mL. With minor bleeding or as prophylaxis, a level greater than 0.05 mmol/mL is all that is required.

ACQUIRED HEMOSTATIC DEFECTS

Platelet Abnormalities

Thrombocytopenia is the most common abnormality of hemostasis that results in bleeding in the surgical patient. The patient may have a reduced platelet count as a result of a variety of disease processes, such as idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, and systemic lupus erythematosus, or secondary hypersplenism and splenomegaly of sarcoid, Gaucher's disease, lymphoma, and portal hypertension. In these circumstances the marrow usually demonstrates a normal or increased number of megakaryocytes. By contrast, when thrombocytopenia occurs in patients with leukemia or uremia, and in patients on cytotoxic therapy, there is generally a reduced number of megakaryocytes in the marrow.

Thrombocytopenia may occur acutely as a result of massive blood loss followed by replacement with stored blood. Exchange of one blood volume (11 units in a 75-kg man) decreases the platelet count from approximately 250,000/mm³ to approximately 80,000/mm³. Thrombocytopenia may be induced acutely by the administration of heparin and may be associated with thrombotic and hemorrhagic complications. This situation, which is thought to have an immunologic basis, has been reported in 0.6 percent of patients receiving heparin. The lowest platelet counts occur after 4 to 15 days of treatment in patients given heparin for the first time and after 2 to 9 days in those given subsequent courses.

Thrombocytopenia is often accompanied by impaired platelet function. Impaired aggregation after the addition of *ADP* has been demonstrated in patients receiving a blood transfusion of more than 10 units. Uremia may be associated with increased bleeding time and impaired aggregation, which can be corrected by hemodialysis or peritoneal dialysis. Defective aggregation and platelet secretion can occur in patients with thrombocythemia, polycythemia vera, or myelofibrosis. A variety of drugs interfere with platelet function, including aspirin, indomethacin, ibuprofen, dipyridamole, phenothiazines, penicillins, chelating agents, lidocaine, dextran, beta-adrenergic blockers, nitroglycerin, furosemide, and antihistamines.

The presence and extent of thrombocytopenia can be defined rapidly by a platelet count. In general, 60,000 platelets/mm³ is adequate for normal hemostasis, but if there is associated platelet dysfunction, there may be a poor correlation between the platelet count and the extent of bleeding. The template bleeding time is the most reliable in vivo test of platelet function.

When thrombocytopenia is present in a patient for whom an elective operation is being considered, it is managed on the basis of how much the platelet count is reduced and the cause of the reduction. A count greater than 50,000/mm³ requires no specific therapy. If thrombocytopenia is caused by acute alcoholism, drug effect, or viral infection, the platelet level will return to near normal within 1 to 3 weeks. Occasionally, severe thrombocytopenia may be secondary to vitamin B₁₂ or folic acid deficiency, in which case it is associated with a megaloblastic bone marrow. This condition generally occurs 2 to 3 years after total gastrectomy or in association with severe intestinal malabsorption. In either case, supplying the appropriate nutrient will correct the thrombocytopenia in 2 to 3 days.

If the patient has idiopathic thrombocytopenia or lupus erythematosus, and a platelet count less than 50,000/mm³, an attempt to raise the platelet count with steroid therapy or plasmapheresis may prove successful (see Chap. 3-1). The administration of platelet transfusions in these patients with the spleen in place is generally ineffective. The administration of g-globulin may temporarily increase the platelet count. Splenectomy alone should not be performed to correct the thrombocytopenia associated with splenomegaly secondary to portal hypertension.

Prophylactic platelet administration as a routine accompaniment to massive blood transfusion is not required or indicated to prevent a hemostatic defect. Platelet packs are administered preoperatively to rapidly increase the platelet count in surgical patients with thrombocytopenia due to marrow depression or in association with massive bleeding and replacement with banked blood. Special platelet transfusion sets are used to reduce the loss of platelets due to adherence. One unit of platelet concentrate contains approximately 5.5×10^{10} platelets and would be expected to increase the circulating platelet count by about 10×10^9 /L in the average 70-kg person. Hence a transfusion of 4 to 8 pool platelet concentrates should raise the count by 40 to 80×10^9 /L and should provide adequate hemostasis, as documented by bleeding time and control of the hemorrhagic manifestations. Fever, infection, hepatosplenomegaly, and the presence of antiplatelet alloantibodies decrease the effectiveness of platelet transfusions. In patients refractory to standard platelet transfusions, the use of *human lymphocyte antigen (HLA)*-compatible platelets coupled with special processors has proved effective. Platelet aggregometry has been applied to screening for potential donors.

Acquired Hypofibrinogenemia Defibrination Syndrome

The largest proportion of patients with fibrinogen-related problems of surgical concern are in this group. The fibrinogen deficiency rarely is an isolated defect, as thrombocytopenia and factors II, V, VII, VIII, and X deficiencies of variable severity usually accompany this state.

The majority of patients with acquired hypofibrinogenemia suffer from intravascular coagulation, more properly known as *defibrination syndrome* or *consumptive coagulopathy*, and it is to this group of patients that the term *disseminated intravascular coagulation (DIC)* has been applied. Systemic bleeding, however, dominates the clinical manifestations; thrombi are rarely found at autopsy. The syndrome, now recognized with increasing frequency, is caused by the introduction of thromboplastic materials into the circulation. Because this material is found in most tissues, many disease processes may activate the coagulation system. Evidence of the thrombotic process includes patchy necrosis of the skin, hematuria and oliguria, confusion due to cerebral ischemia, gastrointestinal bleeding, and hemorrhage into the adrenal cortex causing acute onset of hypotension. The hemorrhagic disasters of the perinatal period, e.g., retained dead fetus, premature separation of the placenta, and amniotic fluid embolus, are due primarily to this pathophysiologic mechanism. The hemorrhagic state that follows hemolytic transfusion reaction is also related to this process. Defibrination has been observed as a complication of extracorporeal circulation, head trauma, mucin-producing and disseminated carcinoma, lymphomas, thrombotic thrombocytopenia, rickettsial infection, snakebite, burns, aortic surgery, and shock from any cause. Release of thromboplastic material has long been a recognized complication of gram-negative sepsis and has been attributed to the effects of circulating endotoxin on platelets. Septicemia caused by gram-positive organisms may also be associated with DIC.

The differentiation of *DIC* with secondary protective fibrinolysis from primary fibrinolytic states can be extremely difficult because the *TT* is prolonged in both cases, as is the *PT* and *PTT*. There is no laboratory test to confirm or exclude the diagnosis. The combination of a low platelet count, a positive plasma protamine test indicating the presence of fibrin monomer-fibrinogen complexes in the plasma, and reduced fibrinogen accompanied by increased fibrin degradation products viewed in the context of the patient's underlying disease is highly suggestive of the diagnosis. The fibrinogen level is generally below 100 mg/dL when there is significant diffuse bleeding.

Treatment

The most important facets of treatment are relieving the patient's causative primary medical or surgical problem and maintaining adequate capillary flow. The use of intravenous fluids to maintain volume, and sometimes vasodilators to open the arterioles, is indicated. If blood flow deficiency is related to the inability of a damaged heart to pump, the use of drugs such as digitalis or isoproterenol may be indicated. Viscosity may be affected by an increased hematocrit concentration, and therefore a plasma expander may be beneficial.

If there is active bleeding, hemostatic factors should be replaced with fresh frozen plasma, which is usually sufficient to correct the hypofibrinogenemia; cryoprecipitate, which also provides fibrinogen (250 mg/10 mL); and platelet concentrates. There is little evidence that this replacement therapy will "fuel the fire" and accelerate the pathophysiologic process. Most studies show that heparin is not helpful in acute forms of *DIC*, but the drug is indicated for purpura fulminans or venous thromboembolism. Fibrinolytic inhibitors such as *ε-aminocaproic acid (EACA)* may be used to block the accumulation of degradation products but are dangerous if the thrombotic process is still active. They should not be used without prior effective antithrombotic treatment with heparin.

Fibrinolysis

The acquired hypofibrinogenemic state in the surgical patient also can be due to pathologic fibrinolysis. This may occur in patients with metastatic prostatic carcinoma, shock, sepsis, hypoxia, neoplasia, cirrhosis, and portal hypertension and in those patients on extracorporeal bypass.

The pathogenesis of this bleeding disorder is complex. Secondary to shock or hypoxia, a release of excessive plasminogen activator into the circulation occurs. This is thought to consist of endogenous kinases that can be released from vascular endothelium and other tissues. Pharmacologic activation of plasminogen also occurs with pyrogens, epinephrine, nicotinic acid, and acetylcholine. Electric shock and pneumoencephalography have also been reported to cause activation. Patients with cirrhosis and portal hypertension have a diminished ability to clear normal amounts of plasminogen activator from the blood. Sufficient urokinase to cause fibrinolysis can be released during operations on the prostate. The administration of exogenous fibrinolytics can also result in diffuse bleeding.

In addition to the reduction in levels of plasma fibrinogen, diminution of factors V and VIII also occurs, since they also serve as substrates for the enzyme plasmin. Thrombocytopenia is not an accompaniment of the purely fibrinolytic state. Polymerization of fibrin monomers, a step in normal fibrin formation, is interfered with by the proteolytic residue of fibrinogen and fibrin. The fibrin and fibrinogen breakdown products usually disappear from the circulation in a matter of hours. The whole blood clot lysis time defines increased fibrinolytic activity if a non-anticoagulated blood sample lyses in a test tube in less than 8 h. A euglobulin lysis time of 20 min or less provides a more rapid assessment.

Treatment

The successful treatment of the underlying disorder usually is followed by rapid spontaneous recovery, since the severity of fibrinolytic bleeding is dependent upon the concentration of breakdown products in the circulation. *EACA*, which is a synthetic amino acid, interferes with fibrinolysis by inhibiting plasminogen activation. The drug may be administered intravenously or orally. An initial dose of 5 g for the average-sized adult is followed by another 1 g every 1 to 2 h until the hemorrhagic state subsides. Treatment rarely is required for more than 2 or 3 days. Just as the administration of *EACA* in a patient with consumptive coagulopathy is potentially dangerous, the administration of heparin in the patient who has a primary pathologic fibrinolysis is fraught with danger. Thus fine clinical judgment and reliable laboratories are needed to avoid therapeutic complications. Restraint is recommended in definitive treatment of fibrinolysis and consumptive coagulopathy, and measures designed to reverse the shock and stabilize the patient are emphasized.

Myeloproliferative Diseases

The polycythemic patient, particularly with marked thrombocytosis, is a major surgical risk. Operations should be considered only for the most grave surgical emergency. If possible, the operation should be deferred until medical management has effected normal blood volume, hematocrit level, and platelet count. Spontaneous thrombosis is a complication of polycythemia vera and can be explained in part by increased blood viscosity, increased platelet count, and increased tendency toward stasis. Paradoxically, a significant tendency toward spontaneous hemorrhage also is noted in these patients.

Myeloid metaplasia frequently represents part of the natural history of polycythemia vera. Approximately 50 percent of patients with myeloid metaplasia are postpolycythemic. There is evidence suggesting qualitative platelet abnormalities in these patients. Abnormalities in platelet factor 3 release and in platelet aggregation with *ADP* have been demonstrated.

Treatment

Thrombocytosis can be reduced by the careful administration of alkylating agents such as busulfan or chlorambucil. Elective surgical procedures should be delayed weeks to months after institution of treatment. Ideally the hematocrit level should be kept below 48 percent and the platelet count under 400,000/mm³. Before operation, a thorough laboratory examination of hemostatic function should be conducted. When an emergency procedure is required, the erythremic and thrombocytotic states should be reduced by phlebotomy and replacement of the blood removed with lactated Ringer's solution. The operation, at all times, must be performed fastidiously.

Other Diseases

Illnesses resulting in severe impairment of hepatic function may limit synthesis of plasma factors essential to normal coagulation. The patient with advanced cirrhosis may be lacking in factors of the prothrombin complex (II, V, VII, X), as well as factor XIII. In addition, there may be increased fibrinolysis as a result of failure of the liver to clear plasminogen activators.

Other diseases, such as macroglobulinemia, may be associated with the abnormal production of proteins that coat the platelets and interfere with their function. Multiple myeloma and the disorders associated with the excessive production of cryoglobulins may also bind certain blood-clotting factors.

Anticoagulation and Bleeding

Spontaneous bleeding may be a complication of anticoagulant therapy with either heparin or the coumarin and indanedione derivatives. The incidence of bleeding complications related to heparin is reduced with a continuous infusion technique, regulating the *PTT* between 60 and 100 s (control: 30 to 35 s). An exaggerated response to oral anticoagulants may occur if dietary vitamin K is inadequate. The anticoagulant effect of the coumarins is consistently reduced in patients receiving barbiturates, and increased coumarin requirements have also been documented in patients taking contraceptives, other estrogen-containing compounds, corticosteroids, and adrenocorticotrophic hormone (ACTH). Therefore, reduced anticoagulant dosage should be instituted after discontinuance of any of these drugs. Medications known to increase the effect of oral anticoagulants include phenylbutazone, the cholesterol-lowering agent clofibrate, anabolic steroids (norethandrolone), d-thyroxine, glucagon, quinidine, and a variety of antibiotics.

Unexplained bleeding in medical and paramedical personnel occasionally is due to self-induced anticoagulation. The onset of hematuria or melena in the patient receiving anticoagulants should be investigated, since it has been shown that anticoagulants may unmask underlying tumors. Patients with bleeding secondary to anticoagulation may present only with epistaxis, gastrointestinal hemorrhage, or hematuria. Physical examination, however, almost always reveals other signs of bleeding such as ecchymoses, petechiae, or hematoma. Bleeding secondary to anticoagulation therapy is not an uncommon cause of rectus sheath hematoma, simulating appendicitis, and intramural intestinal or

retroperitoneal hematoma.

Surgical intervention may prove necessary in patients receiving anticoagulation therapy. Increasing experience suggests that surgical treatment can be undertaken without discontinuing the anticoagulant program. The risk of thrombotic complications reportedly is increased when anticoagulation therapy is discontinued suddenly. If so, this may not be related to what has been called the “rebound phenomenon” but may represent an event in a patient who has an underlying thrombotic tendency. When the clotting time is less than 25 min in the heparinized patient or when the *PT* is greater than 20 percent of normal in a patient on a coumarin drug, reversal of anticoagulant therapy may not be necessary. Meticulous surgical technique is mandatory, and the patient must be observed closely.

Certain surgical procedures should not be performed in the face of anticoagulation. In sites where even minor bleeding can cause great morbidity, e.g., the central nervous system and the eye, anticoagulants should be discontinued and, if necessary, reversed. Because of the added problem of local fibrinolysis, prostatic surgical treatment should not be carried out in a patient on anticoagulants. Procedures requiring blind needle introduction should be avoided. Deaths have been reported after sympathetic block for peripheral vascular disease in patients receiving anticoagulation.

Emergency operation occasionally is necessary in patients who have been heparinized as treatment for deep venous thrombosis. The first step in managing these patients is discontinuation of heparin; this may be sufficient if the operation can be delayed for several hours. For more rapid reversal, 1 mg of protamine sulfate for every 100 units of heparin most recently administered is immediately effective. For each hour that has elapsed since the last heparin dose, the amount of protamine should be halved. The formation of both extrinsic and intrinsic prothrombinase can be retarded, prolonging the one-stage *PT* test and the *PTT* test. Some patients exhibit the phenomenon of “heparin rebound” after apparently adequate heparin neutralization with protamine; prolongation of the clotting time recurs after adequate postoperative antagonism of the heparin, which can contribute to postoperative bleeding. In the author's experience, this is the major cause of “unexplained” postoperative bleeding after cardiac and vascular surgical procedures. Activation of fibrinolysis and thrombocytopenia may also contribute to this problem.

Bleeding infrequently is related to hypoprothrombinemia if the prothrombin concentration is greater than 15 percent. In the elective surgical patient receiving coumarin-derivative therapy sufficient to effect anticoagulation, the drug can be discontinued several days before operation and the prothrombin concentration then checked. A level greater than 50 percent is considered safe. If emergency surgical treatment is required, parenteral injection of vitamin K can be used. Since the reversal effect may take 6 h, transfusion of whole blood or, preferably, freshly frozen plasma may be required. Parenteral administration of vitamin K also is indicated in elective surgical treatment of patients with biliary obstruction, malabsorption, and hypoprothrombinemia. The drug should result in a normal *PT*. By contrast, if the hypoprothrombinemia is related to hepatocellular dysfunction, vitamin K therapy is ineffective and should not be prolonged over 1 week if no response is noted. Vitamin K is an oxidant, and one must be aware that patients with red cell enzyme deficiencies may sustain hemolysis after its administration.

Cardiopulmonary Bypass

Overheparinization, heparin rebound, inadequate protamine neutralization, protamine excess, and thrombocytopenia all have been indicted as causes of excessive bleeding in patients undergoing cardiopulmonary bypass. *DIC* is difficult to document in most patients. The predisposing factors that seem to be associated with excessive bleeding are prolonged perfusion times, prior use of oral anticoagulants, cyanotic heart disease, hypothermia, and prior use of antiplatelet drugs. It is currently believed that the two factors most important in triggering excessive bleeding associated with cardiopulmonary bypass are excessive fibrinolysis and platelet function defects, with the latter the more important element.

The laboratory evaluation of patients with bleeding should include *PT*, *PTT*, complete blood count (CBC) and platelet count, peripheral blood smear examination, and measurement of fibrin degradation products. Heparin assay can indicate the heparin level; plasminogen and plasmin assays are also available.

The management of cardiopulmonary bypass hemorrhage should include the empiric administration of 6 to 8 units of platelet concentrates as rapidly as possible. If hyperheparinemia is believed to be the major factor, 25 percent of the calculated dose of protamine should be administered and repeated every 30 to 60 min until the bleeding ceases. If there is laboratory evidence of excess fibrinolysis, *EACA* should be given at an initial dose of 5 to 10 g followed by 1 to 2 g/h until bleeding ceases. *EACA* may be associated with ventricular arrhythmia, hypotension, and hypokalemia. Aprotinin, a protease inhibitor that acts as an antifibrinolytic agent, has been shown to reduce transfusion requirements associated with cardiac surgery and orthotopic liver transplantation. Desmopressin acetate is also effective in reducing blood loss during cardiac surgery.

TESTS OF HEMOSTASIS AND BLOOD COAGULATION (TABLE 3-3)

The most important assessment of hemostasis is a careful history and physical examination. Only the history can indicate whether the patient has a hemorrhagic diathesis. Rather than asking a patient if he or she is a “bleeder,” specific questions should be asked. These should include queries to determine whether there was untoward bleeding during a major surgical procedure, or if there was any bleeding after a minor operation such as tonsillectomy, circumcision, or dental extraction, or if spontaneous bleeding was ever experienced. If there is any suggestion of a bleeding diathesis, the age of onset and family history is helpful to determine whether a hereditary or acquired defect should be investigated. Questions should uncover a history of exposure to toxic agents, oral anticoagulants, and drugs that might interfere with hemostasis. Aspirin and ibuprofen are two of the more common medications in this category. A history of a recent regimen of broad-spectrum antibiotics should alert the physician to the possibility of a deficiency of vitamin K-dependent clotting factors. Patients with malignant disease may have a variety of abnormalities, such as compensated intravascular coagulation and increased circulating fibrin complexes. Complex hemostatic disorders may accompany liver and renal failure.

Platelet Count

Because thrombocytopenia is the most common abnormality of hemostasis in the surgical patient, determination of the level of circulating platelets is a critical screening test. Direct enumeration of blood platelets can be accomplished quite accurately. *Spontaneous* bleeding only rarely can be related to thrombocytopenia with platelet counts greater than 40,000/mm³. Platelet counts of 60,000 to 70,000/mm³ usually are sufficient to provide adequate hemostasis after trauma or surgical procedures if other hemostatic factors are normal. An abnormal count should be confirmed by inspection of the blood smear.

When an area is examined where the red blood cells display their customary central pallor and where few of the red blood cells overlap one another, 15 to 20 platelets per oil immersion field should be noted. If the blood is not anticoagulated before the smear is prepared, as many as half of these may be in clumps of three or four platelets. A well-stained blood smear that fails to display more than three or four platelets in at least every other oil immersion field can be considered significantly thrombocytopenic. In this situation, the patient's platelet count generally is less than 75,000/mm³. Blood smears that must be searched because platelets appear in only every four or five oil immersion fields usually represent platelet counts of fewer than 40,000/mm³. If coverslip smears have been prepared, the coverslips always should be mounted as matched pairs. Platelets occasionally stick to one of the coverslips, and examination of both will obviate a false impression of thrombocytopenia. Lightly stained blood smears may appear thrombocytopenic if the platelets are not prominent enough to attract the examiner's attention.

Inspection of the blood smear has the additional advantage of permitting the examiner to identify other pathologic features that may have meaning in the care of the patient. The presence of nucleated red blood cells or abnormal white cells can provide information important to the diagnosis. The presence of giant platelets or large fragments of megakaryocyte cytoplasm will alert the examiner to possible pathologic platelet function.

Bleeding Time

Bleeding time provides an assessment of both the interaction between platelets and a damaged blood vessel and the formation of the platelet plug. Bleeding time may be abnormal in patients with thrombocytopenia, qualitative platelet disorders, von Willebrand's disease, and also in some patients with factor V deficiency or hypofibrinogenemia. Aspirin ingested within 1 week will affect the results. The tests can be performed by a variety of techniques that do not have the same normal times or the same degree of accuracy. The Duke method of measuring bleeding time, performed by incising the most dependent portion of the earlobe and measuring the time lapse until the bleeding ceases, normally should not exceed 3½ min. The modified Ivy method has an upper limit of normal of 7 min.

Other Tests of Platelet Function

Platelet aggregation can be assessed with a variety of induction agents to uncover specific abnormalities. The results may be affected by venipuncture, blood pH, temperature, duration of storage, and the equipment itself. The degree of abnormality detected by the test is not correlated with the extent of untoward bleeding. Aspirin is the most common cause of platelet aggregation abnormality. Failure of platelets to aggregate with the addition of arachidonic acid indicates an aspirin effect. The failure of platelets to aggregate with *ADP*, epinephrine, and collagen is characteristic of Glanzmann's thrombasthenia. Abnormal platelet aggregation with ristocetin occurs in von Willebrand's disease and in Bernard-Soulier syndrome.

The ability of the platelets to liberate platelet factor 3 (phospholipid), essential in tiny amounts at several stages of the blood-clotting process (see Fig. 3-3), also can be measured. Impairment of platelet factor 3 release has been reported in conditions described as *thrombocytopathia*. This defect can represent a primary disease entity, but similar impairment has been described as a secondary phenomenon in uremia and liver disease. The inability of the platelet to make platelet factor 3 available for the clotting process may be a part of a more fundamental surface membrane abnormality. The ability of *ADP*, epinephrine, collagen, and arachidonic acid to liberate serotonin, b-thromboglobulin, or platelet factor 4 can be measured.

Prothrombin Time

This test measures the speed of the events described earlier as the extrinsic pathway of blood coagulation. A tissue source of procoagulant (thromboplastin), a lipoprotein, is added with calcium to an aliquot of citrated plasma and the clotting time determined. The laboratory should establish a normal dilution curve and normal values daily. The PT will be prolonged in the presence of even minute amounts of heparin. The presence of heparin, by its antithrombin action, will artificially prolong the clotting time of the mixture so that it appears that the prothrombin complex is low. Accordingly, an accurate prothrombin determination cannot be carried out in a patient receiving anticoagulation treatment with heparin until the heparin has disappeared from the plasma. This should be at least 5 h after the last intravenous dose. The amount of heparin used to maintain patency of an intravenous line is usually insufficient to alter the PT.

The use of tissue procoagulants in the test eliminates the roles of factors VIII, IX, XI, XII, and platelets. Properly done, the test will detect deficiencies of factors II, V, VII, X, and fibrinogen. The one-stage PT is the preferred method of controlling anticoagulation with the coumarin and indanedione drugs.

Partial Thromboplastin Time

The PTT is a screening test for the intrinsic clotting pathway. The in vitro clotting system now is sensitive to factors VIII, IX, XI, and XII, as well as the factors normally detected by

the one-stage *PT*. The range of normal with this test varies with the product used. The patient's plasma must be compared with a normal control sample.

The PTT, when used in conjunction with the one-stage PT, can help to place a clotting defect in the first or second stage of the clotting process. If the PTT is prolonged and the one-stage PT is normal, factors VIII, IX, XI, or XII may be deficient. If the PTT is normal and the one-stage PT is prolonged, a single or multiple deficiency of factors II, V, VII, or X or of fibrinogen may be present. The PTT is also abnormal in the presence of circulating anticoagulants or during heparin administration. It may be prolonged when heparin is used to maintain the patency of an intravenous line. The sensitivity of the test is such that only extremely mild cases of factor VIII or IX deficiency may be missed.

Thrombin Time

This test is of value in detecting qualitative abnormalities in fibrinogen and in detecting circulating anticoagulants and inhibitors of fibrin polymerization. The clotting time of the patient's plasma is measured after the addition of a standard amount of thrombin to a fixed volume of plasma. Control samples of normal plasma must be run in parallel. Failure of the clot to form, in the absence of circulating inhibitors such as heparin or the fibrinolytic degradation products of fibrin and fibrinogen, is consistent with severe diminution of fibrinogen, usually well below 100 mg/dL. It is also prolonged when fibrinolysis is taking place.

Other Tests of Coagulation

The fibrinogen level can be determined by clotting-time measurements or gravimetrically. Specific assays of coagulation factors are performed by measuring the clotting time of plasma from patients congenitally lacking in one of these factors and noting the effect of the addition of each factor. Relatively simple tests permit identification of circulating anticoagulants. The simplest of these are based on the retardation of clotting of normal recalcified plasma by varying mixtures of the test plasma. The sensitivity of such tests usually can be increased by incubating the test plasma with the normal plasma for 30 min at body temperature before recalcification. Detection of factor XIII deficiency requires a special test.

Tests of Fibrinolysis

Fibrin degradation products (FDP) can be measured by immunologic methods. Normally, dissolution of a recently formed blood clot will not occur for 48 h or more. When fibrinolysis is a significant factor in hemostatic failure, dissolution of the whole blood clot is observed in 2 h or less. The test has the disadvantage of being time-consuming in a circumstance where time may be of the essence. In addition, a false impression of increased fibrinolytic activity may be gained from clots formed in patients with high hematocrit levels or in thrombocytopenia, in which red cells may fall away from the clot. The euglobulin clot lysis time and dilute whole-blood or plasma-clot-lysis time are more sensitive indices and permit more rapid evaluation of fibrinolysis.

The *thromboelastogram* is a graphic representation of clotting. The record obtained provides information about the clotting time, the speed of fibrin polymerization, and the clot's strength and tendency toward dissolution.

EVALUATION OF THE SURGICAL PATIENT AS A HEMOSTATIC RISK

Preoperative Evaluation of Hemostasis

The patient's history provides meaningful clues to the presence of a bleeding tendency. It is reasonable to use a questionnaire on which the patient indicates: (1) prolonged bleeding or swelling after biting the lip or tongue, (2) bruises without apparent injury, (3) prolonged bleeding after dental extraction, (4) excessive menstrual bleeding, (5) bleeding problems associated with major and minor operations, (6) medical problems receiving a physician's attention within the past 5 years, (7) medications including aspirin or remedies for headache taken within the past 10 days, and (8) a relative with a bleeding problem.

Four levels of concern have been proposed on the basis of the history and surgical procedure being considered. At Level I, the history is negative and the procedure contemplated is relatively minor, e.g., breast biopsy or hernia repair: no screening tests are recommended. At Level II, the history is negative, screening tests may have been performed in the past, and a major operation is planned, but the procedure usually is not attended by significant bleeding: a platelet count and blood smear and *PTT* are recommended to detect any thrombocytopenia, circulating anticoagulant, or intravascular coagulation. Level III pertains to the patient whose history is suggestive of defective hemostasis and also to the patient who is to undergo an operative procedure in which hemostasis may be impaired, e.g., operating using pump oxygenation or cell savers, or procedures in which a large, raw surface is anticipated. Level III also pertains to situations in which minimal postoperative bleeding could be injurious, such as intracranial operations. At this level, a platelet count and bleeding time test should be performed to assess platelet function; a *PT* and *PTT* should be used to assess coagulation, and the fibrin clot should be incubated to screen for abnormal fibrinolysis. Level IV pertains to patients who present with a history highly suggestive of a hemostatic defect. A hematologist should be consulted, and, in addition to the tests prescribed for Level III patients, the bleeding time test should be repeated 4 h after the ingestion of 600 mg of aspirin, provided that the operation is scheduled to take place 10 or more days after this study. In the case of an emergency procedure, platelet aggregation tests using *ADP*, collagen, epinephrine, and ristocetin should be performed, and a *TT* is indicated to detect any dysfibrinogenemia or a circulating, weak, heparin-like anticoagulant. Patients with liver disease, renal failure, obstructive jaundice, and the possibility of disseminated malignant disease should have a platelet count, PT, and PTT performed preoperatively. In uremic patients the most common deficit is a qualitative platelet abnormality. This is best detected by the bleeding time test.

Evaluation of Excessive Intraoperative or Postoperative Bleeding

Excessive bleeding during or shortly after a surgical procedure may be due to one or more of the following factors: (1) ineffective local hemostasis, (2) complications of blood transfusion, (3) a previously undetected hemostatic defect, (4) consumptive coagulopathy, and/or (5) fibrinolysis. Excessive bleeding from the field of the procedure, unassociated with bleeding from other sites, e.g., central venous pressure line, intravenous line, or tracheostomy, usually suggests inadequate mechanical hemostasis rather than a defect in the biologic process. An exception to this rule applies to operations on the prostate, pancreas, and liver because operative trauma may stimulate local plasminogen activation and lead to increased fibrinolysis on the raw surface. In these circumstances 24 to 48 h interruption of plasminogen activation by the administration of *EACA* may prove effective.

Although one may be reasonably certain on clinical grounds that surgical bleeding is related to local problems, laboratory investigation must be confirmatory. Prompt examination should be made of the blood smear to determine the number of platelets, and an actual platelet count should be done if the smear is equivocal. A *PTT*, a one-stage *PT*, and a *TT* all can be determined within minutes. Correct interpretation of the results should confirm the clinical impression or identify the problem.

As pointed out previously, massive blood transfusion is a well-documented cause of thrombocytopenia. Although most patients who receive 10 units or more of banked blood within a period of 24 h will be measurably thrombocytopenic, this is usually *not* associated with hemostatic failure. Therefore, prophylactic administration of platelets is not indicated, but if there is evidence of diffuse bleeding, 8 to 10 packs of fresh platelet concentrates should be given empirically, because no clear association has been documented between the platelet count, bleeding time, and the occurrence of profuse bleeding.

Another cause of hemostatic failure related to the administration of blood is a hemolytic transfusion reaction. The first hint of a transfusion reaction in an anesthetized patient may be diffuse bleeding in an operative field that had previously been dry. The pathogenesis of this bleeding is thought to be related to the release of *ADP* from hemolysed red cells, resulting in diffuse platelet aggregation, after which the platelet clumps are swept out of the circulation. Release of procoagulants may result in progression of the clotting mechanism and intravascular defibrination. In addition, the fibrinolytic mechanism may be triggered.

Transfusion purpura is an uncommon cause of thrombocytopenia and associated bleeding after transfusion. When this occurs the donor platelets are of the uncommon PI_{A1} group. These platelets sensitize the recipient, who makes antibody to the foreign platelet antigen. The foreign platelet antigen does not completely disappear from the recipient circulation but seems to attach to the recipient's own platelets. The antibody, which attains a sufficient titer within 6 or 7 days after the sensitizing transfusion, then destroys the recipient's own platelets. The resultant thrombocytopenia and bleeding may continue for several weeks. This uncommon cause of thrombocytopenia should be considered if bleeding follows transfusion by 5 or 6 days. Platelet transfusions are of little help in the management of this syndrome, since the new donor platelets usually are subject to the binding of antigen and damage from the antibody. Corticosteroids may be of some help in reducing the bleeding tendency. Posttransfusion purpura is self- limited, and the passage of several weeks inevitably leads to subsidence of the problem.

DIC and disseminated fibrinolysis occur intraoperatively or postoperatively when control mechanisms fail to restrain the hemostatic process to the area of tissue damage. Either process can cause diffuse bleeding and can be caused by trauma, incompatible transfused blood, sepsis, necrotic tissue, fat emboli, retained products of conception, toxemia of pregnancy, large aneurysms, and liver diseases. It is important to distinguish between the two processes or the dominant element causing intraoperative or postoperative bleeding. No single test can confirm or exclude the diagnosis or distinguish between the two disorders. The combination of thrombocytopenia, defined by smear or platelet count, positive plasma protamine test for fibrin monomers, a low fibrinogen level, and an elevated level of *FDP* provides strong indications for DIC. The euglobulin lysis time provides a method of detecting diffuse fibrinolysis.

Diffuse intraoperative and postoperative bleeding is a complication of biliary tract surgery in cirrhotic patients. This has been related to portal hypertension and coagulopathy associated with chronic liver disease. The tests used to distinguish *DIC* from fibrinolysis pertain. The therapeutic approach includes the intravenous administration of vasopressin to effect a temporary reduction in portal hypertension, and *EACA* to correct the increased fibrinolysis.

An operation performed in a patient with sepsis sometimes is attended by continued bleeding. Severe hemorrhagic disorders due to thrombocytopenia have occurred as a result of gram-negative sepsis. The pathogenesis of endotoxin-induced thrombocytopenia has been studied in detail, and it has been suggested that a labile factor, possibly factor V, is necessary for this interaction. Defibrination and hemostatic failure also may occur with meningococcemia, *Clostridium perfringens* sepsis, and staphylococcal sepsis. Hemolysis appears to be one mechanism in sepsis leading to defibrination. Evaluation of these patients includes platelet count, *PT*, *PTT*, and *TT*.

LOCAL HEMOSTASIS

Surgical bleeding, even when alarmingly excessive, is usually caused by ineffective local hemostasis. The goal of local hemostasis is to prevent the flow of blood from incised or transected blood vessels. This may be accomplished by interrupting the flow of blood to the involved area or by direct closure of the blood vessel wall defect. The techniques may be classified as mechanical, thermal, or chemical.

Mechanical Procedures

The oldest mechanical method of effecting closure of a bleeding point or preventing blood from entering the area of disruption is digital pressure. When pressure is applied to an artery proximal to an area of bleeding, profuse bleeding is reduced, permitting more definitive action. A classic example is the Pringle maneuver of occluding the hepatic artery in the hepatoduodenal ligament as a method of controlling bleeding from a transected cystic artery or from the surface of the liver. Direct digital pressure over a bleeding site, such as

a lateral rent in the inferior vena cava, is also effective. The finger has the advantage of being the least traumatic vascular hemostat. All clamps, including the so-called atraumatic vascular clamps, do result in damage to the intimal wall of the blood vessel. The most obvious disadvantage of digital pressure is that it cannot be used permanently.

The hemostat also represents a temporary mechanical device to stem bleeding. In smaller and noncritical vessels, the trauma and adjacent tissue necrosis associated with the application of a hemostat are of little consequence. These minor disadvantages are outweighed by the mechanical advantage that the instrument offers to subsequent ligation. When bleeding occurs from a vessel that should be preserved, relatively atraumatic hemostats should be employed to limit the extent of intimal damage and subsequent thrombosis.

In general, a ligature replaces the hemostat as a permanent method of effecting hemostasis in a single vessel. When a vessel is transected, a simple ligature usually is sufficient. For large arteries with pulsation and longitudinal motion, transfixion suture to prevent slipping is indicated. When the bleeding site is from a lateral defect in the blood vessel wall, suture ligatures are required. The adventitia and media constitute the major holding forces within the walls of large vessels, and therefore multiple fine sutures are preferable to fewer larger sutures.

Historically, Aulus Cornelius Celsus devised the use of ligatures in the first century a.d. Because of the strong influence of Galen, who was inclined to cautery, this method did not gain popularity. Paré, in 1552, rediscovered the principle of ligature. In 1800 Physick used absorbable sutures of buckskin and parchment. In 1858 Simpson introduced the wire suture, and in 1881 Lister employed chromic catgut. Halsted, in the early 1900s, emphasized the importance of incorporating as little tissue as possible in the suture and indicated the advantages of silk. In 1911 Cushing reported on the use of silver clips to effect hemostasis in delicate vessels in critical areas. A wide variety of staples made of different metals, relatively inert in tissue, have been used.

All sutures represent foreign material, and their selection is based on the characteristics of the material and the state of the wound. Nonabsorbable sutures, such as silk, polyethylene, and wire, evoke less tissue reaction than absorbable materials, such as catgut, polyglycolic acid (Dexon), and polyglactin (Vicryl). The latter are preferable, however, in the face of overt infection. The presence of nonabsorbable material in an infected wound can lead to extrusion or sinus tract formation. Wire is the least reactive of the nonabsorbable sutures but the most difficult to handle. Monofilament wire and coated sutures have an advantage over multifilament sutures in the presence of infection. The latter tend to fragment and permit sinus formation.

Diffuse bleeding from multiple transected vessels may be controlled by mechanical techniques that employ pressure directly over the bleeding area, pressure at a distance, or generalized pressure. These techniques are based on the premise that as pressure and flow are decreased in the area of vascular disruption, a clot will develop. As a standard procedure of military surgeons in the seventeenth century, pressure at a distance was effected by application of tourniquets and other pressure devices at pressure points proximal to bleeding sites. Now it is generally believed that direct pressure is preferable and is not attended by the danger of tissue necrosis associated with prolonged use of tourniquets. Gravitational suits have been used to create generalized pressure and temporarily decrease bleeding from ruptured major intraabdominal vessels.

Direct pressure applied by means of packs affords the best method of controlling diffuse bleeding from large areas. Rarely is it necessary to leave a pack at the bleeding site and remove it at a second sitting. If this is done, several days should elapse before removal, and the possibility of recurrent bleeding should be anticipated. The question of whether hot wet packs or cold wet packs should be applied has been investigated. Unless the heat is so great as to denature protein, it may actually increase bleeding, whereas cold packs promote hemostasis by inducing vascular spasm and increasing endothelial adhesiveness. Bleeding from cut bone may be controlled by packing beeswax in the area. This material effects pressure and is relatively nonirritating to the body.

Thermal Agents

Galen's favoring of cautery influenced medicine for 1500 years, until the teachings of Paré were appreciated. The use of cautery was revitalized in 1928, when Cushing and Bovie applied this technique for effecting hemostasis of delicate vessels in recessed areas, such as the brain. Heat achieves hemostasis by denaturation of protein, which results in coagulation of large areas of tissue. With actual cautery, heat is transmitted from the instrument by conduction directly to the tissue; with electrocautery, heating occurs by induction from an alternating-current source.

When electrocautery is employed, the amplitude setting should be high enough to produce prompt coagulation but not so high as to set up an arc between the tissue and the cautery tip. This avoids burns outside the operative field and prevents the exit of current through electrocardiographic leads or other monitoring devices. A negative plate should be placed beneath the patient whenever cautery is employed to avoid severe skin burns. The advantage of cautery is that it saves time; its disadvantage is that more tissue is necrosed than with precise ligature. Certain anesthetic agents cannot be used with electrocautery because of the hazard of explosion.

A direct current can also result in electrical hemostasis. Since the protein moieties and cellular elements of blood have a negative surface charge, they are attracted to the positive pole, where a thrombus is formed. Direct currents in the 20- to 100-mA range have been applied to control diffuse bleeding from large serous surfaces. Argon gas has been applied successfully to the control of bleeding from superficial erosions.

At the other end of the thermal spectrum, cooling has been applied to control bleeding, particularly from the mucosa of the esophagus and stomach. Generalized hypothermia is of little avail, since in order to reduce the blood flow to visceral organs, the systemic temperature must be brought down to the level of 35°C. At this point shivering and ventricular fibrillation may occur. Thrombocytopenia may also be a consequence of generalized cooling. Direct cooling with iced saline is effective and acts by increasing the local intravascular hematocrit concentration and decreasing blood flow by vasoconstriction.

Extreme cooling, i.e., cryogenic surgery, has been applicable particularly in gynecology and neurosurgery. Temperatures ranging between -20 to- 180°C are used, and freezing occurs around the tip of the cannula within 5 s. At temperatures of -20°C or below, the tissue, capillaries, small arterioles, and venules undergo cryogenic necrosis. This is caused by dehydration and denaturation of lipid molecules. The muscular walls of large arteries are an exception. Although the major arteries and blood may be frozen solid, the blood contained in these vessels does not clot. When thawing occurs, normal circulation is resumed.

Chemical Agents

Chemical agents vary in their hemostatic action. Some are vasoconstrictive, while others have coagulant properties. Still others are relatively inert but possess hygroscopic properties which increase their bulk and aid in plugging disrupted blood vessels.

Epinephrine, applied topically, induces vasoconstriction, but extensive application can result in considerable absorption and systemic effects. The drug generally is used on oozing sites in mucosal areas, e.g., during tonsillectomy.

Historically, skeletal muscle was one of the first materials with locally hemostatic properties to be employed, its use having been introduced by Cushing in 1911. Shortly thereafter, hemostatic fibrin was manufactured. The properties required for local hemostatic materials include handling ease, rapid absorption, hemostatic action independent of the general clotting mechanism, and they should be nonirritating. The most widely used of the commercially available materials are gelatin foam (Gelfoam), oxidized cellulose (Oxycel), oxidized regenerated cellulose (Surgicel), and micronized collagen (Avitene). All these materials act, in part, by transmitting pressure against the wound surface, and the interstices provide a scaffold on which the clot can organize (Table [3-4](#)).

Gelfoam is made from animal skin gelatin that has been denatured. In itself Gelfoam has no intrinsic hemostatic action, but it can be used in combination with topical thrombin, for which it serves as an absorbable carrier. Its main hemostatic activity is related to the contact between blood and the large surface area of the sponge and to the pressure exerted by the weight of the sponge and absorbed blood. Before Gelfoam is applied, the sponge should be moistened in saline or thrombin solution and all the air should be removed from the interstices.

Oxycel and Surgicel are altered cellulose materials capable of reacting chemically with blood and producing a sticky mass that functions as an artificial clot. These substances are relatively inert and are removed by liquefaction in 1 to 4 weeks. They should be dry when they are applied. Like Gelfoam, these materials are nontoxic and relatively nonirritating but are somewhat detrimental to wound healing and require phagocytosis to be removed. Surgicel has been shown to have an antibacterial effect. Microcrystalline collagen has been shown to be as effective as other materials as a topical hemostatic agent for large oozing surfaces.

Fibrin glue is commercially available in Europe and Canada but not in the United States, because of the potential of disease transmission when fibrinogen is obtained from pooled plasma. Single-donor fibrinogen can be mixed with bovine thrombin to make the sealant. The glue is particularly effective in controlling surface bleeding from the liver and spleen.

TRANSFUSION

Background

In 1967, the tercentennial anniversary of the transfusion of blood into human beings was celebrated. In June 1667 Jean-Baptiste Denis and a surgeon, Emmerez, transfused blood from a sheep into a 15-year-old boy who had been bled many times as treatment for fever. The patient apparently improved, and a successful experience was reported simultaneously in another patient. Because of two subsequent deaths associated with transfusion from animals to humans, criminal charges were brought against Denis. In April 1668 further transfusions in humans were forbidden unless approved by the Faculty of Medicine in Paris. It was not until the nineteenth century that human blood was recognized as the only appropriate replacement. In 1900 Landsteiner and his associates introduced the concept of blood grouping and identified the major A, B, and O groups. In 1939 the Rh group was recognized. The introduction of various preservative solutions, such as *acid-citrate-dextrose (ACD)*, *citrate- phosphate-dextrose (CPD)*, and citrate-phosphate-double-dextrose adenine (CP2D-A) and newer additive solutions extended the shelf life of blood to up to 6 weeks.

Preservation of blood and its constituents has been achieved by freezing, and emphasis has been placed on the use of plasma expanders and component therapy.

Characteristics of Blood and Replacement Therapy

Blood

Blood has been described as a vehicular organ that perfuses all other organs. It provides transportation of oxygen to satisfy the body's metabolic demands and removes the by-product carbon dioxide. Blood also transports chemical nutrients for, and waste products from, metabolic activity. Homeostatic governors, including hormones, coagulation factors, and antibodies, are carried to and from appropriate sites within the fluid portion of the blood. Red blood cells, with their oxygen-carrying capacity; white blood cells, which function in body defense processes; and platelets, which contribute to the hemostatic process, comprise the formed elements.

Replacement Therapy Banked Whole Blood

Banked whole blood is now rarely indicated and rarely available. With the new preservatives, the shelf life has been extended to 40 ± 5 days. At least 70 percent of the transfused erythrocytes remain in the circulation for 24 h after transfusion and are viable. The changes in the red cell that occur during storage include reduction of intracellular adenosine triphosphate (ATP) and *2,3-diphosphoglycerate (2,3-DPG)*, which alters the curve of oxygen dissociation from hemoglobin, decreasing oxygen transport function. Banked blood is a poor source of platelets because platelets lose their ability to survive transfusion after 24 h of storage. Among the clotting factors, II, VII, IX, and XI are stable in banked blood. Within 21 days of storage, the pH decreases from 7.00 to 6.68, and the lactic acid level increases from 20 to 150 mg/dL. The potassium concentration rises steadily to 32 mEq/dL, and the ammonia concentration rises from 50 to 680 mg/dL at the end of 21 days for CPD whole blood. The hemolysis that occurs during storage is insignificant.

Typing and Crossmatching

In selecting blood for transfusion, serologic compatibility is established routinely for the recipients' and donors' A, B, O, and Rh groups. Crossmatching between the donors' red cells and the recipients' sera (the "major" crossmatch) is performed. As a rule, Rh-negative recipients should be transfused only with Rh-negative blood. Since this group represents 15 percent of the donor population, the supply may be limited. If the recipient is an elderly male who has not been transfused previously, the transfusion of Rh-positive blood is acceptable if Rh-negative blood is unavailable. Anti-Rh antibodies form within several weeks of transfusion. If further transfusions are needed within a few days, more Rh-positive blood can be used. Rh-positive blood should not be transfused to Rh-negative females who are capable of childbearing. Administration of hyperimmune anti-Rh globulin to Rh-negative women shortly before or after childbirth largely eliminates Rh disease in subsequent offspring.

In the patient who is receiving repeated transfusions, serum drawn not more than 72 h before crossmatching should be utilized for matching with cells of the donor. Emergency blood transfusion can be performed with type O blood. O-negative and type-specific red blood cells are equally safe for emergency transfusion. Problems are associated with the administration of 4 or more units of O-negative blood because there is a significant increase in the risk of a hemolytic reaction.

In patients with malignant lymphoma and leukemia, cryoglobulins may be present, and the blood should be administered through a blood warmer. If these antibodies are present in high titer, hypothermia may be contraindicated.

In patients with thalassemia who have been multiply transfused and, more particularly, with acquired hemolytic anemia, typing and crossmatching may be difficult, and sufficient time should be allotted during the preoperative period to accumulate blood that may be required during the operation. Crossmatching should always be carried out prior to the administration of dextran, since dextran interferes with the typing procedure.

Because banked blood may be stored for 40 ± 5 days, the use of autologous predeposit transfusion is growing. In otherwise healthy, nonanemic patients, up to 5 or 6 units of blood may be collected for use in elective surgical procedures. Patients may donate blood if the hemoglobin level exceeds 11 g/dL or if the hematocrit concentration is greater than 34 percent. The first procurement is performed 40 days before the planned operation and the last one, 3 days before the procedure. Donations can be scheduled at intervals of 4 to 5 days. Recombinant human erythropoietin (r-HuEPO) accelerates generation of red cells and allows for more frequent harvest for elective operative procedures.

Fresh Whole Blood

This term refers to blood that is administered within 24 h of its donation. It is rarely indicated. Because of the time requirements of testing for infectious diseases, fresh blood is only available untested. One unit of platelet concentrate has more viable platelets than 1 unit of fresh whole blood, which is also an inadequate source of factor VIII.

Packed Red Cells and Frozen Red Cells

Packed red cells is the product of choice for most clinical situations. Concentrated suspensions of cells can be prepared by removing most of the supernatant plasma after centrifugation. The preparation reduces but does not eliminate reaction caused by plasma components. It also reduces the amount of sodium, potassium, lactic acid, and citrate administered. Essentially it provides oxygen-carrying capacity.

Frozen red cells are not available for use in emergencies. They are often used for patients who have been previously sensitized because they have been selected for lack of certain antigens. The red cell viability is improved, and the ATP and *2,3-DPG* concentrations are maintained.

Leukocyte-Poor Washed Cells

This product is prepared by aspirating the buffy coat and supernatant plasma and passing them through a specific white-cell filter. The red cells then are washed with sterile isotonic solution. This should be done only for patients with demonstrated hypersensitivity to leukocytes or platelets (buffy coat reactions). Usually this syndrome is manifest by fever, chilly sensations, and urticaria due to plasma proteins in the absence of hemolysis.

Platelet Concentrates

The indications for platelet transfusion are as follows: thrombocytopenia due to massive blood loss and replacement with platelet-poor products, thrombocytopenia due to inadequate production, and qualitative platelet disorders. The preparations should be used within 120 h of blood donation. One unit of platelet concentrate has a volume of approximately 50 mL. Platelet preparations may transmit infectious diseases and account for allergic reactions similar to those caused by whole blood. When treating thrombocytopenic bleeding or preparing some thrombocytopenic patients for surgery, it is advisable to elevate the platelet levels to the range of 50,000 to 100,000/mm³ to provide continued protection. The development of isoimmunity remains one of the most important factors limiting the usefulness of platelet transfusion. Isoantibodies are demonstrable in about 5 percent of patients after 1 to 10 transfusions, in 20 percent after 10 to 20 transfusions, and in 80 percent after more than 100 transfusions. The use of HLA-compatible platelets addresses this problem.

Frozen Plasma and Volume Expanders

Frozen plasma prepared from freshly donated blood or fresh plasma is necessary to provide factors V and VIII. The other plasma clotting factors are present in banked preparations. The risk of infectious disease is the same whether fresh frozen plasma or whole blood/red cells is administered. Lactated Ringer's solution or buffered saline solution administered in amounts two to three times the estimated blood loss, is effective and is associated with fewer complications. Dextran or a combination of lactated Ringer's solution and normal human serum albumin are preferred for rapid plasma expansion. Commercially available dextran preparations probably should not be administered in amounts exceeding 1 L/day, since prolongation of bleeding time and hemorrhage can occur. Low-molecular-weight dextran, i.e., molecular weight of 30,000 to 40,000, has become popular because it possesses a higher colloidal pressure than plasma and effects some reversal of erythrocyte agglutination.

Concentrates

Antihemophilic concentrates are prepared from plasma and are available for the treatment of factor VIII deficiency. Some of these concentrates are twenty to thirty times as potent as an equal volume of fresh frozen plasma. The simplest factor VIII concentrate is the plasma cryoprecipitate. *Albumin* also has been concentrated, so 25 g may be administered and provide the osmotic equivalent of 500 mL of plasma. The advantage of albumin is that it is a hepatitis-free product.

Indications for Replacement of Blood or Its Elements

Improvement in Oxygen-Carrying Capacity

Oxygen-carrying capacity is primarily a function of the red cell. When anemia can be treated by specific therapy, such as erythropoietin, transfusion should be withheld. Acute anemias, such as hemolytic anemia, are more disabling physiologically than chronic anemia, since most patients with chronic anemia have undergone an adjustment to the condition. In pregnancy there is a moderate drop in hematocrit level, and transfusions are not indicated to correct the physiologic anemia of pregnancy before surgical treatment. The correction of chronic anemia before surgical treatment, though often performed, is difficult to justify. A 1988 National Institutes of Health Consensus Report challenged the dictum that a hemoglobin value of less than 10 g/dL or a hematocrit level of less than 30 percent indicates a need for a preoperative red cell transfusion. It is suggested that cardiac output does not increase significantly in healthy individuals until the hemoglobin value decreases to approximately 7 g/dL. Patients with chronic anemia and a hemoglobin value less than 7 g/dL in whom significant bleeding intraoperatively is not anticipated do not require a transfusion preoperatively. There is no correlation between anemia and dehiscence or severity of postoperative infection.

Blood volume may be replaced with dextran solution or lactated Ringer's solution with a reduction of the hemoglobin value to levels below 10 g and little demonstrable change in the effects of a reduction in oxygen-carrying capacity or the capacity to remove metabolic gaseous by-products. A stroma-free hemoglobin solution has been shown to have the ability to carry and exchange oxygen. Also, a whole blood substitute, Fluosol-DA, has been proposed as a solution with oxygen-handling capabilities.

Volume Replacement

The most common indication for blood transfusion in surgical patients is the replenishment of the circulating blood volume. It is difficult to evaluate the volume deficit accurately.

Values for "normal blood volume" are variable, and the techniques of measurement are relatively inaccurate when there is a rapidly changing situation, such as hemorrhage. Chronically ill and elderly patients may have a diminution of blood volume. In patients with cardiac decompensation, the blood volume may be greater than normal. Many patients with chronically reduced blood volume are well accommodated to that volume.

Measurement of hemoglobin or hematocrit levels is also used to interpret blood loss. These measurements are misleading in the face of acute blood loss, since the hematocrit level may be normal in spite of a severely contracted blood volume. It has been shown that, after a healthy adult male lost approximately 1000 mL of blood rapidly, the venous hematocrit fell only 3 percent during the first hour, 5 percent at 24 h, 6 percent at 48 h, and 8 percent at 72 h, thus indicating the time required for the body to restore blood volume.

Both the amount and the rate of bleeding are factors in the development of the signs and symptoms of blood loss. A healthy person can lose 500 mL in 15 min with only minor effects on the circulation and little change in blood pressure or pulse. Loss of 15 to 30 percent of blood volume (class II hemorrhage) is associated with tachycardia and decreased pulse pressure. Loss of 30 to 40 percent (class III hemorrhage) generally results in tachycardia, tachypnea, hypotension, oliguria, and changes in mental status.

Loss of blood may be evaluated in the operating room by estimating the amount of blood in the wound and on the drapes and by weighing sponges. The loss determined by weighing sponges is only about 70 percent of true loss. In patients who have normal preoperative blood values, blood loss up to 20 percent of total blood volume (TBV) is replaced with crystalloid solutions. Blood loss up to 50 percent of TBV is replaced with crystalloids and red blood cell concentrates. Blood loss above 50 percent of TBV is replaced with crystalloids, red blood cells, and albumin or plasma. Continued bleeding above 50 percent of TBV should receive the same components and fresh frozen plasma. If electrolyte solutions are used to replace blood volume, an amount three to four times the lost volume is required because of immediate diffusion into the interstitial space.

Replacement of Clotting Factors

Transfusion of platelets and/or proteins contributing to coagulation may be indicated in specific patients either before or during operation (Table 3-5). In the treatment of certain hemorrhagic conditions, it must be kept in mind that the clotting defects may be multiple. The efficacy of fresh frozen plasma in the management of coagulopathy in patients with liver disease and in patients receiving large amounts of volume replacement for acute blood loss is not well defined. There are insufficient data to specify criteria for transfusion of fresh frozen plasma. The initial volume of fresh frozen plasma needed for an effect on coagulation ranges from 600 to 2000 mL administered in 1 to 2 h. The rigid use of the *PT* and *PTT* to anticipate the effect of fresh frozen plasma is not justified.

Specific Indications Massive Transfusion

The term *massive transfusion* implies a single transfusion greater than 2500 mL, or 5000 mL transfused over a period of 24 h. The approximate percentages of *original* blood volume remaining after varying degrees of hemorrhage and transfusion are shown in Table 3-6. A variety of problems may attend the use of massive transfusion. Circulatory overload or *DIC* may occur. Dilutional thrombocytopenia, impaired platelet function, and deficiencies of factors V, VIII, and XI may occur. Routine alkalization is not advisable, since this could have an adverse effect on the oxyhemoglobin dissociation curve and presents an additional sodium load to a compromised patient. The increased potassium content of multiple units of stored blood does not provide clinical effects unless the patient is severely oliguric.

Citrate toxicity may be associated with massive transfusion, particularly in young children and patients with severe hypotension or liver disease. This toxicity is related to an excessive binding of ionized calcium and is usually corrected by spontaneous mobilization of calcium from bone. The physiologic consequences of citrate toxicity rarely have a significant effect. The function of hemoglobin is altered by storage, since the concentration of 2,3-DPG falls to a negligible level by the third week. This results in an increased affinity of the red blood cells for oxygen and a less efficient oxygen delivery system. In itself, reduction of 2,3-DPG may not have a significant effect, but when combined with acute anemia it may be an important factor.

When large transfusions are administered, a heat exchanger may be used to warm the blood, since hypothermia may cause a decrease in cardiac rate and output and a reduction in the blood pH. Warming the blood decreases significantly the frequency of intraoperative cardiac arrest.

The use of blood from many donors increases the possibility of hemolytic transfusion reaction due to incompatibility. This can be reduced by screening each potential donor in the pool and eliminating those who show possible incompatibility. Paradoxically, patients who survive a massive transfusion do not have a high probability of developing isoantibodies subsequently, and the risk is no greater than that from a single transfusion. The risk of infectious disease increases progressively with each succeeding unit. When administering massive transfusions, the pH, blood gases, and potassium should be measured regularly. Acidosis and abnormalities should be corrected. If diffuse bleeding occurs, coagulation screening tests and platelet counts should be performed and deficits corrected with frozen plasma and platelet concentrates.

Methods of Administering Blood

Routine Administration

The rate of transfusion depends on the patient's status. Usually 5 mL/min is administered for 1 min, after which 10 to 20 mL/min may be administered to complete routine transfusion. When marked oligemia is being treated, the first 500 mL may be given within 10 min, and the second 500 mL may be given equally rapidly in most cases. Cold blood may be used for this amount, but when larger amounts are administered, warm blood is desirable. As much as 1500 mL/min can be administered through two 7.5F catheters.

When large transfusions are administered, it is important not to overload the circulation, and the use of central venous pressure monitoring is particularly pertinent. There is no practical advantage in the use of intraarterial transfusion over the intravenous route in the treatment of oligemia. It has been shown that coronary flow and systemic arterial pressure respond as rapidly and to the same extent whether the blood is administered intravenously or intraarterially.

Other Methods

Blood may be instilled intraperitoneally or into the medullary cavity of the sternum and long bones. Intrasternal and intramedullary transfusion may be painful, and the rate of administration is limited. Approximately 90 percent of red cells injected intraperitoneally enter the circulation, but uptake is not complete for at least a week, and therefore the method is not suitable when immediate transfusion is required.

Intraoperative autotransfusion has become increasingly popular; it is a potentially life-saving adjunct to the management of trauma and is useful in elective operations in which multiple transfusions are likely to be required. Approximately 250 mL of blood can be retrieved, washed or filtered, and returned to the patient over a 5- to 6-min period. A comparison between cell washing and simple filtration revealed that filtration allowed a greater percentage of blood to be returned and was associated with less thrombocytopenia. Another approach to anticipated intraoperative large blood losses is hemodilution. At the onset of the procedure, red cells are removed while the intravascular volume is maintained with crystalloid or colloid. The reduced blood viscosity improves microcirculatory perfusion. The removed blood can then be retransfused during the operation to replace lost blood or be reinfused near the completion of the procedure.

Complications

Hemolytic Reactions

The incidence of nonfatal hemolytic transfusion reactions is approximately 1 per 6000 units of blood administered. Fatal hemolytic transfusion reactions occur once in every 100,000 units administered. Hemolytic reactions due to incompatibility of A, B, O, and Rh groups or many other independent systems may result from errors in the laboratory of a clerical or technical nature or the administration of the wrong blood at the time of transfusion. Hemolytic reactions are characterized by intravascular destruction of red blood cells and consequent hemoglobinemia and hemoglobinuria. Circulating haptoglobin is capable of binding 100 mg hemoglobin/dL plasma, and the complex is cleared by the reticuloendothelial system. When the binding capacity is exceeded, free hemoglobin circulates, and the heme is released and combines with albumin to form methemalbumin. Heme in plasma is detected by a positive Schumm's test. When free hemoglobin exceeds 25 mg/dL plasma, some is excreted in the urine, but in most subjects hemoglobinuria occurs when the total plasma level exceeds 150 mg/dL. The renal lesions that may occur consist of tubular necrosis and precipitation of hemoglobin within the tubules. Red cell stromal lipid is liberated, and this may initiate a disseminated intravascular coagulation. But *DIC* is more likely initiated by antibody-antigen complexes activating factor XII and complement, leading to activation of the coagulation cascade. The kallikrein-bradykinin system may be activated and affect the circulatory system. Minor incompatibilities may occur, causing hemolysis within the reticuloendothelial system manifested by fever, a mild decrease in hemoglobin, and an increase in bilirubin. If the recipient has a low antibody titer at the time of transfusion, reaction may be delayed for several days.

Clinical Manifestations

There is an increased hazard in patients who have had a previous transfusion reaction. If the patient is awake, the most common symptoms are the sensation of heat and pain along the vein into which the blood is being transfused, flushing of the face, pain in the lumbar region, and constricting pain in the chest. The patient may experience chills, fever, respiratory distress, hypotension, and tachycardia from amounts as small as 50 mL. In patients who are anesthetized and undergoing operation, the two signs that may draw attention are abnormal bleeding and continued hypotension despite adequate replacement. The mortality and morbidity resulting from hemolytic reactions is high if the patient receives a full unit of incompatible blood. Acute hemorrhagic diatheses occur in 8 to 30 percent of patients. There is a sudden fall in the platelet count, an increase in fibrinolytic activity, and consumption of coagulation factors, especially V and VIII, due to disseminated intravascular clotting.

Rudowski reported the following incidences of clinical manifestations in a large series with hemolytic posttransfusion reactions: oliguria, 58 percent; hemoglobinuria, 56 percent; arterial hypotension, 50 percent; jaundice, 40 percent; nausea and vomiting, 30 percent; flank pain, 25 percent; cyanosis and hypothermia, 22 percent; dyspnea, 20 percent; chills, 18 percent; diffuse bleeding, 16 percent; neurologic signs, 10 percent; and allergic reaction, 6 percent. The laboratory criteria are hemoglobinuria with a concentration of free hemoglobin over 5 mg/dL, a serum haptoglobin level below 50 mg/dL, and serologic criteria to show antigen incompatibility of the donor and recipient blood. The simplest clinical diagnostic test is insertion of a bladder catheter and evaluation of the color and volume of the excreted urine, since hemoglobinuria and oliguria are the most characteristic signs. A positive Coombs' test indicating transfused cells coated with patient antibody also provides evidence.

Treatment

If a transfusion reaction is suspected, the transfusion should be stopped immediately, and a sample of the recipient's blood should be drawn and sent along with the suspected unit to the blood bank for comparison with the pretransfusion samples. The serum bilirubin level should be determined in the recipient. Each gram of hemoglobin is converted to about 40 mg of bilirubin. The hemolytic reaction is characterized by an increase in the indirect reacting fraction.

A Foley catheter should be inserted and the hourly urine output recorded. Since renal toxicity is affected by the rate of urinary excretion and the pH, and since alkalizing the urine prevents precipitation of hemoglobin within the tubules, attempts are made to initiate diuresis and to alkalize the urine. This can be accomplished with mannitol or furosemide plus 45 mEq bicarbonate. If marked oliguria or anuria occurs, the fluid intake and potassium intake are restricted, and the patient is treated as a case of renal shutdown. In some instances, dialysis is required. After recovery from oliguria or anuria, diuresis is often copious and may be associated with significant losses of potassium and sodium, which require replacement.

Febrile and Allergic Reactions

These are relatively frequent, occurring in about 1 percent of transfusions. Reactions usually are mild and are manifested by urticaria and fever occurring within 60 to 90 min of the start of transfusion. In rare instances the reaction is severe enough to cause anaphylactic shock. Allergic reactions are caused by transfusion of antibodies from hypersensitive donors or the transfusion of antigens to which the recipient is hypersensitive. Reactions may occur after the administration of whole blood, packed red cells, plasma, and antihemophilic factor. Treatment consists of administration of antihistamines, epinephrine, and steroids, depending on the severity of the reaction. Repeated reactions can be prevented by the use of leukocyte-depleted or washed red cells.

Bacterial Sepsis

Bacterial contamination of infused blood is rare and may be acquired either from the contents of the container or the skin of the donor. Gram-negative organisms, especially coliform and *Pseudomonas* species, which are capable of growth at 4°C, are the most common cause. Clinical manifestations include fever, chills, abdominal cramps, vomiting, and diarrhea. There may be hemorrhagic manifestations and increased bleeding if the patient is undergoing surgical treatment. In some instances bacterial toxins can produce profound shock. If the diagnosis is suspected the transfusion should be discontinued and the blood cultured. Emergency treatment includes administration of adrenergic blocking agents, oxygen, antibiotics, and, in some cases, judicious transfusion.

Embolism

Although air embolism has been reported as a complication of intravenous transfusion, healthy animals tolerate large amounts of air injected intravenously at a rapid rate. It has been suggested that the normal adult generally can tolerate an embolism of 200 mL of air. Smaller amounts, however, can cause alarming signs and may be fatal. Manifestations of venous air embolism include a rise in venous pressure, cyanosis, a “mill wheel” murmur heard over the precordium, hypotension, tachycardia, and syncope. Death usually is related to primary respiratory failure. Treatment consists of placing the patient on the left side in a head-down position with the feet up. Arterial air embolism is manifested by dizziness and fainting, loss of consciousness, and convulsions. Air may be visible in the retinal arteries, and bubbles of air may flow from transected vessels.

Plastic tubes used for transfusion have also embolized after they have broken off within the vein. Plastic tubes have passed into the right atrium and the pulmonary artery, resulting in death. Embolized catheters have been removed successfully.

Thrombophlebitis

Prolonged infusions into peripheral veins using either needles, cannulae, or plastic tubes are associated with superficial venous thrombosis. Intravenous infusions that last more than 8 h are more likely to be followed by thrombophlebitis. There is an increased incidence in the lower limb as compared to upper limb infusions. Treatment consists of discontinuation of the infusion and local compression. Embolism from superficial thrombophlebitis of this nature is rare.

Overtransfusion and Pulmonary Edema

Overloading the circulation is an avoidable complication. It may occur with rapid infusion of blood, plasma expanders, and other fluids, particularly in patients with heart disease. In order to prevent this complication, the central venous pressure should be monitored in these patients and whenever large amounts of fluid are administered.

Circulatory overloading is manifested by a rise in the venous pressure, dyspnea, and cough. Rales generally can be heard at the base of the lungs. Treatment consists of stopping the infusion, placing the patient in a sitting position, and, occasionally, venous section for removal of blood.

Although acute pulmonary edema occurs more frequently after large transfusions, it has been reported in patients receiving small transfusions. A syndrome that can be confused with pulmonary edema consists of postoperative hypoxia, seen in patients who have undergone cardiac surgical treatment and extracorporeal bypass procedures. A damaging factor apparently is carried by the perfusing blood, and immature plasma cells are found in the interalveolar tissue. The illness represents an immune response to blood. The incidence is reduced by employing the hemodilution technique of pump priming.

Transmission of Disease

Malaria, Chagas' disease, brucellosis, and syphilis are among the diseases that can be transmitted by blood transfusion. Syphilis has been reported after the transfusion of platelets. The storage temperature used for all other blood components (4°C or lower) kills the spirochete. The incubation period ranges from 4 weeks to 4 months. The first manifestation is the skin rash of secondary syphilis. Cure is readily achieved with brief penicillin therapy. Malaria can be transmitted by all blood components, including platelets, fresh frozen plasma, and frozen or deglycerolized red cells. The species most commonly implicated is *Plasmodium malariae*. The incubation period ranges from 8 to 100 days; the initial clinical manifestation is shaking chill and spiking fever. Cytomegalovirus (CMV) infection, causing a syndrome resembling infectious mononucleosis, was commonly observed after open-heart surgery when large amounts of heparinized blood were used to prime the pump. The most significant morbidity and mortality occurs after transfusion of CMV-infected blood in low-birth-weight infants born of mothers who were CMV antibody–negative.

Posttransfusion viral hepatitis remains the most common fatal complication of blood transfusion. It is estimated that for every case of icteric posttransfusion viral hepatitis there are four anicteric cases, many of which are asymptomatic. Hepatitis is caused either by hepatitis B virus, or the non-A, non-B viruses, including C. The incubation period of the former is up to 6 months, the latter's may be as short as 2 weeks. Serologic markers for hepatitis B surface antigen (HB sAg) and hepatitis C are available, and collecting agencies are required to test all units of blood for these antigens. The risk of hepatitis transmission per unit of blood is 0.035 percent.

The clinical manifestations of hepatitis include lethargy and anorexia as part of anicteric disease, icterus, and chronic liver disease. HB sAg persists in about 35 percent of patients who develop serum hepatitis of type B. There is no risk from human serum albumin and other plasma protein fractions.

Immune globulin is effective in preventing type A hepatitis but is inconsistent in preventing type B hepatitis. Accidental self-inoculation with material that is definitely known to contain HBsAg, or transfusion of blood that is HB sAg-positive, constitutes an indication for immediate use of immunoglobulin (human) anti-HB sAg. The recommended dose is 0.02 to 0.06 mL/kg BW of IgG given as an intramuscular injection. A vaccine has been developed against HB sAg, and it is recommended that all surgeons undergo vaccination.

The incidence of AIDS following blood transfusion has been estimated to be one case per 225,000 patients transfused, and blood collecting agencies have taken measures to preclude donors in high-risk groups and to apply screening techniques.

CHAPTER 4 - Shock

Annabel Barber
G. Tom Shires III
G. Tom Shires

DEFINITION

Shock is a pathophysiologic condition clinically recognized as a state of inadequate tissue perfusion. A constant internal environment was first suggested by the French physiologist Claude Bernard. In the mid–nineteenth century Bernard proposed that higher animals lived in two very different environments—a *milieu int érieur*, in which the tissue elements live, and a *milieu ext érieur*, in which the body resides. He stated that “the stability of the *milieu int érieur* is the primary condition for freedom and independence of existence: the mechanism which allows this is that which insures in the *milieu int érieur* the maintenance of all the conditions necessary to the life of the elements.” Bernard went on to declare that “the circulation of the blood forms a true organic environment, intermediary between the external environment in which the individual as a whole lives and the molecules of the living cells which would otherwise not come into direct relationship with that external environment.” The notion that the constancy of the internal environment is protected by multiple intrinsic mechanisms, including renal, pulmonary, hepatic, and cell- membrane function, evolved over the next fifty years. Walter Cannon coined the term “homeostasis,” which led to the concept that an organism's fitness for survival is directly related to its capacity to maintain homeostasis. From this evolved the biologic precept that the extracellular fluid, including circulation, is the true milieu of life because it enables the cells of the body to function.

In the first part of this century a variety of theories addressed the cause of vascular collapse in injured patients. It was assumed that this vascular collapse was caused primarily by toxins. In a series of innovative experiments beginning with Blalock, researchers determined that almost all acute injuries are associated with changes in fluid and electrolyte metabolism. These studies showed that the alterations were primarily the result of reductions in the effective circulating blood volume and that this reduction may be the result of loss of blood as in hemorrhage, but also as a result of loss of vascular tone (e.g., in septic or neurogenic shock), pump failure (cardiac tamponade) or myocardial infarction, or loss of large volumes of extracellular fluid, which occurs in patients with diarrhea, vomiting, or fistula drainage. Blalock's studies showed that fluid loss in injured tissues was loss of extracellular fluid that was unavailable to the intravascular space for maintenance of circulation. The original concept of a “third space” in which fluid would be sequestered and thus unavailable to the intravascular space, evolved from those studies.

During World War II plasma became a favored resuscitative solution in addition to whole-blood replacement. However, the principle that a limited amount of salt and water should be given to the patient after surgical or other injury prevailed through the Korean War, largely because of the work of Collier and Moyer in experiments done at the University of Michigan. By the time of the Vietnam War, the provision of volume resuscitation in excess of replacement of shed blood became standard to maintain adequate homeostasis. During World War II acute tubular necrosis had been seen commonly after hypovolemic shock, but with the liberal use of fluid resuscitation during the Vietnam conflict, the incidence of acute tubular necrosis dramatically decreased (Table 4-1).

The etiologic classification offered by Blalock in 1934 remains a useful outline for a modern definition. Blalock suggested four categories: hematogenic, neurogenic, vasogenic, and cardiogenic. It now is clear that shock is a systemic disorder that disrupts vital organ function as the eventual result of a variety of causes. Whereas hemorrhagic or traumatic shock is characterized by global hypoperfusion, septic shock may be associated with hyperdynamic circulation resulting in a maldistribution of regional or intraorgan blood flow. Consequently, Cerra's description of shock as a “disordered response of organisms to an inappropriate balance of substrate supply and demand at a cellular level” may more accurately reflect the unifying functional abnormality at the metabolic level.

CIRCULATORY HOMEOSTASIS

Preload

The majority of the blood volume at rest is contained within the venous system. The effect of the return of this venous blood to the heart produces ventricular end-diastolic wall tension, a major determinant of cardiac output. Gravitational shifts in blood volume distribution are rapidly compensated for by active and passive alterations in venous capacity. The thin-walled systemic veins are highly compliant. As arteriolar inflow increases, the venous pressure rises and venous capacitance passively increases. With decreased arteriolar inflow, active contraction of the venous smooth muscle cells and passive elastic recoil combine to increase return of blood flow to the heart, maintaining adequate ventricular filling and supporting cardiac output.

In the normal heart, most changes in cardiac output are a reflection of alterations in preload. Changes in position, intrathoracic pressure, intrapericardial pressure, and circulating blood volume produce major changes in cardiac output. Different venous beds play different roles in regulating preload. Veins in the skeletal muscles show a minor response to sympathetic stimulation and respond more to external factors, predominantly the balance between gravitational forces and the muscle pump. Increases in sympathetic outflow to the splanchnic vascular bed produce a rapid and dramatic reduction in the splanchnic blood volume that normally contains about 20 percent of the total blood volume. Exercise and the response of central baroreceptors during hemorrhage reflexively decrease the splanchnic capacitance after these stimuli of sympathetic outflow. Cutaneous noradrenergic nerves respond to hypothalamic control and alter the venous tone of the skin to promote thermal regulation during resting heat stress, exercise demands, and the febrile response.

The normal circulating blood volume is maintained within narrow limits by balancing salt and water intake with external losses by the kidney's ability to respond to alterations in hemodynamics and the hormonal effects of renin, angiotensin, and antidiuretic hormone. The summation of these relatively slow responses, which maintain adequate preload by altering the circulating blood volume, are overshadowed in the acute setting by the changes in the venous tone, systemic vascular resistance, and intrathoracic pressure. In addition, the net effect of preload on the ventricle also responds to the cardiac determinants of ventricular function, including coordinated atrial contraction, which augments ventricular diastolic filling, and tachycardia, which drops the effect of preload on the ventricle by compromising diastolic filling time.

Ventricular Contraction

The Frank-Starling curve describes the varying force of ventricular contraction as a function of its preload. The changes in force development are explained by the ultrastructural property of the myocardium, which generates a force of contraction dependent on initial muscle length. A variety of disease states, including myocardial injury, valve dysfunction, and cardiac hypertrophy, may alter the mechanical performance of the heart. Experimental studies in burn, septic, hemorrhagic, and traumatic shock have documented deteriorating intrinsic cardiac function during these injury states. While the mechanisms of these alterations in myocardial performance are unclear, their effect on the evaluation and management of global perfusion in clinical shock may be assessed by Swan-Ganz catheterization that measures preload indirectly as end-diastolic pressure, thermodilution cardiac output, and estimations of calculated vascular resistance.

Afterload

Afterload is the force acting to resist myocardial work during contraction. Arterial pressure is the major component of afterload that influences the ejection fraction. This vascular resistance is primarily determined by precapillary smooth muscle sphincters in conjunction with other rheologic factors such as blood viscosity. If afterload increases, stroke volume can be maintained in the presence of an increase in preload. Unlike in normal heart function, in which stroke volume can be maintained in the face of increased vascular resistance by increasing preload, the decreased effective circulating volume in shock states prevents this compensatory maintenance of cardiac output. This imbalance of preload-after-load effects overwhelms the normal increase in inotropic state produced by increased sympathetic nerve activity in the heart and by increased circulating catecholamines released by the stress response.

PATHOPHYSIOLOGY OF HYPOVOLEMIC SHOCK

Hypovolemic shock results from a decrease in the circulating or effective intravascular volume. Consequently, most of the signs of clinical shock are characteristic of peripheral hypoperfusion and increased adrenergic activity. Young, healthy patients in shock initially appear anxious and exhibit restlessness. This behavior gives way to apathy and lethargy after initiation of treatment. Frank coma rarely results from blood loss alone; usually it is a sign of concomitant direct brain injury, or it is coincident with complete cardiovascular collapse.

As intravascular volume is lost, an increase in peripheral vascular resistance occurs to defend the blood pressure in compensation for falling cardiac output. Differential increases in peripheral resistance in regional arteriolar beds, particularly in the skin, gut, and kidney, further defends pressure at the cost of further decreasing organ flow. The pale, cool skin noted on examination and the blanching of the bowel with decreased pulses in the mesentery are gross signs seen at the bedside and at laparotomy.

A decrease in circulating blood volume also results in tachycardia in response to decreased stroke volume from inadequate preload. The tachycardic response depends on the rate of blood loss and the position of the patient; orthostatic testing may unmask cardiovascular instability with tachycardia and hypotension in a patient who appears stable when examined in the supine position. Significant orthostasis reflects a 30 percent reduction in circulating blood volume in young patients.

Compensatory Responses

The following compensatory responses occur during shock:

- (1) Loss of circulating intravascular volume results in increased vascular tone, which elevates peripheral vascular resistance, resulting in a redistribution of blood flow among the organ systems of the body. Blood flow to those organs that are “autoregulated, ” such as the heart and the brain, is maintained at the expense of cutaneous, splanchnic, and renal circulatory beds, which depend on sympathetic tone for blood flow.
- (2) Decreases in intravascular volume stimulate increased sympathetic activity, which diminishes vagal inhibition of the rate and the force of cardiac contraction. Greater myocardial contractility and enhanced venous return, which help to improve stroke volume, accompany the tachycardia present during shock. Cardiac output is increased by these responses, as is myocardial oxygen consumption. Blood pressure is maintained by increases in total peripheral resistance and cardiac output.
- (3) Loss of circulating intravascular volume leads to decreased capillary hydrostatic pressure. Transcapillary influx of extravascular extracellular fluid then occurs from the interstitial space as a result of this alteration in Starling forces. This mobilization of the interstitial fluid pool into the intravascular space has two major effects: circulating intravascular volume is increased, and blood viscosity is decreased secondary to dilution.
- (4) In addition to the increased systemic oxygen-carrying capacity produced by hemodilution, tissue extraction of oxygen is enhanced in hemorrhagic shock by the presence of acidosis and elevated levels of erythrocyte 2,3-diphosphoglycerate (2,3-DPG). Decreased delivery of cellular substrates leads to increased anaerobic metabolism of glucose and accumulation of lactic acid. The resultant tissue acidosis produces a rightward shift in the oxyhemoglobin dissociation curve, decreasing the affinity of hemoglobin for oxygen,

thereby making more oxygen available to the tissues. Hypoxia also stimulates respiratory centers, leading to hyperventilation and respiratory alkalosis and a subsequent increased rate of erythrocyte synthesis of 2,3-DPG. This produces a further, more prolonged rightward shift of the oxyhemoglobin dissociation curve (Fig. 4-1).

(5) Arteriolar constriction and loss of circulating volume diminish renal blood flow. Both afferent and efferent arterioles are then stimulated, with resultant corticomedullary shunting of the remaining flow in an attempt to maintain an effective glomerular filtration rate. Urine output subsequently decreases as water and sodium are retained. Clearance of urea and acids, as well as buffering capacity, are diminished, leading to a loss of control of acid-base balance.

(6) Changes in blood volume in association with afferent sensory impulses lead to marked release of epinephrine and norepinephrine early in the course of hemorrhagic shock. The increased secretion of these catecholamines by the adrenal glands is an acute, short-lived response, usually limited to the day of injury unless complications occur. Epinephrine and norepinephrine produce vasoconstriction and tachycardia, resulting in increased cardiac output and blood pressure. Glycogenolysis, lipolysis, and skeletal muscle breakdown are stimulated, and insulin release is inhibited, promoting glucose mobilization, protein catabolism, and negative nitrogen balance. Epinephrine incites insulin resistance in skeletal muscle, and perhaps in other tissues, thus favoring glucose utilization by insulin-independent tissues such as the heart and the brain. The acute catecholamine response also results in retention of sodium and water in the proximal tubule of the nephron.

(7) Pituitary *adrenocorticotrophic hormone (ACTH)* release is stimulated in hemorrhagic shock by decreased blood volume, decreased arterial pressure, pain, hypoxemia, and hypothermia. After severe hemorrhage, circulating cortisol provides no feedback inhibition on ACTH release, but feedback is restored once blood volume has been reexpanded. Cortisol potentiates the actions of epinephrine and glucagon on glucose metabolism and insulin resistance and further stimulates mobilization of amino acids from skeletal muscle. Increased cortisol secretion also results in renal sodium and water retention.

(8) Unlike the counterregulatory hormones, insulin secretion is diminished in shock. This relative hypoinsulinemia augments the mobilization of glucose, amino acids, and fat stores stimulated by epinephrine, glucagon, cortisol, and growth hormone.

(9) Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), is secreted in response to increased serum osmolarity and hypovolemia (Fig. 4-2). It appears, however, that hypovolemia is the more potent stimulus, producing a picture similar to the syndrome of inappropriate antidiuretic hormone secretion in response to hemorrhage and shock. Arginine vasopressin increases water permeability and passive sodium transport in the distal tubule of the nephron, allowing increased water resorption. Arginine vasopressin is also a potent splanchnic vasoconstrictor. Activation of the renin-angiotensin system occurs in shock in response to increased sympathetic stimulation of the juxtaglomerular cells via a beta-adrenergic mechanism, decreased renal perfusion pressure, and compositional changes in tubular fluid. Renin, released from the juxtaglomerular apparatus, results in increased production of angiotensin I, which is rapidly converted to angiotensin II in the lung. Angiotensin II is a powerful arterial and arteriolar vasoconstrictor and stimulates renal prostaglandin production as well as the release of aldosterone and *ACTH*. Increased aldosterone secretion during shock occurs in response to increased circulating levels of angiotensin II and ACTH. Aldosterone increases sodium resorption in the distal nephron in exchange for potassium and hydrogen ions and represents the principal mechanism by which the kidney may excrete the accumulated by-products of anaerobic metabolism and cellular damage. Prostaglandins, particularly PGE₂, and kallikreins, produced in the kidney, function locally to dilate renal vessels and increase renal blood flow. Thromboxane A₂ results in splanchnic and cutaneous vasoconstriction and may promote cardiovascular dysfunction. Platelet-activating factor, produced by stimulated macrophages, results in coronary vasoconstriction and cardiac depression and increases platelet aggregation. The leukotrienes, produced by activated mast cells, also are potent vasoconstrictors and appear to promote muscle catabolism and amino acid release.

(10) The response of the extracellular fluid to acute hemorrhagic shock has been demonstrated experimentally in animal models. Using different isotopes to measure simultaneously the total-body red blood cell mass, plasma volume, and interstitial fluid volume, researchers can determine the distribution of these components of the extracellular fluid after shock. A 10 percent blood loss in splenectomized dogs produces no evidence of clinical shock. Red blood cell and plasma loss in this model were determined to be equal to the volume of shed blood, with no evidence of additional extracellular fluid loss. However, a 25 percent blood loss in the same model results in hypotension and an 18 to 26 percent reduction of functional extracellular fluid volume in addition to the measured losses of red blood cells and plasma. Further losses of extracellular fluid volume in addition to red blood cells and plasma can be demonstrated when the magnitude of hemorrhage is increased to 35, 45, or even 50 percent of circulating blood volume. With less severe shock models, there remains a reduction in the early equilibrating extracellular fluid available for intravascular influx, while total anatomic extracellular fluid may be normal. As there is no measured external loss of this functional extracellular fluid volume in any of these models, it is presumed that these changes represent an internal redistribution of the extracellular fluid in response to hemorrhagic shock (Fig. 4-3). It has been demonstrated that blood reinfusion after hemorrhagic shock restores the measured deficit in red blood cell mass and plasma volume, but not the deficit in extracellular fluid volume. However, the addition of a balanced salt solution or extracellular fluid "mimic," such as lactated Ringer's solution, to the shed blood infusion results in return of extracellular fluid volumes to control levels. Mortality in a model of "irreversible" shock was reduced from 80 percent in animals given only blood to 30 percent by restoration of the functional extracellular fluid volume with balanced salt solutions in addition to return of shed blood. This loss of functional extracellular fluid volume during shock is partially explained by the transcapillary influx of interstitial fluid into the intravascular space in response to decreased capillary hydrostatic pressures. However, the magnitude of intravascular refilling is inadequate to explain the total reduction of extracellular fluid observed. The isotonic movement of interstitial water and sodium into the cellular mass represents the most likely mechanism for the additional reduction of extracellular fluid volume, and isotonic movement of water and sodium into muscle cells has been demonstrated during hemorrhagic shock (Fig. 4-4).

(11) A semipermeable cell membrane functions through active transport mechanisms to maintain the ionic differences between intracellular and extracellular fluid. A negative cellular membrane potential difference ensues and is important for cell homeostasis and control of volumes and concentrations in the fluid compartments. This transcellular membrane potential difference may be measured serially in vivo using Ling-Gerard ultramicroelectrodes. In muscle and liver tissue this membrane potential difference serves as a reliable indicator of cellular dysfunction during hemorrhagic shock. During profound acute hemorrhagic shock, the transcellular membrane potential difference in skeletal muscle falls from -90 to -60 mV. This fall in potential difference is specific to the state of shock and independent of acid-base status. Alterations in membrane potential difference in primate models of acute hemorrhagic shock are reversible, with recovery of the normal difference after adequate fluid resuscitation, including replacement of losses from the extracellular fluid compartment (Fig. 4-5). Muscle biopsies obtained concomitantly with measurements of transcellular membrane potential allow measurements of intracellular water and electrolytes. These studies demonstrate the correlation of altered membrane potential difference and cellular swelling, marked by increased intracellular water, an influx of extracellular sodium and chloride, and an efflux of intracellular potassium. There appears to be little change in intracellular sodium activity, indicating that the extra sodium that diffuses into the cell during membrane dysfunction is bound to fixed charges or compartmentalized into the organelles. Decreased production of ATP in association with anaerobic metabolism results in a diminished ability to control sodium flux and has been proposed as a cause of cellular dysfunction during hemorrhagic shock. However, levels of high-energy phosphate compounds are maintained in liver and skeletal muscle early in hemorrhagic shock at a time when alterations in membrane potential difference have already occurred. Cellular membrane dysfunction is not prevented by administration of such high-energy phosphates as ATP-MgCl₂. The fall in concentration of intracellular ATP appears to be the effect of cellular dysfunction and not its primary cause. Other possible explanations for cellular dysfunction during hemorrhagic shock are decreased activity of the sodium-potassium pump responsible for maintenance of membrane potential difference independent of ATP content, or changes in membrane permeability. These effects might occur through the actions of inflammatory mediators generated in response to injury and hemorrhage. Tumor necrosis factor-alpha (TNF-α), a cytokine produced by activated macrophages, is implicated in the mediation of alterations in skeletal muscle membrane dysfunction and the hemodynamic consequences of sepsis and may play a similar role in hemorrhagic shock. Other factors, such as platelet-activating factor, leukotrienes, thromboxane A₂, and complement activation, have also been implicated.

(12) Nitric oxide is a potent regulator of basal blood vessel tone. It is a ubiquitous free radical produced as a result of two forms —constitutive and inducible —of nitric oxide synthase. The inducible form (iNOS) is up-regulated by endotoxin and proinflammatory cytokines, such as interleukin-1 (IL-1) and *tumor necrosis factor (TNF)* in macrophages, Kupffer cells, vascular smooth muscle, and endothelium. It is likely that nitric oxide plays vital regulatory roles in the cardiovascular, pulmonary, gastrointestinal, immune, and central nervous systems.

Pulmonary Derangements in Shock

Accompanying successful fluid resuscitation is the emergence of pulmonary dysfunction in 1 to 2 percent of the survivors of shock. This occurs in some patients without lung injury per se. Originally referred to as shock lung, adult respiratory distress syndrome was first described in 1967. This disorder, now referred to as *acute respiratory distress syndrome (ARDS)*, is characterized by hypoxia (despite oxygen therapy), decreased pulmonary compliance, diffuse or patchy infiltrates on chest x-ray, and noncardiac pulmonary edema.

Etiology

The pulmonary system exhibits a stereotypic response to insult. That is, a variety of injuries can trigger a final common pathway, resulting in the symptom complex known as *ARDS*. These include direct pulmonary injury, such as that seen in aspiration, inhalation injury, pulmonary contusion, and near drowning, and seemingly unrelated disorders, such as multiple transfusions and trauma such as fractures. Common to all these disorders is the initiation of inflammatory mediators. These result in increases in microvascular permeability and subsequent proteinaceous fluid deposition in the alveolar epithelial and pulmonary capillary endothelial interface. Resulting from this disruption are abnormal ventilation and perfusion relationships and subsequent hypoxia (Fig. 4-6).

The phenomenon of noncardiac edema occurs as a result of derangements of lung microvascular permeability. Under normal conditions, a small amount of fluid moves out of the pulmonary capillaries and is cleared from the interstitium by pulmonary lymphatics (Fig. 4-7). Flux is governed by Starling forces described by the equation:

$$Q = K_f(P_{mv} - P_t) - s(P_{mv} - P_t)$$

where: Q = transcapillary exchange

K_f = filtration coefficient of water

P_{mv} = capillary hydrostatic pressure

P_t = tissue interstitial pressure

s = osmotic reflection coefficient

P_{mv} = capillary colloid osmotic pressure

P_t = tissue interstitial colloid osmotic pressure

In the pathologic state, the alveolar–capillary interface is disrupted and the resultant fluid overwhelms pulmonary lymphatic clearance. These abnormalities have been documented to occur prior to, or without, associated chest-x-ray abnormalities. Diuretics and fluid restriction have no impact on this pathophysiology and are not useful. Likewise, colloid administration has not been shown to effectively decrease extravascular lung water, because the normal barrier is disrupted and is permeable to large molecules such as albumin.

Pulmonary failure associated with sepsis has been studied extensively, and it is likely that similar mechanisms are operative in other conditions resulting in ARDS. Endotoxin or lipopolysaccharides (LPS) have a direct effect on pulmonary endothelial cells, increasing cellular permeability. This has been observed in in-vitro and in-vivo models. Other active mediators include complement, eicosanoids, platelet-activating factor, leukotrienes, and thromboxane A₂.

Diagnosis

The diagnosis of ARDS begins with clinical suspicion and is based on documentation of hypoxia, abnormal chest x-ray, and a measured decreased lung compliance. Multiple scales for grading the severity of lung injury are in use, most of which include percentage of abnormal lung seen on x-ray and the amount of *positive end-expiratory pressure (PEEP)* required to maintain adequate oxygenation. These scales have been criticized because of the subjective nature of grading of x-rays and practice variations in the use of PEEP.

Therapy for ARDS

The therapeutic goal is to maintain tissue oxygenation. Supplemental oxygen is supplied to maintain Pa_{o2} of 65 mmHg or more. Hemoglobin concentration should be maintained at 12 g/dL or higher, with buffering of pH to allow optimal oxygen transport. A pulmonary artery catheter is desirable to monitor central volumes and mixed venous saturations. Fluid overload or underresuscitation can adversely effect the patient with ARDS. Standard pulmonary management includes the use of a volume ventilator in the mandatory mode with tidal volume and rate set to allow adequate carbon dioxide exchange. This usually can be accomplished with rates of 10 to 12 breaths per minute and tidal volumes of 10 to 12 mL/kg dry weight. PEEP is initiated at 5 cmH₂O to approximate glottic pressure. Sedation and paralysis may be necessary. PEEP is used in order to maintain oxygenation at nontoxic (50 percent or less) levels of oxygen. In managing the patient with ARDS, the ventilator is set at 100% oxygen and the optimal level of PEEP is identified. This level is found by increasing PEEP by increments of 2.5 cmH₂O, allowing at least 30 min for equilibration and measuring arterial and mixed venous blood gases, pulmonary capillary wedge pressure, and cardiac output. PEEP is increased to as much as 20 cmH₂O, and optimal settings (highest oxygenation without compromise of cardiac output) are identified. PEEP is then set at this level and oxygen decreased incrementally to maintain a Pa_{o2} of 65 mmHg, with a goal of 50% inspired oxygen or less. PEEP can then be decreased, if oxygenation is maintained, by increments of 2.5 cmH₂O every 12 h.

The potential risks of PEEP are exacerbated by hypovolemia. Volume loading to assure adequate filling pressures before PEEP is applied is beneficial in interpreting changes in wedge pressure and cardiac output that may occur after use of PEEP. Increased intrathoracic pressure and decreased venous return can cause depression of cardiac output. Lowering of PEEP is necessary if cardiac output becomes compromised. Wedge pressure measurements may be corrected in the patient with noncompliant lungs by subtracting one-fourth of the applied PEEP from the measured wedge pressure.

Pneumothorax can occur at high pressures (>20 cmH₂O) and can be catastrophic. Peak airway pressures should be carefully monitored. Patients with chronic obstructive lung disease characterized by preexisting increases in functional residual capacity may not benefit from PEEP therapy.

Trials of early application of PEEP in patients at high risk for ARDS failed to show any benefit in overall mortality or complications. The course of ARDS has been relatively unaffected in trials of anti-inflammatory drugs such as ibuprofen and sepsis trials using anticytokine therapy (interleukin-1 receptor antagonist, monoclonal antibodies to TNF).

THERAPY FOR SHOCK

Hypovolemic Shock

Initial care of the injured patient should follow the guidelines from the advanced trauma life support procedures of the American College of Surgeons Committee on Trauma. In a patient who has undergone trauma, more than one causative factor may be operating. Once the diagnosis of shock has been made and supportive therapy begun, a diligent search can be made for the causative factor or factors. Deficits of total body water and electrolytes usually is subtle, and correction requires specific therapy with crystalloid solutions. Reductions in the extracellular fluid volume (plasma and interstitial fluids) as a result of burns, peritonitis, and some forms of crush injury are more easily recognized. Specific therapy should be started with electrolyte solutions; occasionally plasma or some source of protein is required as well. External blood loss should be corrected immediately with appropriate fluid therapy.

Fluid Resuscitation Composition of Resuscitation Fluids

Lactated Ringer's Solution

Lactated Ringer's solution is the most widely available and most frequently used balanced salt solution (crystalloid) for fluid resuscitation during shock. It is safe and inexpensive, and it equilibrates rapidly throughout the extracellular compartment, restoring the extracellular fluid deficit associated with blood loss. Concern that the lactate content of Ringer's solution might aggravate the lactic acidosis coexisting with hemorrhagic shock is unwarranted. Studies in animal models and human beings demonstrate that the use of lactated Ringer's solution in addition to blood replacement results in more rapid return of serum lactate and pH to normal levels than does replacement with blood alone. Lactate is rapidly converted to bicarbonate in the liver.

Because of the rapid equilibration of balanced salt solutions into the extracellular space, larger volumes may be required for adequate resuscitation, resulting in decreased intravascular oncotic pressure. Although there has been no documented increase in morbidity or mortality secondary to the appropriate use of balanced salt solutions, it has been speculated that loss of large volumes of balanced salt solution into the interstitial space during resuscitation may subsequently contribute to postresuscitation organ dysfunction, particularly pulmonary edema and respiratory failure. These potentially deleterious effects of balanced salt solution appear to be offset by the active lymphatic circulation, which buffers against fluid overload and helps to maintain normal oncotic gradients between the intravascular and interstitial spaces.

Colloid Solutions

The use of colloidal substances that tend to remain intravascular continues to be advocated by some, in lieu of balanced salt solution, for resuscitation. Administration of fluid preparations containing colloidal substances such as albumin raise the intravascular colloidal pressure, leading to intravascular influx of interstitial fluid. Because colloids remain briefly in the intravascular space, a lower total volume of resuscitative fluid is required to attain hemodynamic stability than when crystalloid solutions are used; it has been theorized this serves to prevent postresuscitation fluid overload. However, colloid solutions are more expensive, may bind and decrease the ionized fraction of serum calcium, decrease circulating levels of immunoglobulins, decrease the immune reaction to tetanus toxoid, and decrease endogenous production of albumin. More important, use of colloid- containing solutions as resuscitative therapy during hemorrhagic shock further compromises the extracellular fluid volume deficit rather than restoring it. This was confirmed in a study by Greenhalgh and colleagues in which serum albumin levels were maintained by exogenous administration of albumin in pediatric burn patients. No differences were demonstrated in terms of resuscitation, maintenance fluid requirements, subsequent complications, length of stay, or mortality.

Numerous experimental and clinical studies have examined the issue of the superiority of crystalloid over colloid resuscitation. Moss and associates demonstrated that adequate resuscitation of primates from potentially lethal hemorrhage with balanced salt solution or balanced salt solution plus 5% albumin resulted in restoration of circulation parameters and perfusion to normal. Although the volume of balanced salt solution required was three times greater than that of the colloid solution, no measurable differences were observed between the two groups in pulmonary compliance or postresuscitation lung water content.

In another study primates were subjected to plasmapheresis sufficient to decrease the serum oncotic pressure significantly, similar to the situation occurring after crystalloid resuscitation. Zarins and coworkers demonstrated that extravascular lung water, pulmonary compliance, oxygenation, and shunt fraction did not change. This was true when pulmonary capillary wedge pressure was not elevated. Holcroft and colleagues also reported that pulmonary edema after resuscitation for hemorrhagic shock with balanced salt solution could be produced only by sustained elevations of pulmonary artery pressure. Guyton and Lindsey found that lowering intravascular colloid oncotic pressure alone does not result in pulmonary edema in dogs, but does lower the level of left atrial pressure necessary to produce pulmonary dysfunction. In a model similar to that of Zarins, Demling and associates further demonstrated a marked increase in pulmonary lymph flow without development of pulmonary edema, apparently compensating for the altered oncotic pressure gradient.

In a clinical study, Horovitz and Shires reported an incidence of pulmonary dysfunction in 2.1 percent of 978 patients undergoing operative procedures after severe trauma, despite receiving large volumes of crystalloid. Carey reported no evidence of acute pulmonary edema in 56 injured patients in Vietnam, despite an average resuscitation volume of 12 L of balanced salt solution.

As it is well established that stabilization of hemodynamic parameters after hemorrhagic shock requires a greater volume of crystalloid than colloid solution, meaningful prospective clinical trials comparing crystalloid and colloid require resuscitation to equal end points and not to equal volumes. Using these guidelines, Virgilio and colleagues found no differences in pulmonary function or shunt fraction among 29 patients undergoing aortic surgery randomized to balanced salt solution or colloid solution resuscitation. In addition, Shires III and coworkers found no differences in extravascular lung water either immediately after operation or 24 to 48 h later in 19 aortic surgery patients randomized to balanced salt solution or colloid resuscitation, despite a markedly lower intravascular oncotic pressure in the balanced salt solution group (Fig. 4-8).

Lowe and associates found no differences in survival rates, incidence of pulmonary failure, or postoperative pulmonary dysfunction in stable and unstable trauma patients undergoing laparotomy who received balanced salt solution or colloid solution resuscitation. Lucas found that the use of colloid not only prolonged the resuscitation phase but also delayed postresuscitation diuresis, perhaps through failure of restoration of the interstitial volume deficit. Further, the incidence of postresuscitation hypertension was higher in patients given albumin, suggesting that renal function may best be protected during resuscitation from shock by rapid replacement of the intravascular and total extracellular fluid deficits. A meta-analysis of colloid versus crystalloid fluid resuscitation that included many of the studies cited here concluded that crystalloid is superior to colloid for resuscitation after trauma in human beings, with a 12 percent reduction in mortality after crystalloid infusion.

There is therefore no clinical evidence that appropriate resuscitation with balanced salt solution is associated with any harmful effects on pulmonary function when guided by hemodynamic parameters. No protective effect of colloid solutions on postresuscitation pulmonary function can be demonstrated, even though colloid solutions do produce transiently greater intravascular expansion per unit volume given than do crystalloid solutions. As the volume expansion with colloid occurs to some extent by further compromise of the extracellular fluid volume, renal function during shock may best be preserved by crystalloid resuscitation.

Hypertonic Saline

Clinical and experimental studies have demonstrated that a small volume of hypertonic saline can be an effective initial resuscitative solution. Hypertonic saline resuscitation results

in a lower water load than equivalent resuscitation with balanced salt solutions. However, patients resuscitated with hypertonic saline solution require close monitoring of electrolytes to prevent hyponatremia and hyperosmolar coma. Recent studies in patients have shown that while blood pressure may be elevated more rapidly in the first few minutes after shock and resuscitation, no changes in survival rates occurred. In view of the need for electrolyte monitoring and lack of the definition of the volumes appropriate for infusion, long-term benefits have not been established. In animal studies showing deterioration of cellular function there was a higher mortality 24 h after hypertonic saline/dextran resuscitation.

Hetastarch

Hydroxyethyl starch (hetastarch) is an artificial colloid derived from amylopectin, with colloidal properties similar to those of albumin. It is less expensive than albumin, and, because of its larger molecular weight and need for enzymatic degradation, it has a longer plasma half-life than albumin. As with any colloidal solution, hetastarch restores intravascular volume at the further expense of the already compromised interstitial space when used in resuscitation during shock. Resuscitation with hetastarch also may be difficult to control, because the slow equilibration of these large molecules can lead to rapid fluctuations in central venous pressure. Mild and transient coagulopathies have been noted in patients resuscitated with hetastarch, and a role in depression of the reticuloendothelial system has been postulated.

Dextran

Dextran, in 40 kD and 70 kD solutions, has also been used as a plasma expander. Although dextran has a shorter half-life than hetastarch, it also approximates the colloidal activity of albumin when given by intravenous infusion. Clinical studies have demonstrated no differences in rates of organ dysfunction or mortality when resuscitation with dextran is compared to that with balanced salt solutions. However, dextran use is associated with a greater risk of anaphylaxis than is hetastarch or albumin and has produced coagulation defects and immunoglobulin depression.

Blood Substitutes

Periodic shortages of blood products and the infectious risks associated with transfusions have fueled the search for an efficacious artificial blood substitute. Early studies using free hemoglobin obtained from outdated blood resulted in allergic reactions, renal failure, coagulopathies, and immune dysfunction secondary to reaction to retained erythrocyte stromal elements. The subsequent purification of stroma-free hemoglobin (SFH) has eliminated these side effects, but problems with the use of SFH for resuscitation remain. SFH has an abnormally high affinity for oxygen, has a short plasma half-life, and is available only from human sources. Although binding with other molecules or incorporation into liposomes may reduce oxygen affinity and improve plasma retention time, SFH will probably not become a practical substitute for blood until an artificial or animal donor source becomes available. Bovine SFH appears to be one useful approach for treating hemorrhage (Fig. 4-9).

Perfluorochemical compounds have uniquely enhanced abilities to dissolve gases, particularly oxygen and CO₂, but require emulsification to be water soluble. Perfluorodecalin (Fluorosol-DA) also contains electrolytes, bicarbonate, and starch to obtain osmotic and pH balance with plasma. The oxygen-carrying capacity of this emulsion is lower than that of hemoglobin, and thus its use requires higher inspired oxygen concentrations (Fig. 4-10). Fluorosol-DA has been extensively used in Japan and in clinical trials has proved an effective substitute for hemoglobin. Potential adverse effects include acute pulmonary edema, activation of complement and the coagulation cascade, acute respiratory failure, and depression of the reticuloendothelial system. It is expensive and requires special storage to prevent gelatinization.

Volumes Appropriate for Resuscitation

Models of “controlled hemorrhage” involve instrumentation of animals and withdrawing blood to various end points to simulate shock. Many of these experiments have been criticized for their failure to reproduce clinical circumstances. In models of uncontrolled hemorrhage, vascular injuries are created to allow free hemorrhage. A “hybrid model” of controlled and uncontrolled hemorrhage was created by Stern and associates. Pigs were subjected to controlled hemorrhage by rapidly withdrawing blood from a femoral catheter to a significant level of shock (30 mmHg) over 30 min, removing an average of 40 mL/kg. Subsequently, uncontrolled hemorrhage was induced by creating a tear in the aorta. Resuscitation volumes of 55.8 mL/kg and 90 mL/kg of saline were used in a short period of time, after which shed blood was reinfused. These were the volumes necessary to attempt to achieve a preselected mean arterial pressure (MAP). The high volumes used in these experiments are roughly equivalent to 6.3L in a 70 kg human being. Despite aggressive fluid and blood administration, the goal MAP was never achieved in the Stern study. It might be argued that the two insults induced in this swine model are too severe, that the model is not clinically relevant, and that the volumes used for resuscitation were excessive. Nonetheless, fluid resuscitation using varying amounts of volume is associated with a lower mortality than when no resuscitation is administered (Fig. 4-11). In the Stern study, the survival rate fell precipitously in animals receiving a large volume in a short amount of time in an attempt to restore a MAP of 80 mmHg. Although significantly increased blood loss also was seen in the large-volume (90 mL/kg) resuscitation group in the Stern study, the mechanism of death was not studied. In the Soucy study, uncontrolled hemorrhage treated with a moderate volume (40 mL/kg) of isotonic saline solution was associated with increased survival times and decreased mortality.

Current studies in unanesthetized animals imply that early resuscitation of hemorrhagic shock with a moderate volume of isotonic solution is superior to delayed resuscitation with isotonic or hypertonic solutions. Volume replacement appears to result in a centrally mediated reflex relaxation of peripheral vascular beds and increased perfusion with little or no associated increase in mean arterial pressure. The existence of this postulated “shock set-point” of autoregulated low blood pressure could account for the poor results in the studies outlined above in which the resuscitative goal was to achieve a predetermined “normal” blood pressure.

Timing of Resuscitation

In the first part of the twentieth century, Cannon stated, “Hemorrhage in the case of shock *may* not have occurred to a marked degree because blood pressure has been low and flow too scant to overcome the obstacle offered by a clot.” Cannon also stated, however, “The low blood pressure of shock has been met by the injection of normal or hypertonic salt.” Experience gained in the treatment of soldiers during the Korean and Vietnam wars established that early resuscitation was associated with a lower incidence of renal failure and with increased survival (see Table 4-1).

Current clinical protocols for resuscitation from hemorrhagic shock are based on numerous studies in the basic and clinical sciences. The practice of early administration of fluids to victims of hemorrhagic shock has been the dominant method of treatment for twenty years, but this method has been challenged.

Animal studies of “delayed resuscitation” in rats after uncontrolled hemorrhage implied that there was no beneficial effect of volume resuscitation. In a swine model, Bruttig and colleagues showed that early resuscitation was associated with higher mortality when compared to animals with “delayed resuscitation,” which was *no* resuscitation. This “early resuscitation” necessitated giving the entire resuscitation volume in 6 min, beginning 4 min after the aortic tear. This resulted in little clot formation, probably because of extremely rapid dilution of clotting factors, and it resulted in three times the bleeding volume compared to controls without fluids. The Bruttig study is at variance with that of Gross and associates, in which delayed resuscitation for uncontrolled hemorrhage was associated with increased mortality when compared to animals that were not resuscitated.

A droperidol-ketamine (DK) mixture was used for anesthesia by many investigators. To examine the mechanism responsible for these increases in mortality associated with resuscitation, Bilytskyj and coworkers demonstrated that DK anesthesia was associated with increases in blood loss and mortality. The poor outcomes were thought to be from the vasodilatory effects of the anesthetic drugs. In the same study, pentobarbital was found not to cause vasodilatation was not associated with excessive blood loss. This effect of anesthesia was confirmed in a study of rats observed after receiving pentobarbital anesthesia.

DK anesthesia was associated with ongoing hemorrhage and increased mortality, but in contrast to several previous studies, all animals resuscitated in the Shires study fared better, regardless of the anesthetic used (Fig. 4-12).

Two large clinical trials were performed to test the “scoop and run” philosophy, delaying resuscitation until the patient reached the hospital. In both studies, delayed resuscitation was not associated with decreased survival. The groups with delayed resuscitation did not progress more favorably than the groups with early resuscitation. Additionally, these studies were performed in selected patients in an urban setting with relatively short prehospital time; therefore, the “delay” was only approximately 30 min. Modern urban emergency medical services usually can be relied on to provide transport to a Level I or II trauma center within 30 min. It should be noted that in both clinical trials fluids were not withheld. The Kaweski study was a retrospective review of data obtained from trauma patients. Patients who were less severely injured received less fluid. In the Mattox study, the “delayed resuscitation” group received 771 ± 1228 mL of fluid preoperatively and were given comparable amounts of crystalloid and blood in the operating room. In neither study did patients who were given fluid have a worse outcome.

Bickell and colleagues reported a randomized clinical trial on the effect of presurgical infusion of isotonic fluids in penetrating trauma to the torso. The study has several methodological problems, including the inclusion of resuscitated patients with the nonresuscitated patients prior to statistical analysis, precluding validation of results. In analyzing the data with appropriate statistical methods, no differences can be found in blood pressure at admission, incidence of complications, length of hospitalization, or survival.

Adjuvant Therapy Vasopressors

The clinical state of hemorrhagic shock is defined by the presence of inadequate tissue perfusion resulting from hypovolemia. Treatment with vasopressors during shock may elevate blood pressure, but at the expense of further increased peripheral resistance and diminished tissue perfusion. Vasopressor therapy also may worsen the plasma volume deficit associated with hemorrhage, and the use of such agents in place of adequate fluid resuscitation is inadvisable.

Adenosine Triphosphate (ATP)

The demonstration of decreased high-energy phosphate levels by some investigators during hemorrhagic shock, as well as a decreased rate of conversion from adenosine diphosphate (ADP) to ATP, led to an interest in ATP replacement as an adjuvant therapy for hemorrhagic shock. In experimental models, ATP-MgCl₂ has been found to improve survival rates in potentially lethal shock when combined with adequate fluid resuscitation. However, because ATP is rapidly degraded in plasma and tissue and cannot cross intact cellular membranes because of its charge, it is unlikely that the improved survival is a result of restoration of cellular ATP content. The improvements may be from the reversal of hypoperfusion secondary to local vasodilatory effects, degradation and provision of phosphate precursors that may cross the cell membrane, or blockade of cellular uptake of calcium. Infusion of ATP-MgCl₂ may result in marked hemodynamic instability in the hypovolemic patient, which limits its usefulness in the clinical treatment of hemorrhagic shock.

Positioning

Most first-aid courses teach that the patient in shock should be placed in the head-down position. It is true that some forms of shock, particularly neurogenic shock, respond to the head-down position, but the effect of posture on the cerebral circulation when confronted with true hypovolemia has not been defined. The patient with multiple trauma often has injuries in the abdomen and chest, so that the routine use of the Trendelenburg, or head-down, position may interfere with respiratory exchange far more than when the patient is left supine. The beneficial effect of the head-down position probably is the result of transient autotransfusion of pooled blood in the capacity or venous side of the peripheral circulation. This beneficial effect can be obtained easily by elevating both legs while maintaining the head, trunk, and arms in the supine position. This is the preferred position for the treatment of hypovolemic shock.

MAST Garment

There has been enthusiasm for the in-the-field application of *military antishock trousers*, the MAST garment. When applied to the extremities with modest pressures, the garment functions well as a splint and may control some venous bleeding. When applied at high pressures, the resultant increase in total peripheral resistance may elevate the systemic pressure while decreasing cardiac output and peripheral perfusion. Additionally, inflation of the abdominal bolster may compress the inferior vena cava, impairing venous return to the heart by further increasing the venous resistance. Several reports of reperfusion injury with compartment syndromes in uninjured limbs have appeared. The MAST device may be of value when used strictly as a temporizing device or occasionally as specific treatment of bleeding pelvic fractures. Its use must not delay the immediate repletion of intravascular and extravascular volume by fluid therapy or interfere with rapid transport of the injured patient.

Pulmonary Support

In the past, most writing on the treatment of hypovolemic shock stated that breathing high oxygen concentrations probably is of little value during a period of hypotension. These conclusions were based on the notion that the principal defects are in volume flow to tissues and decreased cardiac output. The oxygen saturation in the majority of patients with uncomplicated hypovolemic shock generally is normal, and the small increase in dissolved oxygen in the blood contributed by raising the P_{O_2} above this level is insignificant, particularly with a markedly decreased cardiac output. This concept continues to be valid in terms of improvement of the shock state or tissue oxygenation. Nevertheless, in the small but significant group of patients in hypovolemic shock in whom the oxygen saturation is not normal, the *initial* use of increased oxygen concentrations may be extremely important, because the fall in cardiac output accompanying hemorrhagic shock has been shown to compound existing defects in oxygenation. This can occur in patients with preexisting defects, such as chronic obstructive lung disease. More frequently, problems in oxygenation arise directly from the patient's injuries and may include a coexisting pneumothorax, pulmonary contusion, aspiration of gastric contents or blood, or airway obstruction. Although oxygen is not routinely administered to patients in shock, if any doubt exists as to the possibility of one of these circumstances or the adequacy of oxygenation of arterial blood, the initial administration of oxygen until the injuries to the patient have been diligently assessed is certainly justified. If oxygen is administered to patients under these circumstances, it should be delivered through a loose-fitting face mask designed for this purpose. If a controlled airway is indicated for other reasons, an endotracheal tube is ideal. The use of nasal catheters, particularly those passed into the nasopharynx, is avoided because of potential complications of pharyngeal lacerations and gastric distention. Gastric rupture has been recorded secondary to a nasal catheter's being inadvertently placed in the esophagus.

Antibiotics

Antibiotics were used in the treatment of hypovolemic shock for many years and were thought to exert a protective mechanism against the ravages of hypovolemia. Subsequent data failed to support this hypothesis. The use of antibiotics in patients who have open or potentially contaminated wounds continues to be sound practice when combined with good surgical debridement and care. The use of wide-spectrum antibiotics is advisable as a preventive measure in the severely injured patient. Cefoxitin 2 g I.V. has proved to be a safe and effective single agent in multiorgan abdominal injuries.

Analgesics

Treatment of pain in the patient with hypovolemic shock is rarely a problem. However, if the causative injury produces severe pain, e.g., fracture, peritonitis, or injury to the chest wall, control of pain becomes mandatory. When the patient is moved to an emergency facility where physicians and care are available, simple supportive measures (administration of intravenous fluids, passing of catheters) will give reassurance. The need for analgesics is greatly reduced, because the need to allay fear and anxiety is decreased. If the patient continues to have severe pain, the observations made by Beecher in World War II are critical. Many battle casualties received morphine or other narcotic agents by subcutaneous administration soon after wounding. Because these analgesics did not enter the circulation immediately, the pain continued and the patient ultimately received several doses that were poorly absorbed. Once effective therapy was begun for shock, the doses previously administered were absorbed, and profound sedation resulted. As a result, the recommendation was made that small doses of narcotics be given *intravenously* for the management of pain in the patient with shock.

Steroids

Adrenocorticoid depletion was regarded as a contributory factor in shock after it was learned that the presence of hypovolemic shock could deplete the adrenal cortex of adrenocortical steroids. Subsequent studies have shown that adrenocortical steroid production is stimulated maximally by the presence of hypovolemic shock. Steroid depletion with hypovolemic shock may occur in the elderly patient or in patients with specific adrenocortical diseases, such as incipient Addison's disease, postadrenalectomy patients, or patients who have had adrenal suppression with exogenous adrenocortical steroids. In these specific instances, the intravenous administration of hydrocortisone is desirable. In the trauma patient with hypovolemic shock, administration of adrenocorticoids is not indicated.

Monitoring

Continuous bedside monitoring of circulatory efficacy, including assessment of the heart rate, arterial blood pressure, urinary output, and peripheral perfusion, remains the cornerstone for resuscitation. Adequate resuscitation is indicated when adequate cerebral function and urinary output are restored. In the patient with multiple injuries, central venous pressure (CVP) monitoring is useful. Although left ventricular overload can occur while right ventricular function and CVP remain normal, this is not often the case in the absence of myocardial injury. Changes over time in the CVP with fluid infusion do indicate the ability of the myocardium to pump the volume presented to it. A normal-to-depressed CVP that does not rise with rapid administration of crystalloid fluid usually indicates continuing hypovolemia. The presence of an elevated CVP or its rapid rise in response to fluid administration is indicative of impairment of the pumping mechanism. Although this usually represents primary myocardial deficiency and should be treated as outlined in the following section on cardiogenic shock, any mechanical obstruction to venous return with cardiac tamponade or mediastinal compression by intrapleural air or blood must be immediately attended to in the injured patient. The use of a balloon- tipped Swan-Ganz catheter allows measurement of pulmonary artery and pulmonary wedge pressures as well as thermodilution cardiac output determinations. The early use of the Swan-Ganz catheter rarely is necessary in the initial emergency department treatment for hemorrhagic shock.

Hemorrhagic shock may become refractory to the therapies described above and become irreversible. Complete vascular collapse with hypotension unresponsive to volume or drug intervention eventually leads to lethal central nervous system and cardiac dysfunction. Irreversibility is difficult to define but has been related to the duration and volume of hemorrhage, the age and preexisting cardiovascular fitness of the patient, and the coexistence of massive trauma with multiple direct organ derangement. Before the physician concludes that refractory shock has occurred, the multiple causes of failure to respond to therapy should be resolved. These include continuing unsuspected blood loss into the chest or abdomen, inadequate volume replacement, inadequate clotting, multisystem trauma with occult thoracic injuries, including cardiac tamponade and hemopneumothorax, and acute myocardial insufficiency from direct injury or secondary to prolonged coronary hypoperfusion.

Cardiogenic Shock

Cardiogenic shock occurs when the heart is unable to generate sufficient cardiac output to maintain adequate tissue perfusion. Unlike hypovolemic shock, cardiogenic shock is manifested by hypotension in the face of adequate intravascular volume. Cardiogenic shock that is unresponsive is associated with significant mortality and morbidity, particularly in conjunction with myocardial infarction and the secondary end-organ injuries of pulmonary edema, oliguric renal failure, and coma.

Pathophysiology

Myocardial failure may result from a variety of diseases, including valvular heart disease, cardiomyopathy, and direct myocardial contusion. Acute myocardial infarction is the most frequent cause of cardiogenic shock, which is often fatal when 40 percent of the left ventricular mass has been lost. Papillary muscle dysfunction, ischemic ventricular septal defects, massive left ventricular infarction, and arrhythmias are complications of acute myocardial infarction that may lead to cardiogenic shock.

The initial compensatory response to diminished myocardial contraction is tachycardia, in an attempt to maintain cardiac output, despite a decreased left ventricular ejection fraction, at the expense of increasing myocardial oxygen consumption. As cardiac index falls below 2 L/min/m² hypotension produces reflex sympathetic vasoconstriction. This attempt to maintain central pressure by increasing peripheral vascular resistance leads to decreasing organ perfusion. An increase in afterload further impairs left ventricular function and increases myocardial work. The combination of increased myocardial oxygen demand, hypotension, and shortened diastole amplifies the mismatch between coronary arterial oxygen delivery and myocardial oxygen demand, extending the zone of infarction in the patient who does not receive prompt intervention.

Treatment

Although the goal of medical management of cardiogenic shock has been to enhance ventricular performance and improve global perfusion, the traditional management with fluids and inotropic drugs continues to yield a mortality of 80 to 90 percent. The techniques that maximize ventricular performance paradoxically increase myocardial oxygen demand at a time when therapy, to limit infarct size and salvage reversibly ischemic myocardium, should include minimizing myocardial demand and attempting to provide early reperfusion. Initial therapy includes optimizing ventricular preload by manipulating filling pressure, decreasing afterload in the patient with adequate systolic pressure, correcting arrhythmias, and improving contractility to sustain vital organ perfusion.

Monitoring and Volume Management

Supplemental oxygen, pain relief and sedation, and continuous electrocardiographic monitoring should be initiated early. A Foley catheter is inserted for monitoring urine output. Cutaneous oximetry and automated arterial blood pressure cuff measurements can be used in place of an intraarterial catheter for continuous arterial pressure monitoring and blood gas determinations. Placement of a Swan-Ganz catheter for measurement of cardiac output and pulmonary artery wedge pressure is crucial to therapeutic decision-making in these critically ill patients. Cardiogenic shock with low cardiac output and arterial hypotension can occur in some patients with normal to slightly elevated pulmonary artery wedge pressures. A small increase in left ventricular filling pressure by volume infusion may maximize cardiac output via the Frank-Starling mechanism. It should be emphasized that although hemodynamic measurements suggest myocardial insufficiency, mechanical obstruction, such as cardiac tamponade in the injured patient or pulmonary embolism in the postoperative patient, may be present. Although these diagnoses are made largely on clinical grounds in the emergency setting, volume infusion usually is of some benefit while echocardiography, pericardiocentesis, or thoracentesis are performed quickly. Constant vigilance is required during volume challenge in this setting; increased filling pressures may lead to further myocardial ischemia and acute pulmonary edema. If any pulmonary complications evolve, early intubation and mechanical ventilation will decrease the myocardial oxygen demand as a consequence of the increased work of breathing and correct arterial hypoxemia that may further impair cardiac performance.

Inotropic Agents

The beta₁-adrenergic receptors of the myocardium respond to exogenous sympathomimetic drugs by increasing contractility and improving cardiac output. These effects are obtained at the cost of increasing myocardial oxygen demand in the setting of already-compromised myocardial perfusion, but intravenous infusion of dopamine may promptly reverse life- threatening hypotension and restore mean arterial pressure to about 80 mmHg. The dopaminergic effects of splanchnic, coronary, and renal vasodilatation at low (2 to 5 mg/kg/min) doses are augmented by adrenergic-mediated increases in contractility and heart rate as dosages rise to 5 to 8 mg/kg/min. At higher doses, alpha-adrenergic receptor effects predominate, and central arterial pressure can increase while coronary artery constriction further decreases coronary blood flow. Dopamine also causes a variable increase in heart rate and can precipitate other arrhythmias, which underscores the need to titrate the lowest acceptable dose. Dobutamine, a synthetic catecholamine with predominantly inotropic effect, appears to be less arrhythmogenic and may redistribute cardiac output to the coronary circulation. Studies appear to favor dobutamine over dopamine for treating cardiogenic shock after cardiopulmonary bypass or myocardial infarction. Digitalis remains a controversial drug in acute pump failure. Although very useful in the treatment of

supraventricular arrhythmias, digitalis increases myocardial oxygen consumption and adds very little hemodynamic benefit relative to therapy with sympathomimetic agents.

Vasodilator Agents

Some patients with low cardiac output and high filling pressures have near- normal arterial blood pressure in the setting of profoundly decreased perfusion by clinical assessment. In these circumstances, systolic ventricular wall stress is high, and reducing afterload should increase cardiac output and decrease myocardial work. An agent such as sodium nitroprusside should be used with extreme caution in hypotensive patients because redistribution of an already depressed cardiac output away from the coronary and cerebral circulation can occur, and any decrease in systemic diastolic pressure would further depress coronary perfusion pressures.

Mechanical Support

As the role of early reperfusion strategies evolves (including thrombolysis, percutaneous transluminal coronary angioplasty, and emergency bypass), mechanical therapy can temporarily support the failing myocardium until these modalities are initiated or some myocardial recovery occurs. Despite significant associated morbidity, successful mechanical cardiac support will maintain organ perfusion while decreasing myocardial oxygen demand by unloading the left ventricle and reducing myocardial work. The intraaortic balloon pulsation device has been used most widely. It can be inserted at the bedside and fulfills the criteria of elevating diastolic blood pressure, which increases pulmonary perfusion, while decreasing myocardial work, by increasing cardiac output distal to the ventricle. It is unclear whether this device improves long-term survival, but it clearly supports the failing myocardium while recovery or other interventions proceed. Those patients with surgically correctable problems after acute myocardial infarction appear to respond better than patients who were not operative candidates after temporary mechanical support.

Left heart bypass by left atrium–to–femoral artery circulatory bypass and temporary implantation of left ventricular assist devices may be even more effective in assuming cardiac work. These techniques usually have been limited to patients with cardiogenic shock after cardiac surgery, because operative placement is required. The role of these techniques may broaden if ongoing studies support improved survival rates from early revascularization by thrombolytic therapy, coronary angioplasty, and emergency surgery.

Arrhythmias

Rapid ventricular rates can depress cardiac output to shock levels. Ventricular end-diastolic pressure decreases as a result of shortened filling time, and ventricular relaxation is incomplete by the end of the abbreviated diastolic period. Cardiac output falls because stroke volume cannot be compensated for by the rapid heart rate. Digoxin is the drug of choice for atrial fibrillation or atrial flutter, but electrical cardioversion should be promptly undertaken for tachycardia that produces hypotension and hypoperfusion. Resistant sinus tachycardia, while well tolerated by the normal heart, may produce a low flow state in the diseased heart. Verapamil has been useful in treating tachyarrhythmias of atrial origin, and propranolol slows sinus tachycardia. Beta blockade can further decrease cardiac output in this setting, and a careful search for the cause of the sinus tachycardia, including fever, hypovolemia, and drug effect, should be undertaken. Immediate nonsynchronized direct-current electrical shock is mandatory treatment for ventricular fibrillation or ventricular flutter that has caused cardiogenic shock with loss of consciousness. Ventricular fibrillation rarely converts spontaneously, and the subsequent rapid development of cardiovascular collapse demands prompt therapy. In the patient with acute myocardial injury, premature ventricular complexes may lead to ventricular tachyarrhythmias. Intravenous lidocaine usually is the initial treatment and also is given after cardioversion to prevent recurrent ventricular fibrillation. Bretylium tosylate has been useful in treating life- threatening ventricular tachyarrhythmias that are unresponsive to lidocaine or class Ia agents, such as procainamide.

Low cardiac output with ventricular rates less than 70 beats/min may occur in patients with impaired cardiac performance. Stroke volume cannot increase to compensate for the pathologic bradycardia. Electrical pacing of the heart at a rate of 80 to 100 beats/min can restore sufficient cardiac output whether the underlying mechanism is sinus bradycardia, atrial fibrillation with slow ventricular rate (e.g., digitalis toxicity), or atrioventricular dissociation.

Neurogenic Shock

Neurogenic shock (“primary shock” in the older classification) is the form of shock that occurs after serious interference with the balance of vasodilator and vasoconstrictor influences to the arterioles and venules. This is the shock that is seen with clinical syncope—the sudden exposure to unpleasant events, such as the sight of blood, the hearing of bad tidings, or the sudden onset of pain. Similarly, neurogenic shock often is observed with serious paralysis of vasomotor influences, as in high spinal anesthesia or injury to the spinal cord. The reflex interruption of nerve impulses also occurs with acute gastric dilatation.

The clinical picture of neurogenic shock is quite different from that classically seen in hypovolemic shock. While the blood pressure may be extremely low, the pulse rate usually is slower than normal and is accompanied by dry, warm, and even flushed skin. Measurements made during neurogenic shock indicate a reduction in cardiac output, but this is accompanied by a decrease in resistance of arteriolar vessels and a decrease in the venous tone. Consequently, there appears to be a normovolemic state with a greatly increased reservoir capacity in the arterioles and venules, thereby inducing a decreased venous return to the right side of the heart and hence a reduction in cardiac output.

If neurogenic shock is not corrected, a reduction of blood flow to the kidneys and damage to the brain result, and the ravages of hypovolemic shock appear. Treatment of neurogenic shock usually is obvious. Gastric dilatation can be treated rapidly with nasogastric suction. Shock due to high spinal anesthesia can be treated effectively with administration of fluids and a vasopressor, such as ephedrine or phenylephrine (Neo- Synephrine). These drugs will increase cardiac output, restore venous tone, and elevate systemic blood pressure by arteriolar constriction. With the milder forms of neurogenic shock, such as fainting, simply removing the patient from the stimulus, relieving the pain, and elevating the legs is adequate therapy while the vasoconstrictor nerves regain the ability to maintain normal arteriolar and venous resistance.

There is rarely a need for hemodynamic measurement in this usually self- limited form of hypotension. An exception is when this form of shock results from injury, as with spinal cord transection from trauma. In this instance there may be significant loss of blood and extracellular fluid into the area of injury surrounding the cord and vertebral column. Considerable confusion can arise as to the relative need for fluid replacement or for vasopressor drugs under these circumstances. Similarly, if surgical intervention for any reason becomes necessary, hemodynamic measurements may be of great value in the management of these patients. In uncomplicated neurogenic shock, central venous pressure should be slightly low, with a near-normal cardiac output. If hypovolemia ensues, central venous pressure and cardiac output decrease. Careful monitoring of central venous pressure may be necessary. Fluid administration without vasopressors in this form of hypotension may produce a gradually rising arterial pressure and cardiac output without elevation of central venous pressure by gradually “filling” the expanded vascular pool; caution must be used during fluid administration.

In managing these patients, slight volume overextension is much less deleterious than excessive vasopressor administration. The latter decreases organ perfusion in the presence of inadequate fluid replacement, particularly in the body proximal to the cord injury. Balance is best obtained by maintaining a normal central venous pressure that rises slightly with rapid fluid administration (ensuring adequate volume) and using a vasopressor such as phenylephrine judiciously to support arterial pressure.

Septic Shock

Sepsis, the sepsis syndrome, and septic shock define the continuum of human response to infection. Although any agent capable of producing infection, including viruses, parasites, and fungi, may generate septic shock, the most frequent causative organisms in the antibiotic era are gram-negative bacteria, and occasionally gram-positive bacteria. The initial infectious process appears to be only a stimulus for a series of host responses that may culminate in death, even in the absence of infection at the time of death. Over the past few decades, the incidence of gram- negative sepsis has risen dramatically, from fewer than 100 reported cases in the early 1920s to an estimate of 400,000 cases per year, of which approximately 100,000 episodes of septic shock are treated in the United States. Even in the most recent series, overall mortality exceeds 30 percent, with mortalities over 80 percent in complicated cases with associated multiple organ system failure.

Gram-negative organisms supplanted gram-positive organisms as the predominant cause of septic shock after the widespread application of effective antibiotics for gram-positive infections. Despite increasingly powerful gram-negative antibiotics, the incidence of gram-negative sepsis continues to rise. Proposed causes for this increasing incidence include a developing reservoir of resistant and virulent organisms, concentration of infected patients in critical-care settings, more extensive operations in elderly and poor-risk patients, initial salvage of the severely injured, and a growing population of patients immunosuppressed by organ transplant protocols, radiotherapy, and chemotherapy.

The most common source of gram-negative infection is the genitourinary system. This frequently follows instrumentation of the urinary tract, which is performed in up to one-third of hospitalized patients. The second most frequent site of origin is the respiratory system, followed by the alimentary system, including the biliary tract. Increasing and prolonged use of indwelling catheters for monitoring and hyperalimentation is responsible for many bloodstream infections. The early and aggressive use of appropriate antibiotic therapy with other treatments outlined below have a crucial role in favorable outcome. Patients with a surgically correctable focus of infection have a more favorable prognosis.

Clinical Manifestations

Gram-negative infections frequently are heralded by the onset of chills and temperature elevations above 38°C (101°F). The patient may rapidly progress to evidence of altered organ function, most often renal and pulmonary in nature. This clinical situation plus the development of hypotension completes the picture of septic shock. Unlike most other forms of shock, the patient who is normovolemic has hypotension despite an increased cardiac output and a reasonable filling pressure. The peripheral resistance is low and produces the paradoxical “warm shock” with pink, dry extremities. The high cardiac output often is associated with a decrease in oxygen utilization and a narrowed arteriovenous oxygen difference.

In a patient who is initially hypovolemic or persists in the shock state, a hypodynamic pattern emerges that is characterized by a falling cardiac output, low central pressures, and increased peripheral resistance with more typical cold, pale extremities consistent with global hypoperfusion. Early volume replacement frequently increases cardiac output and produces a hyperdynamic circulation, while the patient later in shock is unresponsive to volume replacement and has a low cardiac output with increasing metabolic acidosis.

Concomitant laboratory tests usually show an elevation in the white blood cell count, but leukopenia may be present in immunosuppressed and debilitated patients or those with overwhelming white cell consumption from sepsis. Thrombocytopenia may be an early indicator of gram-negative sepsis, particularly in pediatric and burn patients. Mild hypoxia with compensatory hyperventilation and respiratory alkalosis are common early findings, despite clinical or radiological evidence of intrinsic pulmonary disease. Although the onset of hypotension may be coincident with these clinical signs of infection, a patient can have relatively subtle findings of hyperventilation, respiratory alkalosis, and altered sensorium for a prolonged period before shock begins.

Septic shock is the result of numerous complex interactions between exogenous and endogenous mediators and host responses to these stimuli. The wide individual variation in septic shock and in response to various interventions in human and experimental studies serves to underscore this intricate and poorly understood pathogenesis. Necessary host responses to local injury and infection form the local defenses against progression to systemic illness. When the ability to contain local infection is overwhelmed, systemic illness may result from the inappropriate systemic effects of these mediators.

At the organ level, cardiovascular response to systemic infection, in the absence of hypovolemia, is the development of a hyperdynamic state. A number of vasoregulatory mediators combine to produce a net decrease in systemic vascular resistance. This is quite distinct from the increased vascular resistance seen in responses to hypoperfusion in

other forms of shock. As cardiac index increases, the arterial-venous oxygen difference narrows. An apparent effect in peripheral oxygen extraction was originally ascribed to pathologic arteriovenous shunting. However, microvascular blood flow in many capillary beds does not appear to be altered in septic shock. Additionally, neither cellular hypoxia nor any defects in the energy- producing metabolic pathways have been documented by studies using in vivo nuclear magnetic resonance spectroscopy. Despite increased cardiac index and decreased oxygen extraction, no direct evidence for cellular hypoxia was detected.

Although patients with hyperdynamic septic shock have an increased cardiac output, detailed studies in patients and animals report a depression in myocardial function. The long-postulated myocardial depressant factor, although poorly characterized biochemically, appears to be a reasonable explanation for documented decreases in left ventricular ejection fraction despite acceptable filling pressures. The pathophysiologic mechanisms that produce organ dysfunction in the septic state, prior to the onset of hypotension, are compounded by the development of refractory hypotension, with tissue ischemia probably contributing a component of cell death in end-stage hypodynamic septic shock.

Pathophysiology

Many studies suggested that the agents responsible for the induction of fever were endogenous products, and this led to the concept of endogenous mediators of the action of endotoxin. While early studies demonstrated that interleukin-1 (IL-1) was an endogenous mediator of infection, recent studies by Beutler and coworkers and by Tracey and coworkers demonstrated that cachectin- *TNF* is a central and proximal mediator of the host response to endotoxemia and bacteremia.

Cachectin is a cytokine secreted by activated macrophages; it was purified to homogeneity by Beutler and Cerami while they were looking for a factor that mediated cachexia. This protein, which is produced predominantly by cells of macrophage lineage, was purified and characterized by Aggarwal and associates. It is a 17-kD protein with 50 percent homology with lymphotoxin, a lymphokine with which it shares many properties. Because of the similarity of function, lymphotoxin has been called TNF-b, and TNF- cachectin is referred to as TNF-a. After protein and complementary DNA (cDNA) sequence analysis was completed, it became apparent that cachectin was identical to a factor called tumor necrosis factor, isolated for its ability to mediate endotoxin-induced tumor cytotoxicity.

Early studies by Shires and colleagues recognized that cellular dysfunction accompanying acute hemorrhagic shock is associated with a reduction in the transcellular membrane potential. Subsequent studies in animal models of septic shock by Illner and associates and a primate model of septic shock by Trunkey and associates demonstrated that similar changes in the transcellular membrane potential occurred during septic shock and that the reduction in the membrane potential preceded the onset of hypotension. A similar decrease in the transmembrane potential occurred in human volunteers in response to endotoxin infusion.

To understand the etiology of the reduction in cellular membrane potential during sepsis, the effects of TNF-a on skeletal muscle membrane potentials were studied. It was found that TNF-a was capable of inducing membrane depolarization in vitro. Using the in vitro measurement of skeletal muscle membrane potentials as a bioassay, Tracey and colleagues were able to demonstrate that plasma from critically ill patients with septicemia in a surgical intensive care unit contained a circulating factor that caused muscle membrane depolarization. Preincubation of the plasma samples with a monoclonal antibody to human TNF-a was able to abrogate the in vitro decrease in the membrane potential. Infusion of TNF-a intraarterially in dogs induced a rapid decrease in skeletal muscle membrane potential and extremity lactate efflux, similar to that seen in sepsis before the onset of shock. These changes preceded the onset of hypertension by 2 to 3 h and were associated with an increased fluid requirement secondary to third-space losses. The time course of these changes, i.e., skeletal muscle membrane depolarization and lactic acidemia preceding circulatory compromise, is consistent with clinical observations of the development of septic shock. These initial studies, confirmed by Schirmer and associates, suggested that TNF-a was an important mediator of septic shock.

To assess the role of TNF-a in bacteremic shock in primates, monoclonal antibodies [F(ab')₂ fragments] to human TNF-a were administered to baboons 2 h before challenge with a lethal dose of *Escherichia coli*. The administration of anti-TNF-a antibodies prevented the development of subsequent septic shock and associated organ dysfunction. Subsequent analysis of plasma samples from these baboons revealed that anti-TNF-a monoclonal antibody pretreatment before the infusion of *E. coli* abrogated the increases in circulating interleukin-1 (IL-1) and IL-6 seen in the untreated animals (Fig. 4-13). In a similar study, Mathison and colleagues demonstrated that administration of anti-TNF-a antibodies protected rabbits from lethal shock induced by endotoxemia. These studies established the role of TNF-a as a central and proximal mediator of experimental septic shock.

Circulating TNF-a can be found in response to endotoxin administration in human beings and peak levels may correlate with sepsis and overall mortality when detected in human disease states. Although endotoxin or gram- negative bacteria infusions may not accurately reproduce the mode of onset of clinical septicemia, the fact that TNF-a is present in human critical disease states strongly supports an important role of TNF-a in the pathophysiology of septic shock in human beings.

The mechanisms through which TNF-a induces the pathophysiologic changes associated with shock are being studied. TNF-a induces the synthesis and secretion of a variety of secondary mediators, including other cytokines, prostaglandins, leukotrienes, platelet-activating factor, complement components, and activation of the clotting cascade, that possess toxic properties capable of causing widespread tissue damage if liberated systemically. In addition, *lipopolysaccharide (LPS)* may synergize with TNF-a to induce many of the toxic effects mediated by TNF-a. The TNF-a-induced release of these factors may be responsible for pathologic changes seen in the lungs, liver, bowel, and kidneys in response to sepsis and septic shock.

Discrepancies in TNF-a detection in the circulation may be partially explained by the presence of circulating TNF receptors that may interfere with the measurement of TNF-a in the plasma. These receptors can neutralize TNF-a cytotoxicity, measured by bioassay, and interfere with the detection of TNF-a by enzyme-linked immunosorbent assay (ELISA) if the antibodies used do not recognize TNF-a-soluble receptor complexes. It also has been noted that competitive radioimmunoassays (RIAs) may overestimate TNF-a concentrations in the presence of soluble TNF receptors. RIA binding of the labeled antigen to the soluble receptors reduces binding to the antibody. This results in a low measured value and a correspondingly high calculated value for the concentration of unlabeled TNF-a.

Concentrations of soluble receptors found in endotoxemic volunteers or critically ill patients are sufficient to neutralize or attenuate the cytotoxicity associated with TNF-a concentrations observed in mild inflammation. Such levels apparently are inadequate to neutralize the toxicity associated with the excessive or persistent TNF-a activity found during overwhelming sepsis.

Evidence of the therapeutic potential of TNF-blockade was obtained by Tracey, who administered monoclonal murine antihuman TNF-a antibodies to baboons before administering a lethal dose of live *E. coli* and demonstrated survival for at least 48 h. In addition to the difference in survival, anti-TNF-a antibodies attenuated the leukopenia and the release of catabolic stress hormones (epinephrine, norepinephrine, and glucagon) that normally accompany such a lethal bacteremia. The appearance of other cytokines known to be produced during sepsis (IL-1b and IL-6) also was significantly reduced.

A different approach to achieving blockade of excessive TNF-a has been provided by the recent identification of naturally occurring inhibitors of TNF-a activity in human serum and urine. The isolation and characterization of these inhibitors revealed them to be the extracellular domains of the type I and type II TNF receptors, which are shed from the cell surface in response to some of the same inflammatory stimuli known to induce TNF-a production. Both naturally occurring soluble TNF receptors (sTNFR-I and sTNFR-II) can be found in human volunteers after endotoxin administration.

To investigate the therapeutic potential of exogenous soluble TNF receptors, recombinant soluble TNFR-I (rsTNFR-I) was administered to baboons with a lethal bacteremia. The baboons received an intravenous bolus of live *E. coli* (LD100), followed by a 3-h primed continuous infusion of rsTNFR-I sufficient to provide a 300-fold molar excess of sTNFR-I over the maximum TNF-a plasma concentration. Administration of rsTNFR-I significantly reduced the volume of resuscitation fluid required to maintain hemodynamic stability and the maximum decline in mean arterial pressure (MAP) (Fig. 4-14).

The term interleukin-1 applies to two different polypeptides, IL-1a and IL- 1b. These biochemically distinct forms share only 26 percent amino acid homology, but both varieties bind to the same cell-surface receptors and induce the same biologic responses. IL-1, like TNF-a, is one of the key mediators of the host response to infection, inflammation, and injury. The two cytokines have been found to have many overlapping biologic functions.

Because much of the circulating IL-1 is thought to represent excess local tissue production, the infrequent detection of IL-1 in the circulation during clinical sepsis is not surprising. There is evidence that local production of IL- 1 and TNF-a is increased in inflammation even in the absence of circulating cytokine, suggesting that assays of local tissue levels may be more appropriate than measurement of circulating concentrations.

A naturally occurring inhibitor of IL-1 was identified in the urine of febrile patients as well as in the plasma of endotoxemic volunteers and critically ill patients. This inhibitor is a 17-kD polypeptide with 26 percent and 19 percent sequence homology to IL-1b and IL-1a, respectively, which binds to IL-1 cell-surface receptors. Despite the sequence homology and the protein's ability to bind to both types of IL-1 receptors, it has no agonist activity, and it was termed interleukin-1 receptor antagonist (IL-1ra).

IL-1ra blocks many functions of IL-1 in vitro, including: lymphocyte proliferation; increased adhesion of endothelial cells for neutrophils and eosinophils; synthesis of IL-1, TNF-a, IL-6, and IL-8 by monocytes; and nitric oxide production in human smooth muscle cells.

Fischer and associates investigated the potential benefit of exogenous IL- 1ra in severe sepsis by administering a lethal bacteremia to nonhuman primates. Administration of IL-1ra significantly decreased the hypotension and fall in cardiac output observed in controls and improved survival. In addition, circulating levels of IL-1b and IL-6 were significantly reduced. TNF- a levels were unchanged by IL-1ra, leading to the conclusion that the control mechanisms of these two cytokines are independent (Fig. 4-15).

These animal models provided the basis for initiating clinical trials of IL-1ra in the treatment of sepsis. In patients in whom IL-1 activity is adequately balanced by endogenous IL-1ra, administration of exogenous IL-1ra may not be beneficial and may potentially exacerbate certain types of infection.

Since endotoxin is the bacterial component largely responsible for the toxic effects of gram-negative infection, methods of blocking endotoxin are being investigated. One approach is the administration of antiendotoxin antibodies. Ziegler and coworkers reported an improvement in survival in a subset of patients with sepsis who had documented gram-negative bacteremia and were treated with HA-1A, a human monoclonal IgM antibody, against the lipid A portion of endotoxin. There was no improvement in those patients without positive blood cultures. Another report showed improved survival in patients with gram-negative sepsis (with positive cultures) but without shock who were treated with E5, a murine monoclonal IgM antibody also against lipid A. A follow-up study failed to confirm the beneficial effects of E5.

Endogenous *LPS*-binding proteins may be used to block the effects of endotoxin. One such protein, first isolated from neutrophil granules, is bactericidal/permeability-increasing protein (BPI). This peptide specifically binds to LPS and has been shown to inhibit endotoxin-mediated TNF-a release in vitro by peripheral blood mononuclear cells and in vivo in the murine lung. BPI, when preincubated with LPS, blocks LPS-mediated pyrogenicity in rabbits. Early data suggest that BPI may have therapeutic potential in the treatment of gram-negative sepsis.

The above factors are only some of the likely mediators of the host response to overwhelming sepsis and septic shock. Classic hormonal responses in septic shock are similar to those observed in hemorrhagic shock. Other potential mediators of septic shock include the kinins, endogenous opiates, and a number of recently purified cytokines believed to mediate host inflammatory responses.

Therapy

The control of infection by antibiotic treatment and early surgical debridement or radiologically guided drainage represent definitive therapy. Other recommended measures, including fluid therapy and the use of vasoactive drugs, represent adjunctive forms of therapy. Adjunctive therapies are useful in preparing patients for surgical or radiologic intervention or supporting patients until the infectious process can be controlled, but if the infection cannot be adequately controlled, the death of the patient is inevitable. It is essential that a prompt search for the source of infection be made as soon as infection becomes evident. It is advisable to institute supportive measures so that arterial and central venous or pulmonary capillary wedge pressures can be measured directly, and urine output and arterial and central venous blood gases should be measured, if indicated. If the infectious process requires drainage, operation should be performed as soon as possible after the patient has been stabilized, because some conditions, such as septic shock secondary to ascending cholangitis, will respond only briefly to adjunctive measures.

Antibiotic treatment should be based on the results of cultures and sensitivity tests when possible, but in the absence of these data broad- spectrum antibiotics should be started, including coverage for anaerobic organisms such as *Bacteroides* species or fungi, if clinically indicated. Antibiotic therapy should be adjusted when culture and sensitivity reports become available.

Correction of preexisting fluid deficits is essential in the septic patient and should proceed rapidly, though carefully, using pulmonary capillary wedge pressure and cardiac output as a guide to target appropriate replacement volumes, so that the detrimental pulmonary effects of fluid overload can be avoided. Monitoring is essential, because fluid requirements may be massive in these patients. Resuscitation requirements in excess of 10L of lactated Ringer's solution are common.

The use of corticosteroids in the treatment of septic shock was controversial until data from two well-controlled, prospective clinical trials demonstrated that the use of high-dose corticosteroids did not confer a survival advantage over non-steroid-treated controls (Fig. 4-16). The only indications for steroid treatment in patients with septic shock are hypoadrenalism and for stress coverage in patients taking steroids (or who recently completed a course of steroids) for immunosuppression or anti- inflammatory purposes.

Future clinical use of anti-TNF antibodies, protein C, or other antimediator treatment regimens probably will depend on early recognition of the sepsis syndrome for success unless used prophylactically in a population of patients at high risk.

Pharmacologic Support

Although fluid resuscitation remains the initial therapy for hypotension in sepsis, it is frequently necessary to administer drugs with inotropic or vasopressor activity. Dopamine is the initial inotropic agent used. As discussed above in the section on cardiogenic shock, dopamine has some vasopressor activity at higher doses that may be required in the volume-loaded patient with persistent profound hypotension. Augmentation of the impaired myocardial performance in septic shock is a reasonable goal. Dobutamine often increases cardiac input with less tachycardia and arrhythmia than dopamine. The beta-adrenergic vasodilatation from dobutamine infusion may not be tolerated by these hypotensive patients. Vasodilator drugs have been shown to improve cardiac output and oxygen delivery in normotensive septic patients. Their use in septic shock is limited by low systemic pressure or decreased cardiac filling pressures. More potent vasopressors, despite their obvious detrimental effect on peripheral perfusion, may be transiently unavoidable in patients who have persistent life-threatening hypotension, despite optimal fluid and dopamine infusions. Norepinephrine is a potent alpha-receptor agonist that usually is effective in raising pressure in patients for whom the measures described above have failed. Its use is sometimes preferred over high-dose dopamine because the cardiac effects are less. Epinephrine, a catecholamine with potent alpha- and beta-adrenergic activity, may support the blood pressure in patients who do not respond to norepinephrine. Polypharmacy frequently is ineffective and may be harmful in patients with complex cardiovascular alterations. Use of pressors is primarily for transient support while primary definitive therapy with antibiotics and drainage of surgical infection are being instituted.

Manipulations of Humoral Responses

Given the obviously complex and ill-defined interactions among a large number of mediators, therapy directed at any single agent is probably ineffective. Carefully tailored multidrug or serial antimediator therapy eventually may allow modulation of the deleterious systemic effects of the necessary host responses to injury and infection.

Initial trials of steroids, fibronectin, and naloxone were disappointing. More specific immunotherapy using monoclonal IgM antibodies to core lipopolysaccharide have been completed. Only small subsets of patients from each study showed statistical benefit. Treatment with HA-1A improved survival and organ function in the presence of gram-negative bacteremia with or without shock. The E5 trial was beneficial in patients with gram-negative bacteremia only in the absence of shock. None of the antibodies directed at lipid A or other epitopes of the core lipopolysaccharide are established therapeutic modalities.

The naturally occurring IL-1 receptor antagonist has been manufactured by recombinant technology. IL-1ra showed benefit in several animal models but failed to show efficacy in human sepsis. Monoclonal antibodies to *TNF* also are available and appear promising in patients with septic shock. The use of anticoagulants such as anti-thrombin III in the treatment of sepsis that is unassociated with shock is currently under investigation. The persistent significant morbidity and mortality from sepsis, despite powerful antibiotic therapy, prompt surgery, and carefully titrated fluid and drug support suggest that the future for improved therapeutic results lies in these exciting new treatments within the next decade.

CHAPTER 5 - Surgical Infections

Richard J. Howard

HISTORICAL BACKGROUND

Infection is encountered by all surgeons: by the nature of their craft, they invariably impair the first line of host defenses—the cutaneous or mucosal barrier. The entrance of microbes into host tissues is the initial requirement for infection. Preventing microbial penetration, reducing the microbial inoculum, and treating established infection have been important developments in reducing the mortality associated with surgery.

For most of surgical history, death from infection was common, although it was not until the end of the nineteenth century that the bacterial cause of surgical infection was appreciated. Death from infection was so common after compound fracture or fracture caused by gunshot wound that amputation was the standard treatment. Before antiseptic practices were instituted, mortality rates for amputation in times of war between 1745 and 1865 were between 25 and 90 percent. Mortality rates for amputation in civilian practice during the same period ranged from 5 to 50 percent.

The introduction of anesthesia by Long in 1842 and by Morton in 1846 increased the scope of surgery by permitting operations on body cavities and allowing surgeons to operate more slowly and deliberately, so that death from blood loss was diminished. Infection remained a great problem, however. Hospital gangrene (or *erysipelas*, a term popularized during the Civil War describing a necrotizing infection presumably caused by *Streptococcus*) and tetanus continued to plague surgeons and their patients. Many surgeons realized that a more favorable prognosis was associated with an infection that developed “laudable pus” rather than a more serious infection that was not associated with purulence. Surgeons did not yet understand the cause of infection.

Joseph Lister (1827–1912) made one of the great contributions to surgery by demonstrating that antisepsis could prevent infection and hence that compound fractures did not have to be treated by amputation. In March 1865 he began placing pure carbolic acid into wounds. Later he reduced the concentration to 10, 5, and 2.5 percent. In 1867 he published his initial series of papers on antisepsis, reporting, among other things, that compound fractures healed without infection when the wounds were treated with carbolic acid.

Wound antisepsis was not new with Lister. More than 20 articles appeared in British medical publications between 1859 and 1865 describing antiseptic treatment of wounds. Numerous agents had been placed in wounds since ancient times in an attempt to foster healing and prevent death—turpentine, pitch and tar, balsams and balms, myrrh and frankincense, honey, alcohol, glycerin, mercuric chloride, silver nitrate, iodine, hypochlorites, creosote, ferric chloride, zinc chloride, and carbolic acid. In 1871 Lister began to use a carbolic acid spray to reduce contamination of the operating room atmosphere, a practice he abandoned in 1887.

The “antiseptic principle” or “Listerian method” emphasized antiseptic treatment of wounds after the operation. Although initially resisted by many surgeons (more by British and American surgeons than by surgeons on the continent), they were gradually adopted.

Even late in the nineteenth century aseptic surgery was not generally practiced. Surgeons washed their hands after, but seldom before, operations. When asked what was new in surgery in 1882, Ernst Bergmann said, “Today we wash our hands before an operation.” Gloves were not worn routinely until the early part of the twentieth century. Only gradually and with much opposition was aseptic surgery adopted. Sterilization of instruments, first by chemicals and then by steam, came into practice in the 1880s and 1890s. Hand washing and the wearing of masks, caps, gowns, and gloves were also introduced about this time.

William Stewart Halsted (1852–1922) introduced rubber gloves for his scrub nurse (and future Mrs. Halsted), Caroline Hampton, because the corrosive sublimate used to sterilize instruments, mercuric chloride, irritated her skin. One of Halsted's students, Joseph Bloodgood, introduced their routine use by the entire operating team.

The introduction of antibiotics was a major step in the treatment of infections. Although the discovery of penicillin was first reported by Alexander Fleming in 1928, it was not used clinically until administered by Howard Florey in the 1940s. Penicillin was then rapidly introduced into general clinical medicine and was followed by streptomycin and numerous other antibiotics. It was hoped that antibiotics would eliminate the risk of infection as a surgical complication and would enable established infection to be cured easily, but this has not been the case. Wound infection and other postoperative infections continue to be a problem even though antibiotics have reduced their risk. The widespread use of antibiotics has even led to the emergence of strains of antibiotic-resistant bacteria. The nature of postoperative infections has also changed because of the many patients (debilitated, elderly, cancer patients) being operated on who have compromised host defenses or who are given drugs that inhibit host defenses (cancer chemotherapy agents, immunosuppressants to prevent organ transplant rejection).

It was also hoped that antibiotics would cure most infections even without operation. While the introduction of antibiotic therapy was a giant step in the treatment of nonsurgical infections, it had a much smaller impact in the treatment of surgical infections. The mortality rate of acute appendicitis was approximately 50 percent in the latter part of the nineteenth century. The recognition in the 1890s that a person with acute appendicitis required an immediate operation led to a dramatic decrease in mortality rates in the early part of the twentieth century. Until that time surgeons believed that waiting a few days would allow the omentum and intestines to isolate the appendix, after which an abscess could be safely drained. The development of intravenous fluid therapy and blood transfusion led to another decrease in mortality rates in the early part of the twentieth century. By the time penicillin became available, the mortality rate of acute appendicitis had already decreased to 5 percent. Continuing improvement in anesthesia, surgical technique, and postoperative care have also contributed to the continuing decline in mortality—as has antibiotic therapy.

Although antibiotic therapy was a monumental advance in the treatment of infections, for patients with surgical infection it constitutes only a part of the treatment. Surgical infections generally require an operative procedure (or radiology-assisted percutaneous drainage) for a successful outcome. In the future, continued improvement in the treatment outcome of surgical infection is more likely to stem from such factors as earlier and better means of diagnosis, improved patient care, and therapy directed against bacterial products or host responses than from improvements in antimicrobial therapy.

GENERAL CONSIDERATIONS

Surgical infections can conveniently be defined as infections that require operative treatment or result from operative treatment. Infections that require operative treatment include (1) necrotizing soft tissue infections; (2) body cavity infections such as peritonitis, suppurative pericarditis, and empyema; (3) confined tissue, organ, and joint infection such as abscess and septic arthritis; and (4) prosthetic device–associated infections. With the possibility of patient-to-surgeon and surgeon-to-patient spread of viral infections such as from the human immunodeficiency virus (HIV) and hepatitis viruses, infections in health care workers have also become of interest to surgeons.

Infections that result from operative treatment include wound infection, postoperative abscess, postoperative (tertiary) peritonitis, other postoperative body cavity infection, prosthetic device–related infection, and other hospital-acquired infections among which are pneumonias, urinary tract infection, and vascular catheter–related infection. Immunocompromised patients are subject to viral and fungal infections that seldom cause infection in the normal host.

Principles of Therapy

The patient's own host defenses and antibiotic therapy are adequate to overcome most infections. Nonoperative treatments can assist recovery from some infections. Chest physiotherapy is useful in patients with pneumonia, especially those with thickened secretions. Increasing fluid intake and thus increasing urine flow is helpful in patients with urinary tract infections. Immobilization and elevation can relieve pain and reduce the swelling of an extremity afflicted with cellulitis or lymphangitis.

Operative treatment is generally required when host defenses cannot function properly or when there is continuing contamination with microorganisms: infected fluid collections must be drained, infected necrotic tissue must be debrided, and infected foreign bodies must be removed. Infected fluid collections such as abscesses must be drained because phagocytic cells cannot function properly with the metabolic conditions usually present. Antibiotics are not very effective against bacteria in abscesses because they penetrate abscesses poorly and because antibiotics work best on actively dividing bacteria—and most bacteria in abscesses are not actively dividing. Drainage is also salutary because necrotic tissue and foreign bodies inhibit the proper functioning of host defenses.

Defects in the gastrointestinal tract provide a continuing source of bacteria that rapidly overwhelms host defenses. Operation is required to end this source by closing the defect in the gastrointestinal tract or by bringing the defect to the outside as an ileostomy or colostomy.

Determinants of Infection

The development of surgical infection depends on several factors: (1) microbial pathogenicity and number, (2) host defenses, (3) the local environment, and (4) surgical technique (for postoperative infection).

Microbial Pathogenicity

The ability of a microbe to cause infection is a balance between host defenses and microbial pathogenicity. Some microbes that have virtually no ability to cause infection in the normal host can cause lethal infection in an individual with compromised host defenses.

Many bacteria (*S. pneumoniae*, *Klebsiella pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Salmonella typhi*) and fungi (*Histoplasma capsulatum*, *Candida albicans*, *Cryptococcus neoformans*) have thick capsules that make them resistant to phagocytosis (see section [Surgical Microbiology](#) below). Other microbes (*Mycobacterium tuberculosis*, *Aspergillus flavus*, and *Toxoplasma gondii*) resist intracellular killing after they have been phagocytosed when lysosomes that contain enzymes that digest microbes do not fuse with the phagosome. Other microbes successfully resist digestion by lysosomal enzymes.

Some bacteria can elaborate toxins, many of which are enzymes that injure or kill cells or promote spread within tissues. Exotoxins play an important role in the pathogenicity of *Clostridium* species, *Staph. aureus*, and *Strep. pyogenes*. Other bacteria (*Clostridium tetani*, *Clostridium botulinum*) elaborate neurotoxins that alter normal neural transmission.

Endotoxins are lipopolysaccharide-protein complexes that are normal constituents of the cell wall of gram-negative bacteria. These molecules activate many biological pathways, including the complement and coagulation systems, and cause release of cytokines and other biologic mediators from macrophages, release of hormones, and alteration in metabolism.

Host Defenses

Local host defenses are important in preventing microbial penetration into the tissues. Systemic host defenses are needed to rid the tissues of microbes once penetration has occurred.

Local Host Defenses

Tissues are protected from microbial invasion by a layer of epithelium. The epithelium of the skin is multilayered, and the superficial layers are keratinized. The epithelium also is multilayered in the nasopharynx, oral cavity, esophagus, and genitourinary tract. At other sites (the tracheobronchial tree, gastrointestinal tract, and eye) a single layer of epithelium protects the underlying tissues. Each site also provides a local environment that is not conducive to microbial attachment and growth. Among these local environmental features may be lack of moisture (skin), the flushing action of tears and urine, cilia (trachea, bronchi), peristalsis, mucus, pH (gastrointestinal tract), and local immunity (IgA).

Systemic Host Defenses

A complex system of defense mechanisms exists throughout the body that can inactivate and kill microbial agents. These host defenses consist of phagocytic cells, the immune system, and other molecular cascades such as the complement system, the coagulation system, and the kinin system. Phagocytic cells that can ingest and kill microbes include polymorphonuclear leukocytes (PMNs) and tissue macrophages (monocytes in the blood). Through a complex set of interactions of microbes with complement and other activation molecules, PMNs adhere to vascular endothelium, migrate across the endothelium and move in the direction of the microbes (chemotaxis), attach to the microbes (which may involve immunoglobulins or other opsonins), and phagocytose the microbes. Finally, lysosomes containing a variety of enzymes fuse with the phagosome, and the microbe is rapidly digested. The initiation of this process and its attendant chemical, cellular, and physiologic changes result in inflammation.

Macrophages are phagocytic cells found throughout the body tissues: in liver (Küpf­fer cells), spleen, lymphoid tissue, lung (alveolar microphages), brain (glial cells), connective tissue (histiocytes), and pleura and peritoneum. Macrophages can also move toward microbes in response to chemotactic agents and phagocytose and kill them. In addition, macrophages are important in initiating the immune response and can elaborate cytokines, tissue necrosis factor, interferon, and other biologically active molecules. Humoral and cellular immunity are important systemic host defense mechanisms for many microbial agents. The complement system, clotting system, kinin system, leukotrienes, cytokines, and other biologically active molecules are also activated by microbial agents and play an important role in host defenses.

Host defenses are altered in malnourished individuals, trauma patients, postoperative patients, burn patients, patients with malignant neoplasms, and patients receiving drugs such as cancer chemotherapeutic agents, immunosuppressive agents to prevent transplant rejection, or steroids or other agents that have immunosuppressive effects.

Local Environmental Factors

Local factors may permit an infection to occur in a person with minimal microbial contamination and with otherwise adequate host defenses. These environmental factors inhibit systemic host defenses from being fully effective. A traumatic wound that normally would heal without infection has a greatly increased likelihood of becoming infected if the trauma has resulted in devitalization of tissue or if foreign bodies have been deposited in the wound. Phagocytic cells do not function effectively in the presence of devitalized tissue or foreign bodies. A suture can reduce the number of *Staph. aureus* required to produce a subcutaneous infection by a factor of 100,000. Fluid collections and edema also increase the likelihood of infection because they inhibit phagocytosis.

Peripheral vascular disease contributes to soft tissue infection by preventing blood and the systemic host defenses that it contains (phagocytic cells, immune globulins, and other mediators) from reaching the site of microbial contamination. Shock also decreases the amount of blood that reaches these sites.

These environmental factors can prevent phagocytic cells from functioning efficiently by lowering tissue oxygen tension (P_{O_2}). The lowered P_{O_2} inhibits function of phagocytic cells and promotes the growth of anaerobes.

Surgical Technique

Surgical technique is an important determinant of postoperative wound infection and other postoperative infections. Surgeons can decrease the likelihood of postoperative infection by handling tissues gently; removing devitalized tissues, blood, and other substances that promote the growth of microbes; using drains appropriately (and avoiding inappropriate use); avoiding excessive cautery; and not performing intestinal anastomoses under tension or when there is any question of inadequate blood supply.

TYPES OF SURGICAL INFECTIONS

Soft Tissue Infections

Infection of the soft tissues (Table 5-1)—skin, subcutaneous fat, fascia, and muscle—usually can be treated by antibiotics unless an abscess has formed or tissue necrosis has developed.

Cellulitis and Lymphangitis

Cellulitis is a spreading infection of the skin and subcutaneous tissues. There may or may not be evidence of injury to the skin. It is characterized by local pain and tenderness, edema, and erythema. Usually the border between infected and uninvolved skin is indistinct, with the region of erythema gradually fading into normal-appearing skin. Erysipelas, which is caused by *Strep. pyogenes*, is characterized by intense erythema with a sharp line of demarcation between involved and uninvolved skin. Cellulitis may be accompanied by systemic manifestations such as fever, chills, malaise, and toxic reaction.

Cellulitis can be caused by numerous bacteria in addition to *Strep. pyogenes*, such as *Staph. aureus*, *Strep. pneumoniae*, other streptococci, *Haemophilus influenzae*, and aerobic and anaerobic gram-negative bacteria. Lymphangitis, inflammation of the lymphatic channels in the subcutaneous tissues, presents as visible red streaks. Bacteria may reach the lymph nodes and cause lymphadenitis.

Cellulitis and lymphangitis can be treated by antibiotics alone, but surgery may be needed to treat the source, such as when an abscess has formed. Treatment includes immobilization and elevation to reduce pain and swelling. Failure to achieve prompt clinical response should suggest that suppuration may have occurred and that surgical drainage may be required.

Other skin infections that can be treated by local cleansing and local or systemic antibiotics include impetigo (*Staph. aureus*), erysipeloid (*Erysipelothrix rhusiopathiae [insidiosa]*), folliculitis, and furunculosis.

Some microbial factors that cause granulomatous infections produce ulcers, nodules, sinuses, or infiltrated plaques. Biopsy with culture and histologic examination of tissue with special stains may be required for such lesions. Mycobacterial and fungal infections can manifest themselves in this way.

Soft Tissue Abscess

Surgical treatment is usually required when soft tissue infection results in abscess or tissue necrosis. Furuncles and carbuncles (boils), breast abscess, and perirectal abscess require surgical incision and drainage and usually antibiotic therapy. A *carbuncle* is a subcutaneous abscess usually formed by a confluent infection of multiple contiguous hair follicles. They are most frequently found on the back of the neck and on the upper back. The most common cause is *Staph. aureus*. Overlying erythema may lead to the mistaken diagnosis of cellulitis, but the presence of a fluctuant mass usually leads to the correct diagnosis. A *felon* is a purulent collection in the distal phalanx of the fingers that causes intense pain and pressure in that compartment. Swelling may be minimal because of the fibrous bands between the skin and bone. Treatment requires incision and drainage. A lateral incision is used to avoid a painful scar on the finger top. *Breast abscess* is usually caused by *Staph. aureus* but can be due to gram- negative bacteria as well. It frequently occurs in nursing mothers. Treatment consists of incision and drainage and antibiotics (see Chap. 14). *Perirectal abscess* begins as an infection of one of the crypt glands that then extends into the perirectal space and may present subcutaneously near the anus. It is caused by aerobic and anaerobic gram-negative bacteria that are normal residents of the colon. Incision and drainage and antibiotic therapy are the appropriate initial treatment. Up to 50 percent of perirectal abscesses may result in a fistula communicating with the anal crypt and may require later treatment. The fistula may be difficult to identify because of the intense inflammation of the abscess, and it is usually best to drain the abscess rather than risk making a passage into the anus looking for a fistula where none existed previously (see Chapter 26).

Necrotizing Soft Tissue Infections

Soft tissue infections that cause necrosis are more serious because of their propensity for extensive tissue destruction and high mortality rates. The nomenclature for necrotizing soft tissue infections is confusing. Terms such as necrotizing fasciitis, streptococcal gangrene, gas gangrene, bacterial synergistic gangrene, clostridial myonecrosis, and Fournier's gangrene are commonly used. Attempts to differentiate these infections on the basis of predisposing conditions, presence of pain, toxic condition, fever, presence of crepitus, appearance of the skin and subcutaneous tissues, and presence of bullae are of little help in diagnosis or initial treatment. Bacteria seldom respect anatomic barriers, and hence necrotizing fasciitis is rarely limited to fascia and myonecrosis is frequently not limited to muscle.

Most necrotizing soft tissue infections are caused by mixed aerobic and anaerobic gram-negative and gram-positive bacteria. *Clostridium* species, of which *C. perfringens*, *C. novyi*, and *C.septicum* are the most common, cause the most dramatic infections, with rapid progression, early toxic condition, and high mortality rates. The term *gas gangrene* has become synonymous with clostridial infection. But the presence of gas in tissue simply means that anaerobic bacterial metabolism has produced insoluble gases such as hydrogen, nitrogen, and methane. Both facultative and obligate anaerobes are capable of such metabolic activity. Aerobic bacteria can also produce gas. Gas in tissues is much more likely to be caused by bacteria other than *Clostridium* species. *Strep. pyogenes* can also cause extensive tissue necrosis. Halophilic marine *Vibrio* species can cause rapidly progressive necrotizing soft tissue infections, especially in individuals with liver disease. Fungi too can cause necrotizing cutaneous and subcutaneous infection, but these infections progress much more slowly than do bacterial infections.

Necrotizing soft tissue infections must be recognized early and treated promptly. Diagnosis is not difficult when skin necrosis or bullae are present, but occasionally the clinical findings are subtle until extensive necrosis has occurred. The overlying skin may appear to be normal or afflicted only with cellulitis. Early confusion, toxic condition, and failure to respond to nonoperative therapy may be the earliest clues to the presence of a necrotizing infection. The presence of cutaneous necrosis, bullae, or crepitus strongly suggests a necrotizing infection, and surgical exploration is warranted.

Surgical treatment requires debridement of all necrotic tissue. Computed tomography is a sensitive method of detecting soft tissue gas and may allow a better appreciation of the extent of tissue necrosis. Amputation may be required for myonecrosis of the extremities. It may be difficult to evaluate fully the extent of necrosis at the initial operation, or viable tissue may become necrotic after the initial debridement. Therefore, the wound must be inspected daily with adequate (usually general) anesthesia either in the operating room or in the intensive care unit in the case of small wounds until the surgeon can be sure that there is no further necrosis. Extensive debridement, which can leave the patient with large

tissue defects and extensive wounds, may be required. The goal of treatment is to remove all necrotic tissue; the surgeon should worry about reconstruction later. Initially, broad-spectrum antibiotics including penicillin should be administered. A Gram stain of the tissue and fluid should be done to look for gram-positive rods (*Clostridium* species) or cocci (*Streptococcus* species).

The use of hyperbaric oxygen to treat necrotizing soft tissue infections is controversial. Patients are placed in a chamber at three times atmospheric pressure absolute. Hyperbaric oxygen inhibits production of alpha toxin by *Clostridium* species. Proponents of hyperbaric oxygen treatment claim that it makes the patient's condition less toxic and diminishes the amount of tissue requiring excision. Although hyperbaric oxygen can decrease mortality due to clostridial infection in experimental animals, there are no controlled clinical trials of hyperbaric oxygen in humans. Even proponents, however, note hyperbaric oxygen does not improve outcome for patients with necrotizing soft tissue infections caused by nonclostridial organisms. Hyperbaric oxygen should not be used before surgical debridement. Some centers favor oxygen therapy at atmospheric pressure because a high arterial oxygen pressure can still be achieved without requiring a hyperbaric chamber. If adequate debridement is carried out, the patient usually improves rapidly and hyperbaric oxygen usually is not required. Since clostridial infections account for only a small proportion of necrotizing soft tissue infections, the number of patients who can benefit from this form of therapy is small.

Hyperbaric oxygen therapy has possible complications. Barotrauma can cause injury to the middle ear if the eustachian tube is blocked, trauma to a sinus, pneumothorax, and air embolism. Oxygen toxicity can cause neurotoxicity resulting in reduced seizure threshold and pulmonary toxicity if treatment is prolonged. A feeling of claustrophobia and reversible visual changes are other potential problems associated with hyperbaric oxygen therapy.

Tetanus

Tetanus is caused by *Clostridium tetani*, a large gram-positive spore- forming bacillus. In recent years the number of cases in the United States has decreased sharply from over 450 in 1955 to fewer than 100 in 1975. Currently there are approximately 50 cases of tetanus reported per year.

C. tetani is usually acquired by implantation of the organisms into tissues by means of breaks in the mucosal or skin barriers. Although it is frequently said that tetanus occurs in dirty, necrotic, and neglected wounds, the majority of cases in the United States appear after punctures, lacerations, and abrasions. Tetanus can appear after surgical wounds, injections, and in patients who have no apparent injury at all. Organisms proliferate at the site of inoculation and have virtually no capacity for causing an invasive infection. Clinical tetanus is as much an intoxication as an infection.

C. tetani elaborates two toxins, tetanospasmin and tetanolysin. Tetanospasmin acts on the anterior horn cells of the spinal cord and on the brainstem. It blocks inhibitor synapses at these sites, leading to muscle spasms and hyperreflexia. These physiologic effects are similar to those of strychnine poisoning. Tetanolysin is cardiotoxic and causes hemolysis, but it is not thought to be of major clinical importance.

The median incubation period for both fatal and nonfatal cases of tetanus is 7 to 8 days. Tetanus usually appears in generalized form but occasionally appears as localized tetanus with increased muscle tone and spasms confined to muscles near the wound and without systemic signs. Neonatal tetanus is recognized as difficulty in sucking beginning at 3 to 10 days of age and progressing to generalized tetanus.

In generalized tetanus the initial symptoms are variable. Some patients have symptoms of restlessness and headache. In other patients the first symptoms are muscle spasms with vague discomfort in the neck, lumbar region, and jaws. Spasm of the pharyngeal muscles makes swallowing difficult. A stiff neck is one of the early signs. Progressively, other muscle groups become involved until the spasms become generalized. Orthotonos, opisthotonos, and emprosthotonos can develop. Generalized toxic convulsions are frequent, exhausting, and unpredictable. Any slight external stimulus (a breeze, sudden movement, noise, or light) and internal stimuli (cough, swallow, distended bladder) may trigger generalized convulsions. These convulsions may involve the laryngeal and respiratory muscles and result in fatal acute asphyxia.

Throughout these spasms, which can be extremely painful and even cause fractures, the patient remains mentally alert. The pulse is elevated and there is profuse perspiration. Fever may or may not be present.

Diagnosis of tetanus is based on the clinical picture associated with no prior history of immunization. Although laboratory studies may show an elevated white blood cell count, they are not helpful in making the diagnosis. The demonstration of gram-positive organisms in the wound does not establish the diagnosis of tetanus; failure to demonstrate that the bacillus is in the wound does not eliminate the diagnosis. Consequently, the diagnosis can be difficult in early tetanus. Even with adequate treatment, the mortality rate can exceed 50 percent.

Treatment

Patients with clinical tetanus require exquisite nursing care to avoid complications. Initially therapy consists of administration of tetanus immune globulin (TIG) 500 to 10,000 units as soon as the diagnosis is made. The precise effective dosage of TIG has not been established. Routine laboratory tests should be obtained and the patient should be monitored. Nursing care must be provided constantly in an intensive care unit setting. Formerly patients with tetanus were cared for in quiet rooms that provided a minimum of stimulation. Currently most are treated in an intensive care unit on a respirator with paralytic drugs given to prevent muscle spasms.

Mild cases can be treated with sedation, but most physicians administer muscle relaxants. Adequate doses of analgesics are required because of the pain associated with muscle spasms. Detailed attention must be given to caring for a paralyzed patient who is on a respirator. Adequate nutrition must be provided. Laxatives are generally indicated so that gastrointestinal elimination can be facilitated. A urinary catheter should be provided. Eye protection to prevent desiccation should be provided. Pressure sores can occur rapidly and must be prevented with appropriate skin protection, hygiene, and cushions. Patients may require tracheostomy if they need a respirator for a prolonged period. Roentgenographic studies are used to monitor the development of fractures. Pulmonary emboli can be a problem in patients who have minimal movement. Cardiac exhaustion and circulatory disruption can occur from sympathetic overstimulation. Hyperbaric oxygen treatment is not recommended because it is ineffective. Oxygen has no effect on the toxemia.

The wound must be treated to remove as much of the *C.tetani* and nonviable tissue as possible. Debridement of all necrotic tissue should be done. Penicillin G should be administered to treat any bacteria that remain behind, but antibiotics are no substitute for good wound care.

Prevention

Active immunization with tetanus toxoid is a safe and effective way of preventing tetanus (Table [5-2](#)). Unfortunately many children in the United States are not adequately vaccinated; immunization is also inadequate in many developing countries.

One month after the diagnosis of tetanus is made, tetanus toxoid immunization should be begun. The amount of tetanus toxin released during an infection is so small that the patient does not make antibody.

Body Cavity Infections

Peritonitis and Intraabdominal Abscess

Primary peritonitis is caused by a single organism and occurs most commonly in young children and in adults with ascites or with renal failure that is being treated by peritoneal dialysis. Primary peritonitis can be treated with antibiotics and other medical measures.

Secondary bacterial peritonitis is usually the result of a defect in the gastrointestinal tract and requires operative intervention. The goals of surgery are to control the source of contamination, to remove bacteria and adjuvant materials from the peritoneal cavity, and to prevent postoperative abscess or recurrent peritonitis. Antibiotic therapy that is effective against aerobic and anaerobic enteric bacteria has an important role in treating patients with secondary bacterial peritonitis, but it should never serve to delay or replace operative intervention. Peritonitis occurring (or persisting) after initial operation for secondary peritonitis is *persistent peritonitis*. *Tertiary peritonitis* is a peritonitis-like syndrome occurring late as a result of a disturbance in the host's immune response and is characterized by peritonitis without evidence of pathogens or peritonitis caused by fungi or low-grade pathogenic bacteria.

Percutaneous or operative drainage along with antibiotic therapy is necessary for the treatment of intraabdominal abscesses. The etiology, clinical presentation, diagnosis, and treatment of peritonitis and intraabdominal abscess are discussed in Chap. [32](#).

Empyema

Empyema is usually due to pneumonia (see Chap. [16](#)). Other causes are pulmonary infarct, septic emboli to the lung, tracheal or bronchial fistula, leaking esophageal anastomosis, hepatic abscess, subphrenic abscess, trauma, leaking bronchial closure, infected hemothorax, and paravertebral abscess.

Empyema may be encapsulated and localized or may involve the entire pleural cavity. Initially the fluid in the chest is thin, but with increasing numbers of polymorphonuclear leukocytes and fibrin deposition the fluid becomes thicker and the visceral and parietal peritoneum adhere to each other.

The clinical manifestations of empyema initially resemble those of pneumonia, with pleuritic chest pain and fever, but unresponsiveness to antibiotic therapy may suggest the diagnosis. Chronic empyema can be manifested by dyspnea, fatigue, anemia, debility, and clubbing of the fingers.

Treatment of empyema is aimed at evacuation of the empyema contents and restoration of normal pulmonary function by expansion of the lung. Most empyemas can be treated by tube thoracostomy, especially in early empyema when the fluid is thin, and antibiotic therapy. The course of the disease is observed by the patient's clinical response and chest roentgenograms. The tube may be converted to open drainage after 2 to 3 weeks when the visceral and parietal pleura have become adherent so that the lung does not collapse.

Open drainage should be used if there are multiple pus pockets, if the pus is very thick, or if the empyema is inadequately drained by tube thoracostomy. In some cases a decortication procedure may be necessary to reexpand the lung, or, if a bronchopleural fistula is present, a thoracoplasty may be required.

Other Closed-Spaced Infections

Purulence in closed spaces usually requires drainage and tetanus toxoid immunization and antibiotic therapy. If the diagnosis of septic arthritis is made promptly, antibiotic therapy alone may be sufficient to treat the infection. If the diagnosis is delayed, surgical treatment is required to preserve joint function and to eradicate the infection.

Suppurative pericarditis generally requires operative intervention. Although antibiotic therapy alone may be sufficient to treat some early infections, operative therapy is usually required once suppuration has occurred.

Prosthetic Device—Associated Infections

Infections in prosthetic devices, such as cardiac valves, pacemakers, vascular grafts, and artificial joints, are associated with great morbidity and the defeat of the goals of the operation and too frequently end with the death of the patient. Although intensive antibiotic therapy alone can occasionally cure the infection, frequently it can be eradicated only by complete removal of all foreign material and antibiotic therapy. Replacement of cardiac valves with new porcine or homograft valves and antibiotic therapy has met with some success. Vascular grafts have occasionally been salvaged without graft removal by treatment with debridement, povidone- iodine–soaked dressings, and antibiotic therapy when the suture line has not been infected. Infected prosthetic joints and pacemakers have occasionally been salvaged by antibiotic irrigation of the joint or pacemaker. Usually infected prosthetic devices require complete removal.

Hospital-Acquired (Nosocomial) Infections

Hospital-acquired infections are infections that develop within a hospital or are acquired within a hospital. These infections are costly in terms of the suffering and death they can cause as well as in terms of the cost of increased hospital stays, time lost from work, and legal liability. Each year in the United States there are an estimated 2 million hospital-acquired infections that result in 150,000 deaths. Hospital-acquired infections add an average of 1.5 days to the hospital stay of patients who develop lymphangitis, 14.8 days for patients with septicemia, and 16.6 days for patients who have infections at multiple sites. The total yearly cost of these infections is estimated at several billion dollars.

The Centers for Disease Control and Prevention (CDC) examines hospital- acquired infections through the National Nosocomial Infections Surveillance System (Table 5-3). Infection rates were greatest on the surgical service, at 44.3 per 1000 discharges. On surgical services urinary tract infections are most common, followed by wound infection, lower respiratory infection, bacteremia, and cutaneous infection. Vascular catheter–related infections are frequently classified under bacteremia or cutaneous infection.

Wound Infections Classification

For many years wounds have been classified into four categories according to the theoretical number of bacteria that contaminate wounds: clean, clean-contaminated, contaminated, and dirty (Table 5-4). Wound infection rates in large series are approximately 1.5 to 3.9 percent for clean wounds, 3.0 to 4.0 percent for clean-contaminated wounds, and approximately 8.5 percent for contaminated wounds. Dirty wounds generally are left open, but wound infection rates for dirty wounds of 28 and 40 percent have been reported (Table 5-5). With over half of all operations currently being performed as outpatient procedures and early discharge of hospitalized patients, most wound infections are recognized when the patient is outside the hospital. Because of the expense and difficulty of detecting wound infections that occur outside the hospital and because surgeons may be penalized for reporting too many wound infections, accurate wound infection data may become more difficult to collect in the future.

Wound infections encompass infections of the wound that occur above the fascia (superficial wound infection) and those that occur below the fascia (deep wound infection). Some authors have proposed more inclusive terms, e.g., “surgical field” or “surgical site infection,” that would include all operative sites potentially exposed to bacteria. These more inclusive terms would include superficial and deep wound infections and infections that do not occur in direct proximity to the surgical incision (e.g., postoperative intraabdominal abscess).

Definition of Surgical Wound Infection

An incisional (superficial) wound infection must meet the following criteria: Infection occurs at an incision site within 30 days after operation, and involves skin or subcutaneous tissue above the fascial layer, and any of the following:

- (1) There is purulent drainage from the incision or a drain located above the fascial layer.
- (2) An organism is isolated from culture of fluid that has been aseptically obtained from a wound that was closed primarily.
- (3) The wound is opened deliberately by the surgeon, unless the wound is culture-negative.

Deep surgical wound infection must meet the following criteria: Infection occurs at the operative site within 30 days after operation if no prosthesis was permanently placed and within 1year if an implant was placed, and infection involves tissues or spaces at or beneath the fascial layer, and any of the following:

- (1) The wound spontaneously dehisces or is deliberately opened by the surgeon when the patient has a fever (>38 °C) and/or there is localized pain or tenderness, unless the wound is culture-negative.
- (2) An abscess or other evidence of infection directly under the incision is seen on direct examination, during operation, or by histopathologic examination.
- (3) The surgeon diagnoses infection.

Bacteria can gain entrance to the wound from endogenous or exogenous sources. Virtually all infections in clean-contaminated and contaminated wounds and also in the majority of clean wounds are caused by endogenous bacteria present on the skin or mucosal surfaces.

Prophylaxis Operating Room Environment

Air-handling systems are designed to reduce the number of airborne microbes. Filtration of air can reduce the number of dust particles to which microbes can adsorb. Operating room air should have a positive pressure relative to air in the corridors so that unfiltered air does not enter the operating room. Special laminar flow systems with high efficiency particulate air (HEPA) filters are frequently used when prosthetic joints are implanted to reduce the likelihood of airborne contamination. Reducing the number of people in the operating room and limiting talking are also advocated by some experts to reduce the number of airborne microbes.

Instruments and Drapes

Properly sterilized instruments should never be a source of infection. If drapes become wet bacteria can move from underneath the drapes to the surgical field by capillary movement. These bacteria theoretically can then enter the wound and cause a wound infection. Disposable drapes with plastic liners and cloth drapes with tighter weaves are designed to minimize this type of bacterial contamination. It is extremely difficult to establish whether the type of drape affects wound infection rates. The choice of drapes should be based on other considerations, such as cost and ease of disposal.

Adhesive plastic drapes do not lower the incidence of wound infection. Cruse found that using adhesive plastic drapes in addition to routine draping was associated with a wound infection rate of 2.3 percent (214 of 9252) compared to 1.5 percent (405 of 26,303) when plastic drapes were not used. Skin bacteria may actually proliferate under the warm, moist environment provided by the plastic drape, and these bacteria may enter the wound if the edge of the plastic drape lifts off the wound margin. Plastic drapes can be helpful, however, in isolating potential sources of contamination such as ostomies or fistulae near the incision.

Hand Washing

Hand washing with soap and an antiseptic agent removes dirt and desquamated skin and reduces the number of microbes on the skin. Although tradition calls for scrubbing for 10 min and using two brushes, washing for 5 min and using one brush accomplishes equal reduction in skin bacterial counts. In practice many surgeons scrub for a shorter time, especially after the day's the first operation, when most dirt and desquamated skin have already been removed.

Hexachlorophene, povidone-iodine, and chlorhexidine are the antiseptics most commonly used for hand washing. Hexachlorophene has the disadvantage of acting slowly. It should be used daily to achieve maximal reduction of skin bacteria. It has been replaced in some hospitals because of its slow action and because it can be absorbed through the skin. Both povidone-iodine and chlorhexidine result in prompt reduction of skin microbes.

Gloves

Gloves should fit snugly over the fingers and hands and over the cuff of the surgical gown. Thirty percent of gloves have defects in them by the end of the operation. Surgeons are potentially exposed to infectious agents harbored by their patients when blood enters through these holes and gets onto their skin. Glove perforations are more likely to occur during long operations, during operations for trauma, and when the patient's blood loss is great. The CDC and some experts advocate wearing two pairs of gloves to reduce the likelihood of exposure to patient's blood.

Other Barriers

Caps prevent hair and skin scales (and adherent bacteria) from falling into the patient's wound, masks prevent droplets produced during speaking or coughing from entering the patient's wound, and gowns prevent desquamated skin and other particles from entering the patient's wound. There are no data that demonstrate unequivocally that wearing these barriers lowers the wound infection rate. In two recent studies the wound infection rate was found not to increase when surgeons did not wear masks. In one study surgeons did not wear masks for a 6-month period, and that period's wound infection rate was compared with that of the preceding 5 years. The wound infection rate actually fell to 1.8 percent from 5.7 percent. In another study more than 3000 patients were randomized to be operated on by surgeons wearing masks or not wearing masks. There was no difference in wound infection rate. But these barriers should still be worn if for no other reason than to prevent blood of the patient from coming in contact with members of the operating room team.

Preoperative Stay

Patients who have longer preoperative hospitalizations are more likely to develop postoperative wound infections. These patients may acquire more virulent or antibiotic-resistant hospital bacteria. Since patients who have long preoperative hospital stays are likely to have compromised host defenses, it is not surprising that they are more likely to develop wound infections.

Preoperative Shower

A shower with an antiseptic soap such as chlorhexidine or povidone-iodine can reduce the resident skin bacteria. Cruse reported that the infection rate was 1.3 percent for patients who took a preoperative shower with soap containing hexachlorophene, 2.1 percent for those who took a shower with ordinary soap, and 2.3 percent for those who did not shower.

But another study of 5536 patients found no reduction in wound infection rates in patients who had a preoperative shower with 4% chlorhexidine detergent.

Remote Infections

Remote infections can triple the rate of wound infection. Elective operations should generally be delayed until the infection has been eliminated. Areas of dermatitis are generally moist, and bacterial growth at these sites increases dramatically. Elective operations should be delayed until the dermatitis is treated, especially if the skin incision is near or through such regions.

Hair Removal

Shaving, clipping, and depilatory agents are used to remove hair. Shaving remains the most commonly used method of hair removal. But nicks and cuts caused by shaving are sites where bacteria can proliferate.

When shaving is done the night before operation, there is ample time for bacterial proliferation in any nicks or cuts, and the wound infection rate is higher than when shaving is done in the operating room immediately before operation. When hair is removed by clipping with an electric clipper, the wound infection rate can be reduced further.

Skin Preparation

Degerming of the operative site usually entails washing the site with a germicidal soap solution for 5 to 10 min followed by painting the site with an antimicrobial solution such as chlorhexidine or povidone-iodine. Painting the operation site with an alcohol solution of povidone-iodine, which can be accomplished in less than 1 min, is as effective as a 5-min scrub with povidone-iodine followed by painting with povidone-iodine solution.

Reduction of Colonic Bacteria

There are approximately 10^{10} to 10^{11} bacteria per gram feces. Colon procedures therefore potentially expose the wound to numerous bacteria. Colonic bacteria can be greatly reduced by cleansing the colon of feces. A variety of enemas or cathartics such as magnesium citrate solution or electrolyte solutions in polyethylene glycol can be used. These agents should be used before all elective colon surgery. Oral antibiotics can further reduce the number of colonic bacteria. A combination of neomycin and erythromycin base is used most commonly, but other antibiotics are also effective.

Improving Host Defenses

Any malnutrition should be corrected to restore the patient's resistance to infection toward normal. Obesity should be corrected since it is associated with an increased rate of wound infection. Weight reduction also lowers the risk of pulmonary complications. Abnormal physiologic states that result from cirrhosis, uremia, and diabetes should be corrected as far as possible. Patients with pulmonary disease should have therapy before elective surgery to optimize their pulmonary status. Patients who smoke should cease smoking before the operation. Since smoking inhibits ciliary movement, people who smoke might not be able to clear tracheal secretions as well as nonsmokers. Although it is desirable to have patients lose weight or stop smoking before elective operations, it is extremely difficult to accomplish in practice.

Surgical Technique

Every surgical incision injures tissues. Bacteria contaminate the wounds of virtually all clean-contaminated and contaminated procedures and probably of most clean operations as well. The surgeon's goal should be to make the local wound environment as unfavorable to the growth of these bacteria as possible.

The incision should be made in such a way to injure as little tissue as possible and to prevent the accumulation of agents that facilitate bacterial growth or inhibit host defense such as devitalized tissue, foreign bodies, blood, and serum. The initial skin incision should be made with a scalpel through the entire skin layer. The subcutaneous fat should then be divided with a single incision down to the fascia. This may not be possible in obese patients, but the number of scalpel passes should be kept to a minimum. It is important to begin each new pass of the scalpel in the depths of the wound so that tissue is not devitalized. Some surgeons prefer to use the laser or electrocautery for the incision. These techniques may result in less bleeding but can cause more tissue destruction. There are no definitive studies showing that one technique results in fewer wound infections than another.

The surgeon should be fastidious in ascertaining that bleeding has been stopped before closure. Blood in the incision provides a good environment for bacterial growth. The surgeon should not rely on drains to remove blood. Blood is more likely to clot and form a hematoma than to be removed by a drain.

The wound edges can become desiccated, leading to tissue necrosis at the wound margins. Desiccation can be prevented by placing moist laparotomy pads over the edges of the wound and keeping them wet. Some surgeons place antibiotics into the irrigant. There is no solid evidence that local antibiotics lessen the likelihood of infection. When the wound is closed there is a potential space where a seroma can collect. There are no definitive studies that provide data on whether subcutaneous sutures affect the risk of wound infection, but it seems advisable to place as few foreign bodies into the wound as possible.

If the surgeon is concerned about the possibility of a wound seroma such as might occur in the subcutaneous tissue of an extremely obese patient, a closed-suction drain should be used. Latex rubber (Penrose) drains should not be used because bacteria can actually enter the wound through the drain tract. Use of latex rubber drains leads to a higher wound infection rate than not using a drain.

All devitalized tissue and foreign bodies should be removed from traumatic wounds. Irrigation with saline solution can facilitate the removal of small particles, especially if the irrigation is performed with the saline solution under pressure. When complete removal of devitalized tissue and foreign bodies cannot be assured, or when the wound is heavily contaminated with bacteria, it can be left open and closed secondarily. If the wound is left open, saline-soaked gauze should be placed in the depths of the wound to keep the edges apart. There are no definitive studies that demonstrate that using antibiotic or antiseptic solutions inhibits infection or improves healing.

Prophylactic Antibiotics

Antibiotic administration can reduce the incidence of postoperative wound infection in patients having certain operations. There are certain principles that guide antibiotic prophylaxis use (Table 5-6). Prophylactic antibiotic therapy should be directed against the bacteria likely to contaminate the wound (Table 5-7). For clean operations for which antibiotic prophylaxis is appropriate, *Staph. aureus*, *Staphylococcus epidermidis*, and gram-negative enteric bacteria are the most likely bacteria to cause wound infections. Gram-negative enteric bacteria are the most likely causes of wound infection following gastroduodenal and biliary tract procedures, colorectal surgery, appendectomy, and gynecologic surgery.

The antibiotics should generally be given intravenously 30 to 60 minutes before operation so that adequate blood and tissue levels are present at the time that the skin incision is made. The antibiotic dose should be repeated if the operation lasts longer than 4 h or twice the half-life of the antibiotic or if blood loss has been great. With many operations currently being performed on patients who are not in a hospital before surgery and with newer antibiotics available, oral antibiotic prophylaxis may also be suitable. Bowel preparation with cleansing of the colon, and oral antibiotics (e.g., neomycin and erythromycin base), can be given to nonhospitalized patients. Prophylactic antibiotics should not be continued beyond the day of operation. The most commonly violated principle is giving the antibiotic longer than is actually needed, which increases costs and the likelihood of antibiotic resistance among hospital strains of bacteria.

Cephalosporins are the most commonly used antibiotics for prophylaxis because of their broad antibacterial spectrum, which provides activity against gram-positive pyogenic cocci and gram-negative enteric bacteria (some cephalosporins) and because of their low toxicity. But despite their safety profile, allergic reactions can occur with these antibiotics, so they should not be used indiscriminately. Cefazolin, a first-generation cephalosporin, is an effective antibiotic prophylaxis for indicated clean gastroduodenal, biliary tract, and head and neck operations and traumatic wounds. Vancomycin can be substituted in hospitals where methicillin-resistant *Staph. aureus* or *S. epidermidis* is a problem and in patients who are allergic to penicillins or cephalosporins. For colorectal procedures oral neomycin plus erythromycin base and/or cefoxitin or cefotetan provide effective coverage.

First- or second-generation cephalosporins provide effective prophylaxis for gynecologic surgery and cesarean section. Third-generation cephalosporins are no more effective than first- or second-generation agents and are more expensive. Many other antibiotic classes are also effective, but none has gained the popularity of the cephalosporins.

Indications

Prophylactic antibiotics are indicated when bacterial contamination of the wound is likely or for patients having clean operations in which a prosthetic device is placed where infection could lead to disastrous results, such as in a cardiac valve, a vascular graft, or a prosthetic joint. Bacterial contamination is likely in traumatic wounds, when the intestinal tract has been entered as a result of trauma, in elective operations on the intestine or colon, in gastroduodenal operations in which the patient has increased gastric flora, in high-risk biliary tract operations, and in gynecologic operations. Studies indicate that prophylactic antibiotics can lower the incidence of all infectious complications in clean surgery (hernia and breast surgery) but the incidence of wound infection is not reduced.

The bacteria in the stomach are increased in patients who have gastric outlet obstruction, decreased gastric acidity (achlorhydria, antacid or H₂-receptor blocker therapy, gastric cancer), and normal or high acidity if bleeding has occurred. High-risk biliary tract operations include the presence of jaundice, bile duct obstruction, stones in the common bile duct, reoperative biliary tract operation, acute cholecystitis, and age greater than 70 years.

Infection Surveillance

An infection surveillance program can help to reduce the rate of wound infections and is required by the Joint Commission on Accreditation of Health Organizations. Large studies have shown the usefulness of regular wound surveillance. The introduction of a good wound surveillance program lowered the wound infection rate of more than 20,000 wounds to 1.9 percent from 4.9 percent over a 5-year period.

Other Hospital-Acquired Infections Urinary Tract Infection

Urinary tract infection accounts for 40 percent of hospital-acquired infections. Two-thirds of patients with hospital-acquired urinary tract infection have had operation on the lower urinary tract, instrumentation of the bladder, or catheterization. Because of the large number of patients who fit one of these categories there are an estimated 400,000 urinary tract infections per year in hospitalized patients. Catheter-associated urinary infections cause bacteremia in 2 to 4 percent of patients and are associated with a case fatality rate three times as high as that of nonbacteremic patients.

Bacteriuria occurs in 1 to 5 percent of patients after a single short-term catheterization. The risk of infection is higher in pregnant patients, in elderly or debilitated patients, and in patients with urologic abnormalities. The risk of bacteriuria in patients with long-term indwelling catheters is approximately 5 to 10 percent for each day the catheter is in place. Therefore, urinary catheters should be placed only when necessary and should be removed as soon as possible. If prolonged urinary tract catheterization is required, as in

comatose patients, incontinent men, or spine-injured patients, suprapubic or condom catheters can be used to reduce the risk of infection.

Appropriate catheter insertion after careful cleansing of the urethral meatus and postinsertion care of the catheter can reduce the risk of infection. Irrigation of the catheter (i.e., to remove blood clots) should be done only by trained personnel.

Lower Respiratory Tract Infection

Lower respiratory tract infections are the third most common hospital- acquired infection, according to the National Nosocomial Infections Surveillance System. Anesthesia, operations on the head and neck, and postoperative endotracheal intubation interfere with the normal protective cough reflex and may permit aspiration of contaminated material. Pain associated with thoracic or upper abdominal operations and trauma interferes with coughing and deep breathing, which promotes collection of material in the tracheobronchial tree and atelectasis, which in turn predispose to infection. Pulmonary edema or adult respiratory distress syndrome resulting from injudicious use of intravenous fluids, cardiac failure, trauma, sepsis, renal failure, or inhalation of hot gases by burn patients also predispose to pulmonary infection. Fluid that accumulates in alveoli inhibits the phagocytic capacity of pulmonary macrophages.

Hospitalized patients may have gram-negative bacteria as part of their oral flora. These bacteria may be aspirated into the lungs during the postoperative period. Tracheostomies and respiratory care devices also predispose to the entry of bacteria into the lower respiratory tract.

The most common causative organisms of lower respiratory tract infection in hospitalized patients are *Staph. aureus*, *Pseudomonas aeruginosa*, *Klebsiella* species, *Escherichia coli*, and *Enterobacter* species. These bacteria, especially in the intensive care unit setting, may be resistant to commonly used antibiotics. Pulmonary infections in hospitalized patients are frequently not associated with sputum production, and culture of sputum specimens may not reflect the cause of pneumonia. Specially protected specimen swabs can be introduced into the lungs through a flexible bronchoscope, with sensitivity rates for diagnosing the pneumonia between 70 and 90 percent. Accuracy is enhanced by using quantitative bacteriology to distinguish better colonization and invasive infection; finding more than 10³ colony-forming-units/mL is indicative of invasive infection. Bronchoalveolar lavage has increased the accuracy of bronchoscopic diagnosis.

Lower respiratory tract infections are common in intubated patients in intensive care units, occurring in as many as 20 to 25 percent of patients, with a mortality rate of 50 percent. Many of these pneumonias are attributed to low levels of aspiration. Oropharyngeal decontamination using topical, nonabsorbable antibiotics or antiseptics can reduce tracheobronchial contamination by gram-negative bacteria and pneumonia in these patients.

Vascular Catheter–Related Infection

The incidence of vascular catheter–related infections has increased greatly with the increased use of central vascular catheters that are left in place for prolonged periods in patients with compromised host defenses. It is estimated that 20 million hospitalized patients each year undergo vascular catheterization of some sort. An estimated 20,000 to 50,000 cases of hospital-acquired bacteremia per year are caused by vascular catheters. Central venous catheters have a higher infection rate than peripheral venous catheters, and polyethylene catheters have a higher infection rate than Silastic catheters. The most common source of catheter sepsis is believed to be microorganisms at the skin exit site that follow the catheter into the vein rather than microorganisms originating from a distant site that colonize the catheter via the bloodstream.

Staph. aureus and *S. epidermidis* usually originate from the skin and cause most catheter–related infections. Most yeast vascular-access infections result from hematogenous dissemination from another site. Gram-negative enteric bacteria also may infect catheters hematogenously.

The duration of catheterization, the number of catheter manipulations, inexperience of the inserter, violations of aseptic technique, and use of multilumen catheters are all associated with an increased risk of infection. Transparent plastic dressings increase the risk of infection two- to fourfold compared with traditional gauze dressings. Teams specially designated for catheter insertion and maintenance can reduce the risk of catheter infection. Skin preparation with chlorhexidine gluconate and use of topical antibiotics can also reduce the risk of infection. There are no data proving that practices such as changing catheters at intervals, changing infusion tubing every 24 to 48 h, and using in-line filters reduce the risk of infection.

Finding bacteria on the catheter tip does not establish that it was infected, since the bacteria may have come from the blood that inevitably adheres to catheter tips. Some investigators have attempted to do semiquantitative cultures of the catheter tips by rolling them on solid culture plates, flushing sterile broth through the catheter, or subjecting them to sonication to remove adherent organisms before quantitative culture as methods of diagnosing catheter–related infection. If there is unequivocal purulent discharge around the catheter insertion site, the diagnosis of vascular- catheter infection can be made without a positive culture.

Any evidence of phlebitis or cellulitis or any suspicion of septic complications caused by intravenous cannulas should lead to prompt removal of the cannulas. Because many central venous catheters are used in compromised hosts who are prone to fever, these catheters generally should not be removed because of fever alone until other potential sources of fever have been eliminated. Most surgeons remove central venous catheters that are suspected of being infected and replace them after 24 to 48 h. Frequently, central venous catheters are required, and the surgeon does not have the luxury of being able to wait before inserting a new catheter. When an infected catheter is removed and another central venous catheter is immediately inserted at the same site, infection of the new catheter usually does not occur.

Catheter infections caused by *S. epidermidis* can occasionally be treated with antibiotics alone or by removal of the catheter. If antibiotics are used, a short course (3 to 7 days) is recommended. Vascular-access infections caused by *Staph. aureus* always require antibiotic therapy. The controversy in the treatment of catheter infections caused by *Staph. aureus* is in the duration of antibiotic therapy, with most experts recommending a 2- to 3-week course. Vascular-catheter infection caused by yeasts should always be treated by catheter removal and administration of an antifungal agent if cultures remain positive following removal or if there is infection elsewhere.

SURGICAL MICROBIOLOGY

Surgical infections are usually caused by bacteria, but fungal and viral infection can also occur, especially as postoperative infections in immunocompromised hosts. Most bacterial infections are caused by organisms that are part of the patient's endogenous flora—bacteria that are normal residents of the skin or gastrointestinal tract.

Bacteria

Bacteria can be classified according to staining characteristics with Gram stain (positive or negative), shape (cocci, rods, spirals), and ability to grow without oxygen (aerobic, facultative, anaerobic), or according to a combination of these characteristics. Gram-positive cocci, gram-negative aerobic and facultative rods, and anaerobic bacteria are three groups into which most bacteria causing surgical infections can be placed.

Gram-Positive Cocci

Staphylococcus and *Streptococcus* species are the gram-positive cocci (often referred to as pyogenic) of interest to surgeons because of their ability to cause primary surgical infections and postoperative infections.

The genus *Staphylococcus* is composed of facultatively anaerobic gram- positive cocci that are found on moist areas of the body, the anterior nares, and mucous membranes. In addition, these bacteria can be found on the body surface of many species of mammals and birds, in the air and dust of occupied buildings, and in milk, food, and sewage.

Staph. aureus is the most common pathogen isolated from wound infections. A major factor in its pathogenicity is coagulase production, although the mechanism whereby coagulase production increases virulence is not known. In addition to coagulase production, a variety of other cell surface components and extracellular products are related to pathogenicity.

Cell wall peptidoglycan inhibits edema production and migration of leukocytes, allowing bacteria to proliferate in tissues. Capsules inhibit opsonization and thus phagocytosis. Some strains produce a surface- associated exopolysaccharide or glycocalyx (slime), which is associated with virulence, probably by permitting the bacteria to resist phagocytosis and adhere to prosthetic materials.

Other extracellular products also contribute to the pathogenicity of *Staph. aureus*. An enterotoxin is responsible for food poisoning. Epidermolytic toxin can cause a variety of skin lesions; the most characteristic are the diffuse exfoliative bullae seen in children with the scalded skin syndrome. Another exotoxin, TSS toxin-1, is responsible for toxic shock syndrome. Other extracellular products make *Staph. aureus* resistant to H₂O₂- mediated intracellular killing (catalase) and cause cell death (leukocidin, alpha toxin, beta toxin).

Staph. epidermidis, a member of the flora of the skin and mucous membranes, was long thought to be a commensal. Although not as pathogenic as *Staph. aureus*, *S. epidermidis* causes infection in the presence of foreign bodies such as plastic catheters, ventricular shunts, and prosthetic joints and heart valves. *Staph. aureus* and *S. epidermidis* are important surgical pathogens. *Staph. aureus* is a major cause of wound infection. It can cause infection of skin and soft tissues and abscesses of these and other structures. Bacteremia can lead to infection of heart valves and other deep structures such as bone, kidney, and brain.

Surgically important members of the genus *Streptococcus* include *S. pyogenes*, *S. pneumoniae*, and the viridans group, which includes *S. mutans*, *S. mitior*, *S. salivarius*, *S. sanguis*, and *S. milleri*. Streptococci are classified according to Lancefield classification, which is based on cell surface antigens, and according to their ability to cause hemolysis on blood agar: in alpha hemolysis, a zone of green discoloration is seen around colonies containing intact red blood cells; in beta hemolysis, there is complete clearing of the area around colonies and destruction of red blood cells; and in gamma hemolysis, there is no hemolysis. *Strep. pyogenes* is Lancefield group A and beta-hemolytic. Group A streptococci have cell surface components and extracellular products that inhibit host defenses or promote spread of the bacterium. The cell surface M protein and the capsule help streptococci resist phagocytosis. Hyaluronidase and streptokinase promote the spread of infection. Streptolysin O and streptolysin S are hemolysins. Streptococcal proteinase may be responsible for tissue invasion. Pyogenic exotoxins share many properties with endotoxins from gram-negative bacteria.

Group A streptococci can cause infection of almost any organ, although the skin, subcutaneous tissues, and pharynx are by far the most frequent sites. *Strep. pyogenes* can cause pharyngitis and result in scarlet fever or rheumatic fever. Erysipelas is streptococcal cellulitis and lymphangitis and is a spreading infection with sharp, irregular, red borders. Erythrogenic toxin produced by streptococci is responsible for the intense cutaneous erythema but is not found in all streptococcal infections.

Streptococci are important pathogens because of their ability to cause postoperative infections, including cellulitis, wound infection, endocarditis, urinary tract infection, and bacteremia. These bacteria can also cause primary necrotizing soft tissue infections and abscesses. In some hospitals streptococci other than group A streptococci are the principal

streptococcal pathogens. *Strep. pyogenes* is currently an uncommon cause of necrotizing soft tissue infections. In the nineteenth century and the early part of the twentieth century streptococci were believed to be the most common cause of necrotizing soft tissue infection.

Enterococcus faecalis, *E. faecium*, and *E. durans* were formerly classified as members of the genus *Streptococcus*, but a separate genus is now recognized. They are part of the normal flora of the gastrointestinal tract and vagina. They are commonly found in patients with peritoneal and pelvic infections as part of the mixed flora typical of these infections. Enterococcal bacteremia has a poor prognosis when associated with intraabdominal or pelvic infection and is found most often in patients who have been hospitalized for a long time. These bacteria are an important problem in intensive care units because of their resistance to antibiotics.

Aerobic and Facultatively Anaerobic Gram-Negative Bacilli

There are numerous gram-negative rods that can cause human disease, but relatively few are of surgical significance. Their cell walls have common chemical constituents, most prominent of which is lipopolysaccharide or endotoxin, which is responsible for most of the biologic effects of these bacteria. Some genera also have capsules. Most are members of the family Enterobacteriaceae that are inhabitants of the gastrointestinal tract. The genera *Escherichia*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, and *Providencia* frequently can be cultured from patients with intraabdominal and pelvic peritonitis and abscess, postoperative wound infection, pneumonia, and urinary tract infection.

The family Vibrionaceae includes *Vibrio* among its genera. Some *Vibrio* species are found in marine water and can cause bacteremia and necrotizing soft tissue infections in susceptible hosts, usually those with hepatic disease. They can be found in seafood and can cause bacteremia and death if the uncooked seafood is ingested.

The family Pseudomonadaceae is composed of obligate aerobes that lack the ability to ferment sugars, unlike members of the Enterobacteriaceae. *Pseudomonas aeruginosa* is the species in this family responsible for most surgical infections. They cause infections similar to those of gram-negative enteric bacteria in association with gastrointestinal disease, pneumonia, urinary tract infection, and burns. They are frequently found in immunologically compromised patients, especially if they have been hospitalized for some time. They cause necrotizing infections, especially pneumonia and vasculitis. Ecthyma gangrenosum is the cutaneous manifestation of necrotizing vasculitis due to *Pseudomonas* bacteremia and is characterized by small, round, necrotic skin lesions. Because of its resistance to antibiotic therapy, *Pseudomonas* infections are frequently treated with a combination of two antibiotics.

Anaerobic Bacteria

Anaerobic bacteria require reduced oxygen tension for growth. They are found predominantly in the mouth, vagina, and gastrointestinal tract, where they greatly outnumber the aerobic bacteria. Anaerobic bacteria, which are pathogenic, can tolerate an initial exposure of up to 3% oxygen. Virtually all anaerobic infections arise endogenously. A low oxidation- reduction potential is common to all anaerobic infection. Vascular disease, cold, shock, edema, trauma, devitalized tissue, operation, foreign bodies, malignant disease, and growth of aerobic microorganisms can lower the oxidation-reduction potential and predispose to infection with these organisms.

In most infections with anaerobic bacteria, facultative or aerobic bacteria are also present. Aerobic or facultative bacteria make conditions favorable for anaerobic bacteria by lowering the oxidation-reduction potential. The aerobic bacteria may also supply a growth factor necessary for another organism or may interfere with local or systemic host resistance.

Anaerobes such as the *Bacteroides fragilis* group have an endotoxin, but it differs chemically from the endotoxin of the enteric facultative or aerobic gram-negative bacilli, and it exhibits poor biologic activity. The cell wall of anaerobic bacteria is important in abscess formation.

The genus *Clostridium* is the most virulent of all anaerobes. *Clostridium*, which can be found in soil and stool, can cause necrotizing soft tissue infection. Clostridia produce exotoxins that have biologic effects in cell culture. Their precise role in clinical disease is unclear, but the exotoxins produced by these bacteria are believed to be responsible for most of the local and systemic manifestations. *C. perfringens*, *C. septicum*, and *C. novyi*, which can cause necrotizing infections, produce toxins that can destroy cell membranes and lyse red blood cells, collagenase, hyaluronidase, and other enzyme toxins that enhance spread of the infection through the tissues.

C. perfringens and *C. difficile* both produce an enterotoxin. *C. difficile* causes pseudomembranous colitis and occurs in patients treated with broad-spectrum antibiotics. It produces a cytotoxin that is cytopathic for almost all tissue culture cell lines. *C. tetani* and *C. botulinum* produce neurotoxins that cause muscle spasms and paralysis, respectively.

In the colon the ratio of anaerobic bacteria to aerobic bacteria is between 300:1 and 1000:1. The most common pathogens in the colon are members of the genera *Bacteroides*, *Fusobacterium*, and *Peptostreptococcus*. Of these, *Bacteroides* is the most commonly cultured genus in patients with intraabdominal infections. The *Bacteroides fragilis* group, composed of *B. fragilis*, *B. thetaiotaomicron*, *B. distasonis*, *B. ovatus*, and *B. vulgatus*, accounts for most infections with this genus. Colonic anaerobes almost never cause infections by themselves but only as part of a mixed flora, often with facultative enteric gram-negative bacilli.

Fungi

Together with algae and protozoa, fungi are classified as protists, the most primitive eukaryotic organisms. They grow as single-celled organisms, as yeasts, or as long, branching filaments known as hyphae. Their cell walls show little similarity to those of bacteria, but they have much in common with mammalian cells. Because of this and other structural and biochemical similarities to mammalian cells (both are eukaryotic cells), they are not sensitive to antibacterial agents and many antifungal agents are toxic to human cells.

Fungi can be grouped as primary pathogens, which can cause disease in individuals with intact host defenses, and opportunists, which cause disease in patients with compromised host defenses. Among the primary pathogens are *Histoplasma*, *Coccidioides*, and *Blastomyces*. *Candida*, *Cryptococcus*, *Aspergillus*, and the phycomycetes (*Mucor*, *Absidia*, and *Rhizopus*) cause most of the opportunistic infections.

In surgical patients opportunists cause most infections. *Candida albicans* and other *Candida* species are by far the most common. They cause infections in patients being treated with broad-spectrum antibiotics and in those receiving steroids and other immunosuppressive agents, in malnourished patients, in patients with malignant neoplasms, and in other compromised hosts. In these patients they can cause vascular catheter-related infections, bacteremia, intraabdominal infection, pneumonia, and urinary tract infection. These infections can be treated by stopping antibiotic administration, correcting host defenses, and therapy with amphotericin B or one of the azole antifungal agents.

Viruses

Viruses are distinguished by their small size, by their being obligate intracellular parasites, and by their having either ribonucleic acid (RNA) or deoxyribonucleic acid (DNA) but not both. Members of the herpesvirus family, especially *cytomegalovirus* (CMV), herpes simplex virus, varicella- zoster virus, and Epstein-Barr virus, can cause infections in immunosuppressed patients such as organ transplant recipients.

CMV causes most viral infections in organ transplant recipients. In these patients CMV can cause ulcerative lesions of the gastrointestinal tract leading to bleeding or perforation for which operations might be required. Epstein-Barr virus is implicated as the cause of a polyclonal B-cell lymphoma in transplant recipients.

Hepatitis B virus, hepatitis C virus, and human immunodeficiency virus (HIV) are of importance to surgeons because of the possibility that they can become infected from patient exposure and that patients can potentially be infected by physicians who harbor these viruses. Hepatitis B prophylaxis is available should a health care worker sustain a percutaneous or permucosal exposure (Table 5-8).

Human Immunodeficiency Virus

An apparently new disease was first reported in December 1981 with the description of opportunist infections and Kaposi's sarcoma occurring in homosexual men. These men also had a profound depletion of T lymphocytes. Human immunodeficiency virus (HIV), the cause of acquired immunodeficiency syndrome (AIDS), was isolated in 1983. Since 1983, more than 600,000 individuals in the United States have developed AIDS.

HIV is a retrovirus of the lentivirus family. It is an RNA virus with a cylindrical core containing RNA, the RNA-dependent DNA polymerase (reverse transcriptase), and core proteins. The core is surrounded by a viral envelope derived from the nuclear membrane of the host cells. A glycoprotein (GP-120) on the envelope has an affinity for the CD4+ receptor on T lymphocytes. After binding of the GP-120 to the CD4+ receptor on helper/inducer T cells, the virus is internalized and uncoated. The reverse transcriptase synthesizes DNA complementary to viral RNA. This DNA is incorporated into the host genome, leading to a lifelong infection.

Infected CD4+ cells are not able to carry out their normal immune functions, which leads to opportunist infections and the development of Kaposi's sarcoma. The development of opportunist infections and tumors (Kaposi's sarcoma and lymphomas) is accompanied by a decrease in the number of T cells to less than 200/mm³. The most recent definition of AIDS includes all patients infected with HIV who have a CD4+ count less than 200 cells/mm³.

Epidemiology

The CDC does not collect data on the number of individuals infected with HIV but estimates that for every person with AIDS there are approximately eight persons with HIV infection who have not yet developed clinical AIDS. There are approximately 5 million people infected with HIV in the United States. Approximately 30.6 million people are infected with HIV worldwide.

HIV has been isolated from blood, semen, saliva, tears, vaginal secretions, alveolar fluid, cerebrospinal fluid, breast milk, synovial fluid, and amniotic fluid. Only blood and blood products, semen, vaginal secretions, and breast milk have been linked to transmission.

The groups at highest risk for HIV infection are (1) homosexual and bisexual men, (2) intravenous drug abusers, (3) persons with hemophilia and other coagulation disorders, (4) heterosexual contacts of the individuals in the three previous categories, and (5) children born to HIV- positive mothers. Recipients of transfusions of blood and blood products from HIV-positive donors have approximately a 95 percent chance of developing HIV infection. The CDC has estimated that the number of cases of transfusion-acquired AIDS could eventually reach 12,000. Since testing blood donors for evidence of HIV became mandatory in 1985, transfusion- acquired HIV infection has been virtually eliminated. The current risk of transmission of HIV by screened blood in the United States is estimated to be between 1 in 450,000 and 1 in 660,000.

HIV seroprevalence varies greatly, depending on the specific population studied, the location of the population, sex, race, and ethnic origin, and year of study. The lowest HIV seropositive rates are found among blood donors (0.0041 percent for repeat female donors, 0.0189 percent for repeat male donors) and are highest among hemophiliacs (50 to 100

percent positive), intravenous drug users (20 to 60 percent positive) homosexual and bisexual men (30 to 60 percent positive).

Relatively few seroprevalence studies have been done among hospital or emergency room patients. Seroprevalence rates vary widely with the type of hospital studied, ranging from 0.24 percent among 26,275 patients in the CDC sentinel hospital study to 9.1 percent at St. Paul–Ramsey Medical Center. One can expect that hospital type, location, and specific hospital population will greatly affect HIV-seropositivity rates. According to a later CDC sentinel hospital study of 89,547 blood specimens from hospitalized patients, the overall seropositivity was 1.3 percent, but the HIV- seropositive rate of individual hospitals ranged from 0.1 to 7.8 percent.

Serologic Events

Patients infected with HIV develop viremia accompanied by a generalized lymphadenopathy, fever, and malaise. Approximately 6 to 12 weeks after infection, antibody to HIV develops. During this time the viral titer in blood decreases markedly from 10⁴/mL to 10 to 100/mL. A low virus titer persists until the patient develops AIDS approximately 7 to 9 years after infection. When AIDS develops, the virus titer rapidly increases to a level of 10⁴/mL. Serologic testing examines antibody to HIV, and seroconversion usually occurs within 12 weeks of infection but has been known to take as long as 6 months. During this period (“the window”) it is possible for patients to have circulating virus and to be potentially infectious to those around them and yet test negative for HIV. Other techniques, measuring viral antigen or using the polymerase chain reaction to look for viral nucleic acid, can detect HIV earlier.

Surgery in HIV-Infected Patients

While surgeons are not the primary caregivers for individuals with HIV infection and AIDS, patients with this infection may require operation for unrelated reasons, for diagnosis of an infection, or for treatment of surgical complications of AIDS. Patients with HIV infection and AIDS generally do not require any extra preoperative preparation. Malnutrition associated with HIV infection may require correction if time permits. Perioperative antimicrobial therapy is given for the same indications as for patients without HIV infection. These patients generally do not have difficulty with wound healing and do not have a higher rate of wound infections or other postoperative hospital-acquired infections. Drains and open wounds require precaution to avoid contamination with HIV-infected blood and other body fluids.

Patients with HIV infection may require surgery for the same reasons that anyone else might need an operation, or for problems related to their viral illness. These problems include peritonitis caused by bowel perforation, which occurs as a result of *CMV* infection; gastrointestinal obstruction as a result of Kaposi's sarcoma or lymphoma of the gastrointestinal tract; gastrointestinal hemorrhage due to *CMV*, lymphoma, or Kaposi's sarcoma; and (4) intraabdominal or retroperitoneal infection by mycobacterial and other opportunistic organisms.

HIV and AIDS in Health Care Workers

Over 7250 *health care workers (HCWs)* with AIDS have been reported to the CDC. There may be more than 50,000 health care workers infected with HIV, based on an estimate of eight persons infected with HIV for every person with AIDS. As of June, 1996 there have been 51 documented cases of HCWs who have acquired AIDS occupationally. There are 108 cases of possible occupationally acquired AIDS.

HCWs with AIDS comprise approximately 5 percent of the total number of patients with AIDS in the United States. HCWs as a whole comprise approximately 5.7 percent of the labor force in the United States. Most HCWs with AIDS are homosexual or bisexual men (Table [5-9](#)). Significantly fewer, however, are intravenous drug abusers. A relatively large “undetermined” category accounts for 5.9 percent of *HCWs* with AIDS; one-half of these patients can be classified under one of the other risk factors, one-fourth are dead or refused to be interviewed, and the remaining one-fourth are still being investigated.

As of June 30, 1997, 166 *HCWs* had developed HIV infection as a result of occupational exposure, most as a result of exposure to blood from HIV- infected patients. Of these, 52 had the occupationally acquired infection confirmed by being seronegative at the time of exposure and becoming seropositive after exposure. The remaining 114 *HCWs* did not have a blood specimen obtained at the time of exposure, but other risk factors were excluded. Most of the infected HCWs are nurses or technicians, and six are surgeons. There are probably other *HCWs* with occupationally acquired HIV infection who are not included in the CDC data set.

Risk of HIV Seroconversion in Health Care Workers

Many prospective studies have examined the actual risk of *HCWs* becoming infected with HIV after sustaining a percutaneous exposure to blood or blood-containing body fluids from patients with HIV infection. Of 1,948 *HCWs* in 12 reports who sustained a total of 1,051 mucous membrane exposures to blood or blood-containing body fluids from HIV-infected patients, six (0.29 percent per exposure) seroconverted. Risk of HIV infection is associated with deep injury, visible blood on the device, procedure involving a needle placed directly in a vein or artery, terminal illness in the source patient, and no postexposure use of zidovudine (AZT).

Surgeons are frequently exposed to patient's blood and other body fluids. Most exposures are to the skin, and their numbers can be minimized by wearing two pairs of gloves and face shields. Survey studies show that percutaneous injuries occur in 5.6 percent of operations, and 86 percent of surgeons report at least one percutaneous injury per year.

Prevention of Blood-Borne Infections in Health Care Workers

Beginning in 1983 the CDC began issuing guidelines designed to minimize the risk of transmission of HIV in the health care setting. In 1987 the CDC issued new guidelines, which have come to be called “universal precautions” (Table [5-10](#)). These guidelines have been updated and extended but not substantially altered. They are applicable to clinical and laboratory staffs, emergency service personnel, and health care workers performing invasive procedures as well as those who are not included in direct patient care (e.g., housekeeping personnel, kitchen staff, and laundry workers). Although universal precautions were issued to reduce the transmission of HIV in health care settings, they are also appropriate for reducing the transmission of other blood-borne viruses, including *hepatitis B virus (HBV)*, *hepatitis C virus (HCV)*, and the recently described *hepatitis G virus (HGV)*.

The intent of the CDC guidelines is that all patients should be regarded as potentially harboring blood-borne pathogens, because the medical history, physical examination, and laboratory testing cannot identify all patients infected with HIV or other blood-borne pathogens and because in emergencies there may be no time for testing patients. Since all patients should be treated alike—i.e., as if they potentially have a blood-borne infection—there is no need for testing patients; testing would not alter health care worker behavior.

Compliance with universal precautions has been examined in the emergency room and hospital environment. Compliance in a large inner-city hospital emergency room was found to be only 18 percent, and it fell to 5 percent if the patient was bleeding from an external injury. The rates of noncompliance with universal precautions are reported to be 74 percent in the surgical intensive care unit and 34 percent on the surgical wards. The noncompliance rate fell to 43 percent in the intensive care unit after an educational program about universal precautions, but it did not change on the surgical wards. Wong and associates found, however, that frequency of use of barrier precautions increased from 54 to 73 percent and blood exposures decreased after universal precautions were put into effect. Although the CDC can only suggest guidelines and has no regulatory authority, the Occupational Safety and Health Administration has made the CDC guidelines mandatory. Failure to adhere to universal precautions is not acceptable and is subject to sanctions.

Testing Patients for Blood-Borne Pathogens

The CDC does not recommend routine HIV testing of all patients. HIV testing of patients is recommended for management of health care workers who sustain parenteral or mucous membrane exposure to blood or other body fluids from a patient, for patient diagnosis and management, and for counseling associated with efforts to prevent and control HIV transmission in the community.

If hospitals, physicians, or health care agencies choose to perform HIV testing, the CDC advocates certain principles: (1) obtain patient consent for testing; (2) inform patients of results and provide counseling for seropositive patients; (3) ensure confidentiality; (4) ensure that seropositive patients will not receive compromised care; and (5) prospectively evaluate the efficacy of the program in reducing the incidence of exposure of health care workers to blood or other body fluids of patients who are infected with HIV. Most states have laws regulating testing of patients for HIV. Many of these laws require written informed consent of the patient with pretest and posttest counseling for both HIV-positive and HIV-negative patients.

Management of Health Care Workers Exposed to Patients' Blood and Other Body Fluids

The CDC and others have issued recommendations for the management of health care workers exposed to patient blood and other body fluids. Hospitals, physicians' offices, and other employers of health care workers should establish a systematic approach for managing adverse exposures that is consistent with CDC and Department of Labor guidelines and state laws. The Department of Labor and the CDC have published detailed employer responsibilities in protecting workers from acquisition of blood- borne diseases in the workplace. Employers should develop standard operating procedures for all activities having the potential for exposure and should provide an initial and periodic workers' education programs.

The CDC recommends that if an exposure occurs, a blood sample should be drawn after consent is obtained from the individual from whom the exposure occurred and tested for hepatitis B surface antigen (HB sAg) and antibody to HIV. Now that a serologic test is available for *HCV* the patient should also be tested for that virus (and probably also for *HGV* when testing becomes available). Local laws regarding consent for testing source individuals should be followed. Policies should be available for testing source individuals when consent cannot be obtained (e.g., an unconscious patient). Pretest counseling, posttest counseling, and referral for treatment, if appropriate, of the source individual should be provided.

HIV Postexposure Management

If a health care worker is exposed percutaneously or by a splash to the eye or mucous membrane from a patient who has HIV infection or AIDS or who refuses to be tested, the worker should be counseled regarding the risk of infection and be evaluated clinically and serologically for evidence of HIV infection as soon as possible after the exposure. The worker should be advised to report and seek medical evaluation for any acute febrile illness that occurs within 12 weeks after exposure. Following the initial test at the time of exposure, seronegative workers should be retested 6weeks, 12 weeks and 6 months after exposure to determine whether transmission has occurred. During this period the worker should refrain from blood or semen donation and should use appropriate protection during sexual intercourse. If the source individual is found to be seronegative, baseline testing of the exposed worker with follow-up 12 weeks later may be performed if desired or recommended by the health care provider.

AZT is used to treat patients with HIV infection and has been proposed as chemoprophylaxis to prevent occupational infection in health care workers. Postexposure AZT use by *HCWs* is associated with a lower risk of HIV transmission. The CDC now recommends that HCWs exposed to blood from HIV-infected individuals be treated with AZT and lamivudine (3TC). If the exposure is high-risk (a large volume of blood containing a high titer of HIV), the protease inhibitor indinavir should also be given. Prophylaxis should be given within 1 to 2 h of exposure. If the HIV status of the source patient is unknown, the use of postexposure prophylaxis should be decided on a case-by-case basis. A dilemma arises when the source individual refuses to be tested; some states permit testing blood specimens obtained for another purpose if a health care worker has been exposed to a patient's blood or other body fluid and the patient refuses testing.

AZT prophylaxis protocols generally advise administering 200 mg AZT every 4 h for 28 to 42 days. Some protocols skip the 4:00 a.m. dose. Since an exposure can occur anytime, AZT should be available 24 hours a day.

Transmission of Blood-Borne Pathogens from Health Care Workers to Patients

Blood-borne pathogens can also be transmitted from *HCWs* to patients. HIV, *HBV*, and *HCV* can potentially be transmitted to a patient during invasive procedures when a surgeon sustains a percutaneous injury with a needle or sharp instrument which then recontacts the patient. Only *HBV* and *HCV* have been demonstrated to be transmitted from physicians to patients. One dentist has transmitted HIV to six patients; the mechanism of transmission is unclear, however. There are no other reports of transmission of HIV from a health care worker to a patient. There are four reports following patients of surgeons with HIV infection. None of 767 serologically tested patients developed HIV infection as a result of being cared for by HIV-infected surgeons. None of more than 1000 patients of another surgeon who died of AIDS developed HIV infection. More than 9000 patients cared for by more than 75 health care workers with AIDS have been followed, and no cases of transmission by health care worker to patient have been reported. Approximately 60 of the 9000 patients were HIV-positive, but they were HIV-positive before being cared for by the health care worker, or they had other risk factors, or transmission from the health care worker was excluded.

Management of the HIV-, HBV-, or HCV-Infected Health Care Worker

The report of a dentist's having passed HIV to his patients sparked considerable discussion in the scientific and popular press about the HIV- positive health care worker, especially surgeons and dentists, since they are most likely to participate in invasive procedures. The CDC first issued guidelines for the management of HIV-infected personnel in 1985. It subsequently issued guidelines for management of HIV-infected *HCWs* who participate in invasive procedures. In its early guidelines the CDC recommended that health care personnel who are otherwise fit for duty and who do not participate in invasive procedures be allowed to perform their regular duties. In its subsequent guidelines the CDC recommended that HIV-infected personnel who do participate in invasive procedures be evaluated on a case-by-case basis. These recommendations were consolidated in 1987 with the suggestion that whether *HCWs* could perform their regular duties be decided on an individual basis.

After a dentist had been reported to have transmitted HIV to patients, the CDC issued another set of recommendations, suggesting that testing of *HCWs* for HIV or *HBV* not be required but that they should be tested voluntarily. (*HCV* testing was not yet commercially available and so was not mentioned in this set of recommendations.) *HCWs* who are infected with HIV or *HBV* should not perform “exposure-prone” procedures unless they have sought counsel from an expert panel; in addition, their patients should be informed of their seropositivity. The recommendations specify the composition of the panel but provide no guidelines on which the panel can base their decisions—and, in fact, defining “exposure-prone” procedures itself has met with resistance from the medical community.

ANTIMICROBIAL THERAPY

The use of antimicrobial agents in treating surgical infection does not differ fundamentally from antimicrobial usage in general medicine. The same basic considerations apply in treating all infections. One difference, however, is that antimicrobial therapy is only an adjunct in treating surgical infection; operative treatment (or percutaneous radiologically guided drainage of infected material) is more important. The goal of antimicrobial therapy is to prevent or treat infection by reducing or eliminating organisms until the host's own defenses can get rid of the last pathogens.

The basic considerations in antimicrobial therapy are efficacy, toxicity, and cost. Efficacy is the most important consideration in choosing an antimicrobial agent. Effective antimicrobial agents must be active against the pathogens causing the infection and must be able to reach the site of infection in adequate concentrations.

All antibiotics have potential toxicity. Toxic effects may be idiosyncratic, such as allergy or the rare instances of bone marrow aplasia caused by chloramphenicol. They can also cause damage to tissues and organs, such as in the renal toxicity or ototoxicity seen with the aminoglycosides or amphotericin B. Antimicrobial agents also exert selective pressures on the microbial ecology of the hospital that lead to resistant microbes, a problem that is especially important in intensive care units.

Cost is the final consideration in the selection of antimicrobial agents. Determining the costs of antimicrobial therapy includes more than just the cost of the drug. Drug administration charges, nursing time, intravenous fluid and lines, and monitoring costs must also be considered. In addition, any increased hospital time that occurs when an inexpensive agent that is less effective or that causes more toxicity is used ultimately makes that agent a more expensive antimicrobial.

Distribution of Antimicrobial Agents

Successful treatment of localized infections with systemic antimicrobial agents requires that an adequate concentration of drug be delivered to the site of infection. Ideally the tissue concentration of antibiotics should exceed the minimum inhibitory concentration. Tissue penetration depends in part on protein binding of antibiotics. Only the unbound form of antibiotics will pass through the capillary wall or act to inhibit bacterial growth. Therapeutic outcome, on the other hand, does not appear to be correlated with protein affinity, presumably because protein binding is easily reversible. Lipid solubility of antibiotics is also an important factor in tissue penetration. It determines the ability of antibiotics to pass through membranes by non- ionic diffusion or into wounds, bone, cerebrospinal fluid, the eye, endolymph of the ear, vegetations of bacterial endocarditis, and abscesses.

Blood

Rapidity of excretion and protein binding are two main determinants of blood concentration of antimicrobial agents. Protein binding affects the rapidity of excretion. Antibiotics that are highly protein bound are not excreted as rapidly as those with a low binding affinity and thus have longer half-lives. Therefore, highly protein-bound antibiotics generally do not have to be given as frequently as those with low protein binding. The efficacy of penicillins, cephalosporins, and other antibiotics that affect bacterial cell wall synthesis depends on the amount of time during which serum levels are above the minimum inhibitory concentrations rather than their peak serum concentration. The efficacy of aminoglycosides, on the other hand, is related to achieving peak serum concentrations that are four to eight times the minimum inhibitory concentration. Monitoring of serum aminoglycoside concentrations is usually necessary to ensure that these concentrations have been achieved; patients more commonly have subtherapeutic levels rather than toxic levels. In contrast, some antimicrobial agents such as nitrofurantoin and norfloxacin are excreted so rapidly in the urine that they never achieve blood (or tissue) levels sufficient to reach effective antibacterial concentrations. They do, however, reach high urinary concentrations and are effective agents for treating urinary tract infections.

Urine

Most commonly used antibiotics (sulfonamides, penicillins, cephalosporins, aminoglycosides, tetracyclines, quinolones, azoles) are excreted principally in the urine and achieve high urinary concentrations—up to 50 to 200 times their serum concentrations. Notable exceptions are erythromycin and chloramphenicol. Since concentrating ability is severely compromised in patients with renal disease, infections of the urinary tract are more difficult to treat in these patients. The pH of urine can be changed to facilitate antibiotic activity. For instance, aminoglycosides are more active in an alkaline medium, whereas other urinary antibacterial agents (tetracyclines, nitrofurantoin, methenamine mandelate) are more active in an acidic environment. Fortunately, the antimicrobials most commonly used to treat urinary tract infections have antimicrobial activity across a broad pH range.

Bile

Besides urine, only bile regularly has antibiotic concentrations higher than serum levels. The biliary concentrations of many of the penicillins (especially nafcillin, piperacillin, mezlocillin, and azlocillin), cephalosporins (especially cefazolin, cefamandole, ceforanide, cefoxitin, cefoperazone, and cefadroxil), tetracyclines, and clindamycin frequently are several times their serum concentrations. Nafcillin and rifampin achieve biliary concentrations 20 to 100 times those of serum. Aminoglycoside antibiotics enter bile less well, especially in the presence of liver disease, and their biliary concentrations are usually lower than serum levels.

Interstitial Fluid and Tissue

High, prolonged serum concentration and low protein binding favor diffusion of antibiotics from serum into extravascular tissue. Absolute tissue levels may not accurately reflect the therapeutic potential of the antibiotic, however, because the agent may be tightly bound to tissue and thus be unavailable for binding to bacteria.

Abscesses

There are few data of clinical relevance concerning the distribution of antibiotics into abscesses. The generalization that no antibiotics penetrate abscesses is not true. While the penicillins, cephalosporins, and some other antibiotics penetrate mature abscesses poorly, others such as metronidazole, chloramphenicol, and clindamycin can achieve inhibitory concentrations in abscesses.

A separate problem is whether, after penetration, an antibiotic can retain its antimicrobial efficacy under the conditions that exist in an abscess. The acidic pH, the low oxidation-reduction potential, and the large numbers of microbial and tissue products that can bind antibiotics all serve to reduce antimicrobial efficacy. Multiple types of bacteria within an abscess make it more likely that one type will inactivate an agent effective against it or another bacterium. The lack of efficacy of penicillins and cephalosporins in treating most abscesses may be a result of the high concentrations of beta-lactamases that accumulate there. Metronidazole and clindamycin can enter abscesses and retain antibacterial activity, but they are not effective against the aerobic gram-negative bacteria that are usually present together with the anaerobic bacteria against which they are effective—so the abscess usually persists.

An additional reason that antibiotics alone are seldom effective in treating abscesses is that antibiotics are most effective against actively metabolizing, rapidly dividing bacteria. Conditions in abscesses are usually unfavorable for bacterial growth, so the antibiotic is not able to enter and be active against the bacteria.

For all these reasons antibiotics alone should not be relied on for the treatment of most abscesses. Despite occasional reports of success with such treatment, drainage remains the mainstay of treating abscess.

Use of Antibiotics in Surgery

Prophylactic Antibiotics

Antibiotics are frequently administered prophylactically to patients undergoing operation to prevent wound infection when the likelihood of infection is high (e.g., when the tissues have been exposed to bacteria such as occurs during colon surgery) or when the consequences of infection are great even though the risk of infection is low (e.g., when a prosthetic device is implanted). The use of prophylactic antibiotics to prevent wound infection was discussed earlier in the section Wound Infection. Antibiotic prophylaxis should be administered to patients with previously placed prosthetic devices such as cardiac valves or artificial joints who are having any operation or dental procedure.

Therapeutic Use of Antibiotics

Many infections can be successfully treated with oral antibiotics on an outpatient basis. Severe surgical infections should be treated with intravenous antibiotics. Initial antibiotic therapy is usually empiric, since it should not be postponed until microbiotic studies are complete (Table 5-11). Antibiotic therapy should generally be initiated before cultures are obtained in patients with peritonitis, abscesses, and necrotizing soft tissue infections. Since cultures are usually obtained promptly during operative procedures or when percutaneous drainage has been performed, it is unlikely that prior antibiotic therapy will affect culture results.

Empiric Therapy

Rational empiric antibiotic therapy requires familiarity with the microbes most likely to cause infection at the involved site and antibiotic susceptibility patterns in the hospital or unit (e.g., intensive care unit). Intraabdominal surgical infections are nearly always caused by mixed gram- negative and gram-positive aerobic and anaerobic bacteria. Initial antibiotic therapy should provide broad-spectrum activity against these bacteria.

Most necrotizing soft tissue infections, especially those originating after an intraabdominal operation or occurring below the waist, are also due to a mixed bacterial flora, and broad-spectrum empiric therapy should be initiated. Because clostridia or streptococci can also cause these infections, penicillin G should generally be included. Once Gram stain and culture results are available, antibiotic therapy can be modified.

Prosthetic device infections usually progress much more slowly than intraabdominal or necrotizing soft tissue infections. Gram-positive cocci, especially *Staph. aureus* and *S. epidermidis*, play a prominent role in these infections, but they can also be caused by gram-negative bacteria.

Numerous single and combination antimicrobials are available for initial and empiric therapy. The Surgical Infection Society (SIS) has made recommendations for use of antimicrobial agents for empiric therapy of intraabdominal infections. The SIS recommends against using drugs such as cefazolin and other first-generation cephalosporins, penicillin, cloxacillin and other antistaphylococcal penicillins, ampicillin, erythromycin, and vancomycin because these drugs do not provide adequate coverage for both aerobic and anaerobic organisms.

Metronidazole and clindamycin should not be used as single agents for mixed infection, because they lack activity against aerobic enteric organisms. Other antibiotics, such as aminoglycosides, aztreonam, cefuroxime, cefonicid, cefamandole, ceforanide, cefotetan, cefotaxime, ceftizoxime, cefoperazone, ceftriaxone, ceftazidime, and polymyxin should not be used alone because of the inadequate coverage of anaerobic gram- negative bacilli. Because of inadequate clinical data documenting efficacy and concerns about resistance, the SIS also recommends against using as single agents for empiric therapy antibiotics such as piperacillin, mezlocillin, azlocillin, ticarcillin, and carbenicillin despite their relative safety and broad in vitro antibacterial activity. Chloramphenicol has an appropriate in vitro spectrum of activity but is not acceptable because it can produce serious side effects.

Acceptable agents for community-acquired intraabdominal infections include cefoxitin, cefotetan, cefmetazole, and ticarcillin/clavulanic acid. However, these antibiotics should not be used for patients whose abdominal infection develops in the hospital after previous antibiotic therapy. For these infections and serious intraabdominal infections antibiotics such as imipenem-cilastatin (Primaxin) should be used. Combination therapy such as metronidazole or clindamycin plus an aminoglycoside or an antianaerobic antibacterial agent plus a third-generation cephalosporin or clindamycin plus a monobactam is acceptable. Cost and toxicity considerations can make one of these recommendations preferable to the others. The combination of an antianaerobic antibiotic plus an aminoglycoside plus penicillin or ampicillin is recommended only if enterococcal infection is suspected on the basis of a Gram stain or thought to be clinically relevant (e.g., associated with enterococcus bacteremia). Community-acquired intraabdominal infections are seldom associated with serious enterococcus infection.

Definitive Therapy

Antimicrobial therapy may have to be altered when the results of Gram stain, culture, and sensitivity data are available (Table 5-12). Sensitivity data may determine that one of the antibiotics currently being used is not active against one of the bacteria isolated. In addition, change to a less toxic or less costly antimicrobial agent may be possible once laboratory results are available.

Infections originating in the intensive care unit are frequently caused by antibiotic-resistant bacteria. This is especially true for hospital-acquired *Staph. aureus*, which is frequently resistant to methicillin. For hospital- acquired staphylococcal infections vancomycin should generally be initiated if methicillin-resistant *Staph. aureus* is a problem in the hospital until definitive sensitivity data are available. If the *Staph. aureus* is sensitive to penicillin G or methicillin, these agents should be used because they are more effective and less costly than vancomycin. Two drugs are generally used to treat *P. aeruginosa* infections, an antipseudomonal beta-lactam drug such as mezlocillin or ceftazidime in combination with an aminoglycoside, in an attempt to prevent development of resistance and to take advantage of possible synergism.

Drug Administration

Route

For seriously ill surgical patients the antimicrobial agent should be administered intravenously to ensure adequate serum levels. Absorption by other routes is inconsistent in seriously ill patients whose gastrointestinal tract is not functioning properly and who have problems maintaining blood pressure. If patients need prolonged antimicrobial therapy, other routes can be used once they have begun to recover, or long-term intravenous antimicrobial therapy can be given on an outpatient basis.

Recommendations provided by the manufacturer should be used as guidelines for appropriate doses of antimicrobial agents. In general there is a wide margin between therapeutic and toxic concentrations with drugs such as the penicillins and cephalosporins. Other agents, such as the aminoglycosides, have a much narrower margin between therapeutic and toxic levels. For these antibiotics the calculated dose in adults is based on lean body weight. For children, antibody dosing is frequently based on surface area.

Duration

There are few data defining the appropriate duration of antibiotic treatment. Most surgical infections can be treated effectively in 5 to 7 days of antibiotic therapy. It is generally safe to stop antibiotics as long as the patient is making clinical progress and has a normal temperature and white blood cell count, and gastrointestinal function has returned in patients with peritonitis. If clinical improvement is not evident within 4 to 5 days after operation and fever or leukocytosis persists after more than 5 days of therapy, a reason for the apparent treatment failure should be sought.

Treatment Failure

Although failure of a bacterial infection to respond to a particular antibiotic is commonly regarded as evidence that the wrong antibiotic was selected, usually other factors are responsible. Patients with intraabdominal infections who remain febrile or have persistent leukocytosis usually have recurrent (tertiary) peritonitis or an intraabdominal abscess that requires drainage. Patients with necrotizing soft tissue infections may have persistent infections. Other causes of fever such as pneumonia, urinary tract infection, vascular catheter-related infections, drug fever, and thrombophlebitis should be investigated.

Finally, the antibiotic may be inappropriate. It may be the wrong antibiotic, or it may have been given in an inadequate dose or by an inappropriate route. The bacteria may not be susceptible to the antibiotic at the concentration achievable at the site of infection, or the site may have become superinfected by another bacterium not sensitive to the antibiotic.

Drug Toxicity

Normally antibiotics are excreted primarily by the kidneys and accumulate in the serum of patients with impaired renal function. Therefore, with many antibiotics it is necessary to reduce the dose or to increase the interval between doses in patients with renal failure (there are many schedules that detail how to estimate dosages of antibiotics strongly excreted by the kidneys, but none of them is perfect). Toxic drugs such as the aminoglycosides should either not be used in patients with renal failure or impaired renal function, or, if used, their serum or plasma concentrations must be obtained frequently to verify that toxic levels are not being reached.

The general approach to antibiotic usage in patients with renal failure is to give a first dose of 80 to 100 percent of the usual amount and then to estimate the timing and the amount of the second dose according to various schedules based on the normal half-life of the antibiotic.

Immunotherapy and Biologic Therapy of Infection

Antibodies to bacterial products and to mediators of sepsis are new (and extremely costly) therapeutic modalities that are currently being evaluated. Results thus far have been disappointing. There are no currently approved immunotherapeutic agents for treating infections. A previously approved anti-endotoxin antibody (HA-1A) has been taken off the market.

Other molecules or antagonists of molecules of the inflammatory or septic response are being investigated in the laboratory or undergoing clinical trials. Although none is currently available for clinical use, they may prove to be efficacious in the future.

CHAPTER 6 - Trauma

Jon M. Burch
Reginald J. Franciose
Ernest E. Moore

Trauma or injury has been defined as damage to the body caused by an exchange with environmental energy that is beyond the body's resilience. Trauma remains the most common cause of death for individuals between the ages of 1 and 44 years, and the third most common cause of death for all ages. The U.S. government classifies accidental death under the following categories: accidents and adverse effects; suicide, homicide, and legal intervention; and all other external causes. Accidents and adverse effects account for approximately 100,000 deaths per year, of which motor vehicle accidents account for nearly 50 percent. Homicides, suicides, and other causes are responsible for another 50,000 deaths each year. Death rates are a poor indicator of the magnitude of the problem, however, because most injured patients survive. For example, in 1985 there were approximately 140,000 trauma-related deaths, but 57 million reported injuries and 23 million hospitalizations. For the same year the aggregate lifetime costs for all injured patients was estimated to be \$158 billion. Trauma is a major public health issue.

INITIAL EVALUATION AND RESUSCITATION OF THE INJURED PATIENT

Treatment of trauma patients often begins in the field by *emergency medical services (EMS)* personnel and completed by rehabilitation specialists. Although the Advanced Trauma Life Support (ATLS) course of the American College of Surgeons Committee on Trauma is directed at primary care physicians in rural communities, its format and basic tenets are sound for all physicians. The initial treatment of seriously injured patients consists of a primary survey, resuscitation, secondary survey, diagnostic evaluation, and definitive care. The concepts are presented in a sequential fashion, but in reality they often proceed simultaneously. The process begins with the identification and treatment of conditions that constitute an immediate threat to life. The ATLS course refers to this as the primary survey or the ABCs- Airway, with cervical spine protection, Breathing, and Circulation. Any life-threatening problem identified in the initial survey must be treated before advancing.

Airway Management

Ensuring an adequate airway is the first priority in the primary survey. Efforts to restore cardiovascular integrity will be futile if the oxygen content of the blood is inadequate. Simultaneously, all blunt-trauma patients require cervical spine immobilization until injury is ruled out. This can be accomplished with a hard (Philadelphia) collar or sandbags on both sides of the head taped to the backboard. Soft collars do not immobilize the cervical spine.

Patients who are conscious and have a normal voice do not require further evaluation or early attention to their airway. Exceptions to this principle include patients with penetrating injuries to the neck and an expanding hematoma, evidence of chemical or thermal injury to the mouth, nares, or hypopharynx, extensive subcutaneous air in the neck, complex maxillofacial trauma, or airway bleeding. These patients initially may have a satisfactory airway, but it may become obstructed if soft tissue swelling or edema progresses. In these cases, elective intubation should be performed before evidence of airway compromise is apparent.

Patients who have an abnormal voice or altered mental status require further airway evaluation. Direct laryngoscopic inspection often reveals blood, vomit, the tongue, foreign objects, or soft tissue swelling as sources of airway obstruction. Suctioning can offer immediate relief in many patients. Altered mental status is the most common indication for intubation because of the patient's inability to protect the airway. Options for airway access include nasotracheal, orotracheal, or operative intervention. Nasotracheal intubation can be accomplished only in patients who are breathing spontaneously and is contraindicated in the apneic patient. Although nasotracheal intubation frequently is used by paramedics in the field, the primary use for this technique in the emergency room is becoming limited to those few patients requiring emergent airway support who are prohibitive candidates for paralyzation.

Orotracheal intubation also can be performed in patients with potential cervical spine injuries provided that manual in-line cervical immobilization is maintained. The advantages of orotracheal intubation are the direct visualization of the vocal cords, the ability to use larger-diameter endotracheal tubes, applicability to apneic patients, and its familiarity to most physicians. The disadvantage of orotracheal intubation is that conscious patients usually require neuromuscular blockade or deep sedation. To a large extent, rapid-sequence induction of anesthesia with orotracheal intubation has become the standard in experienced trauma centers with the availability of pulse oximetry. The major advantage is rapid, definitive airway control. The disadvantages include the inability to intubate, aspiration, and complications of the required medications. Those who attempt rapid-sequence induction must be thoroughly familiar with the details and contraindications of the procedure.

Patients in whom attempts at intubation have failed or are precluded because of extensive facial injuries require a surgical airway. Cricothyroidotomy (Fig. 6-1) and percutaneous transtracheal ventilation are preferred over tracheostomy in most emergency situations because of their simplicity and safety. One disadvantage of cricothyroidotomy is the inability to place a tube greater than 6 mm in diameter because of the limited aperture of the cricothyroid space. Cricothyroidotomy also is contraindicated in patients under the age of twelve because of the risk of damage to the cricoid cartilage and the subsequent risk of subglottic stenosis.

Percutaneous transtracheal ventilation is accomplished by inserting a large-bore intravenous catheter through the cricothyroid membrane into the trachea and attaching it with tubing to an oxygen source capable of delivering 50 psi or more. A hole cut in the tubing allows for intermittent ventilation by occluding and releasing the hole. Adequate oxygenation can be maintained for more than 30 min. Because exhalation occurs passively, ventilation is limited and carbon dioxide retention can occur. Emergent tracheostomy has fallen into disfavor because of its technical difficulties; it may be necessary in cases of laryngotracheal separation or laryngeal fractures when cricothyroidotomy might cause further damage or result in the complete loss of the airway.

Breathing

Once a secure airway is obtained, adequate oxygenation and ventilation must be assured. All injured patients should receive supplemental oxygen therapy and be monitored by pulse oximetry. The following conditions may constitute an immediate threat to life because of inadequate ventilation: (1) tension pneumothorax, (2) open pneumothorax, or (3) flail chest/pulmonary contusion. These diagnoses can be made with a combination of physical examination and chest x-ray.

The diagnosis of tension pneumothorax is implied by the finding of respiratory distress in combination with any of the following physical signs: tracheal deviation away from the affected side; lack of or decreased breath sounds on the affected side; distended neck veins or systemic hypotension; or subcutaneous emphysema on the affected side. Immediate tube thoracostomy is indicated without awaiting chest x-ray confirmation (Fig. 6-2). In tension pneumothorax the collapsed lung acts as a one-way valve so that each inhalation allows additional air to accumulate in the pleural space. The normal negative intrapleural pressure becomes positive, depressing the ipsilateral hemidiaphragm and forcing the mediastinal structures into the contralateral chest. The contralateral lung is then compressed, and the heart is rotated about the superior and inferior venae cavae, decreasing venous return and cardiac output while distending the neck veins. An unrecognized simple pneumothorax can be converted to a tension pneumothorax if the patient is placed on a positive-pressure mechanical ventilator. A tension pneumothorax also can develop in a patient who is breathing spontaneously.

An open pneumothorax or sucking chest wound occurs with full-thickness loss of the chest wall, permitting a free communication between the pleural space and the atmosphere. This compromises ventilation by two mechanisms. In addition to collapse of the lung on the injured side, if the diameter of the injury is greater than the narrowest portion of the upper airway, air preferentially moves through the injury site rather than the trachea and impairs ventilation on the contralateral side. Occlusion of the injury may result in converting an open pneumothorax into a tension pneumothorax. Proper treatment in the field involves placing an occlusive dressing over the wound, which is taped on three sides. The occlusive dressing permits effective ventilation on inspiration while the untaped side allows accumulated air to escape from the pleural space, preventing a tension pneumothorax. Definitive treatment requires wound closure and tube thoracostomy.

Flail chest occurs when four or more ribs are fractured in at least two locations. Paradoxical movement of this free-floating segment of chest wall may be sufficient to compromise ventilation. It is of greater physiologic importance that patients with flail chest frequently have an underlying pulmonary contusion. Pulmonary contusion with or without rib fractures may compromise oxygenation or ventilation to the extent that intubation and mechanical ventilation is required. Respiratory failure in these patients may not be immediate, and frequent reevaluation is warranted. The initial chest x-ray usually underestimates the degree of pulmonary contusion, and the lesion tends to evolve with time and fluid resuscitation.

Circulation

With a secure airway and adequate ventilation established, circulatory status is determined. A rough first approximation of the patient's cardiovascular status is obtained by palpating peripheral pulses. A systolic blood pressure of 60 mmHg is required for the carotid pulse to be palpable, 70 mmHg for the femoral pulse and 80 mmHg for the radial pulse. At this point in the patient's treatment, hypotension is assumed to be caused by hemorrhage. Blood pressure and pulse should be measured at least every 15 min.

External control of hemorrhage should be obtained before restoring circulating volume. Manual compression and splints frequently control extremity hemorrhage as effectively as tourniquets and with less tissue damage. Blind clamping should be avoided because of the risk to adjacent structures, particularly nerves. The importance of digital control of hemorrhage for penetrating injuries of the head, neck, thoracic outlet, groin, and extremities cannot be overemphasized. This should be done with a gloved finger placed through the wound directly on the bleeding vessel applying only enough pressure to control active bleeding. The surgeon performing this maneuver must then walk along beside the patient on the way to the operating room for definitive treatment. Scalp lacerations through the galea aponeurotica tend to bleed profusely; these can be temporarily controlled with Rainey clips or a full-thickness large nylon continuous stitch.

Intravenous access for fluid resuscitation is begun with two peripheral catheters, 16-gauge or larger in an adult. Blood should be drawn simultaneously and sent for typing and hematocrit measurement. Because the flow of liquid through a tube is proportional to diameter and inversely proportional to length, venous lines for volume resuscitation should be short with a large diameter. For patients requiring vigorous fluid resuscitation, saphenous vein cutdowns at the ankle (Fig. 6-3) or percutaneous femoral vein catheter introducers are preferred. The saphenous vein is reliably found 1 cm anterior and 1 cm superior to the medial malleolus. Short 10-gauge catheters can be quickly placed even in an exsanguinating patient with collapsed veins. Venous access in the lower extremities provides effective volume resuscitation in cases of abdominal venous injury, including the inferior vena cava. Jugular and subclavian central venous introducers are less desirable for initial access in trauma patients because placement can interfere with the work of staff members performing other lifesaving procedures. Secondary central venous introducers should be placed in the operating room in the event that vena caval cross-clamping is performed.

In hypovolemic pediatric patients less than 6 years of age, percutaneous femoral vein cannulation is contraindicated because of the risk of venous thrombosis. If two attempts at percutaneous peripheral access are unsuccessful, interosseous cannulation should be performed in the proximal tibia, or in the distal femur if the tibia is fractured (Fig. 6-4). This is a safe emergency technique; however, once alternative access has been established, the cannula should be removed because of the risk of osteomyelitis.

Initial Fluid Resuscitation

Initial fluid resuscitation is a 1-L intravenous bolus of normal saline, lactated Ringer's solution, or other isotonic crystalloid in an adult, or 20 mL/kg of body weight lactated Ringer's solution in a child. In the United States crystalloid alone is used, whereas in other parts of the world colloid is often added. This is repeated once in an adult and twice in a child before administering red blood cells. The goal of fluid resuscitation is to reestablish tissue perfusion. Classic signs and symptoms of shock are tachycardia, hypotension, tachypnea, mental status changes, diaphoresis, and pallor. None of these signs or symptoms taken alone can predict the patient's organ perfusion status, but when viewed together they can help in evaluating the patient's response to treatment. Patients who have a good response to fluid infusion, i.e., normalization of vital signs, clearing of the sensorium, evidence of good peripheral perfusion (warm fingers and toes with normal capillary refill) are presumed to have adequate perfusion.

There are several caveats to keep in mind when making this presumption. Although tachycardia may be the earliest sign of ongoing blood loss, individuals in good physical condition, particularly trained athletes with a low resting pulse rate, may manifest only a relative tachycardia. Patients on beta-blocking medications may not be able to increase their heart rate in response to stress. In children, bradycardia or relative bradycardia can occur with severe blood loss and is an ominous sign, often heralding cardiovascular collapse. Conversely, hypoxia, pain, apprehension, and stimulant drugs (e.g., cocaine, amphetamines) produce a tachycardia unrelated to physiologic demands. Hypotension is not a reliable early sign of hypovolemia. In healthy patients blood volume must decrease by 30 to 40 percent before hypotension occurs (Table 6-1). Younger patients with good sympathetic tone can maintain systemic blood pressure with severe intravascular deficits until they are on the verge of cardiac arrest. In contrast, pregnancy increases circulating blood volume, and a relatively larger volume of blood loss must occur before signs and symptoms become apparent.

Acute changes in mental status can be caused by hypoxia, hypercarbia, or hypovolemia, or they may be an early sign of increasing intracranial pressure (ICP). An abnormal mental status should prompt an immediate reevaluation of the ABCs and consideration of an evolving central nervous system injury. A deterioration in mental status may be subtle and may not progress in a predictable fashion; for example, a previously calm and cooperative patient may become anxious and combative as hypoxia develops, or a patient who is agitated and combative from drugs or alcohol may become somnolent if hypovolemic shock develops. Urine output is a quantitative and relatively reliable indicator of organ perfusion. Adequate urine output is 0.5 mL/kg/h in an adult, 1 mL/kg/h in a child, and 2 mL/kg/h in an infant less than 1 year of age.

On the basis of the initial response to fluid resuscitation, hypovolemic injured patients may be placed into three broad categories: responders, transient responders, and nonresponders. Individuals who are stable or have a good response to the initial fluid therapy as evidenced by normalization of vital signs, mental status, and urine output are unlikely to have significant continuing hemorrhage, and further diagnostic evaluation for occult injuries can proceed. At the other end of the spectrum are nonresponders with persistent hypotension. This group requires immediate diagnosis and treatment to prevent a fatal outcome. Patients who respond transiently and then deteriorate present the most complex decision-making challenge. They usually are underresuscitated or have ongoing hemorrhage. In patients with penetrating trauma, the need for operative intervention for the control of hemorrhage usually is evident. Blunt trauma patients with multisystem injury, however, require careful planning. It is in this group that the greatest number of preventable deaths is likely to occur.

Persistent Hypotension Nonresponders

The spectrum of disease in this category ranges from nonsurvivable multisystem injury to problems as simple as a tension pneumothorax. Persistent hypotension in these patients usually is cardiogenic or a result of uncontrolled hemorrhage. An evaluation of the patient's neck veins and *central venous pressure (CVP)* usually distinguishes between these two categories. CVP determines right ventricular preload; in otherwise healthy trauma patients, its measurement yields objective information regarding the patient's overall volume status. Central venous catheters are inappropriate for administering large volumes of fluid, but they are valuable for measuring CVP. A hypotensive patient with flat neck veins and a CVP less than 5 cmH₂O is hypovolemic and is likely to have ongoing hemorrhage. A hypotensive patient with distended neck veins or a CVP more than 15 cmH₂O is likely to be in cardiogenic shock. The CVP may be falsely elevated if the patient is agitated and straining or fluid administration is overzealous; isolated readings must be interpreted with caution.

In trauma patients the differential diagnosis of cardiogenic shock is indicated by: (1) tension pneumothorax, (2) pericardial tamponade, (3) myocardial contusion or infarction, and (4) air embolism. Tension pneumothorax is the most frequent cause of cardiac failure. Traumatic pericardial tamponade is most often associated with penetrating injury to the heart. As blood leaks out of the injured heart, it accumulates in the pericardial sac. Because the pericardium is not acutely distensible, the pressure in the pericardial sac rises to match that of the injured chamber. This pressure usually is greater than that of the right atrium; right atrial filling is impaired, and right ventricular preload is reduced. This leads to decreased right ventricular output and increased CVP. Increased intrapericardial pressure also impedes myocardial blood flow, which leads to subendocardial ischemia and a further reduction in cardiac output. This cycle may progress insidiously with injury of the venae cavae or atria, or precipitously with injury of either ventricle. With acute tamponade, as little as 100 mL of blood within the pericardial sac can produce life-threatening hemodynamic compromise. The usual presentation is a patient with a penetrating injury in proximity to the heart who is hypotensive and has distended neck veins or an elevated CVP. The classic findings of Beck's triad (hypotension, distended neck veins, and muffled heart sounds) and pulsus paradoxus are not reliable indicators of acute tamponade. Ultrasound imaging in the emergency room using a subxiphoid or parasternal view is extremely helpful if the findings are clearly positive (Fig. 6-5), but equivocal findings are common. Early in the course of tamponade, blood pressure and cardiac output transiently improve with fluid administration, which may lead the surgeon to question the diagnosis—or lull the surgeon into a false sense of security.

Once the diagnosis of cardiac tamponade is established, pericardiocentesis should be performed (Fig. 6-6). Evacuation of as little as 15 to 25 mL of blood can dramatically improve the patient's hemodynamic profile. Pericardiocentesis should be done even if the patient stabilizes with volume loading because subclinical myocardial ischemia can lead to sudden lethal arrhythmias, and patients with tamponade can decompensate unpredictably. While pericardiocentesis is being performed, preparation should be made for emergent transport to the operating room. Emergent pericardiocentesis is successful in decompressing the tamponade in approximately 80 percent of cases; most failures are a result of clotted blood within the pericardium. If pericardiocentesis is unsuccessful and the patient remains severely hypotensive (systolic blood pressure <70 mmHg) or shows other signs of hemodynamic instability, emergency room thoracotomy should be performed (Fig. 6-7). This is best accomplished using a left anterolateral thoracotomy and a longitudinal pericardiotomy anterior to the phrenic nerve, followed by evacuation of the pericardial sac and temporary control of the cardiac injury. The patient is then transported to the operating room for definitive repair (Fig. 6-8).

Myocardial contusion from direct myocardial impact occurs in approximately one-third of patients sustaining significant blunt chest trauma. The diagnostic criteria for myocardial contusion include specific electrocardiogram abnormalities, i.e., ventricular dysrhythmias, atrial fibrillation, sinus bradycardia, and bundle branch block. Transient sinus tachycardia is not indicative of contusion. Serial cardiac enzyme determinations (CPK-MB fraction) lack sensitivity and are not predictive of complications under these conditions, and they are not recommended. While the diagnosis is common, acute life-threatening complications of ventricular arrhythmias and cardiac pump failure occur in less than 5 percent and less than 1 percent, respectively, of patients sustaining major blunt chest trauma. Arrhythmias are treated by pharmacologic suppression. The management of cardiogenic shock from cardiac pump failure includes early placement of a Swan-Ganz pulmonary artery catheter to optimize fluid administration, inotropic support, and urgent echocardiography to rule out septal or free wall rupture, valvular disruption, or pericardial tamponade. Patients with refractory cardiogenic shock might require placement of an intraaortic balloon pump to decrease myocardial work and enhance coronary perfusion.

Acute myocardial infarction is itself frequently the cause of motor vehicle accidents or other trauma in older patients. While the ideal initial management is to provide optimal treatment for the evolving infarction, decisions regarding lytic therapy and emergent angioplasty must be individualized according to the patient's other injuries.

Air embolism is a frequently overlooked lethal complication of pulmonary injury. It occurs when air from an injured bronchus enters an adjacent injured pulmonary vein and returns to the left heart. Air accumulation in the left ventricle impedes diastolic filling, and during systole it is pumped into the coronary arteries, disrupting coronary perfusion. The typical scenario is a patient with a penetrating chest injury who appears hemodynamically stable but suddenly goes into cardiac arrest after being intubated and placed on positive-pressure ventilation. Air emboli also have been described in conjunction with blunt thoracic trauma and can occur at any time when a pulmonary venous injury is being manipulated. The patient should be placed in the Trendelenburg position to trap the air in the apex of the left ventricle. Emergency thoracotomy is followed by cross-clamping the pulmonary hilum on the side of the injury to prevent further introduction of air. Air is aspirated from the apex of the left ventricle with an 18-gauge needle and 50-mL syringe. Vigorous open cardiac massage is used to force the air bubbles through the coronary arteries. The highest point of the aortic root also is aspirated to prevent air from entering the coronary arteries or embolizing to the brain. The patient should be kept in the Trendelenburg position and the hilum clamped until the pulmonary venous injury is controlled.

A state of persistent hypotension and flat neck veins resulting from uncontrolled hemorrhage is associated with a high mortality. A rapid search for the source or sources of hemorrhage, including visual inspection with knowledge of the injury mechanism, abdominal ultrasound imaging, anteroposterior chest and pelvic x-rays, usually indicates the regions of the body responsible for the blood loss. Type O red blood cells (O-negative for women of childbearing age) or type-specific red blood cells should be administered and the patient taken directly to the operating room for exploration. For patients with a sustained systolic blood pressure of less than 70 mmHg, in spite of crystalloid and blood administration, emergency room thoracotomy should be considered. The clearest indication for this procedure is penetrating chest trauma, and survival is reported as high as 30 percent. A small number of patients with penetrating abdominal trauma survive, but the role of emergency room thoracotomy in blunt abdominal trauma is controversial. The goal of emergency room thoracotomy for thoracic injuries is control of hemorrhage; for abdominal injuries the goal is to sustain central circulation and limit abdominal blood loss by clamping the descending thoracic aorta. Every effort should be made to replace the aortic clamp to below the renal arteries within 30 min. Longer clamping times proximal to the abdominal viscera are seldom associated with survival. The decision to perform an emergency room thoracotomy can be assisted by use of the algorithm in Fig. 6-9.

Transient Responders

Hypotensive patients who transiently respond to fluid administration usually have some degree of active hemorrhage. Those with penetrating injuries should be taken to the operating room for exploration. Those with multiple blunt injuries constitute a diagnostic and therapeutic dilemma. These patients often require sophisticated evaluation such as computed tomography (CT) and angiography. It is during these diagnostic evaluations and the necessary transportation that the greatest hazard exists, because monitoring is compromised and the environment is suboptimal for dealing with acute problems. The surgeon must accompany the patient and be prepared to abort the examination if hypotension recurs. If it does, the patient should be given type-specific red blood cells and transported immediately to the operating room to localize the hemorrhage. An operating room should be immediately available when these patients arrive in the emergency room.

The traditional volume resuscitation (described above) of patients sustaining penetrating torso trauma has been questioned. It has been assumed that any hypotension is dangerous and must be treated, preferably with blood or crystalloid, but some have argued that hemostatic mechanisms frequently control hemorrhage initially, and increased venous and subsequent arterial pressure from fluid resuscitation can disrupt tenuous hemostasis. Furthermore, active bleeding increases as venous and arterial pressure increases. Laboratory studies support these concepts. In a prospective randomized study of hypotensive patients who sustained penetrating torso trauma and required operative treatment, half the patients received volume resuscitation and fluid was withheld in the others until the operation was begun, but there was no survival advantage for those resuscitated in the traditional fashion. Subgroup analysis suggested a survival disadvantage for pericardial tamponade. Patients with profound hypotension (systolic blood pressure <70 mmHg) are at risk for sudden death. Controlled hypotension is the optimal middle ground.

Secondary Survey

When the conditions that constitute an immediate threat to life have been attended to or excluded, the patient is examined in a systematic fashion to identify occult injuries. Special

attention should be given to the patient's back, axillae, and perineum because injuries in these areas are easily overlooked. Patients should undergo digital rectal examination to evaluate sphincter tone and to look for blood, perforation, or a high-riding prostate. A Foley catheter should be inserted to decompress the bladder, obtain a urine specimen, and monitor urine output. Stable patients at risk for urethral injury should undergo urethrography before catheterization. Signs of urethral injury include blood at the meatus, perineal or scrotal hematomas, or a high-riding prostate. In the case of persistent hypovolemic shock, an initial attempt at a Foley catheterization should be made; if this is unsuccessful, a percutaneous suprapubic cystostomy should be placed. A nasogastric tube should be inserted to decrease the risk of gastric aspiration and allow inspection of the contents for blood suggestive of occult gastroduodenal injury.

Selective radiographs are obtained early in the emergency room evaluation. For patients with severe blunt trauma, anteroposterior chest and pelvic radiographs should be obtained as soon as possible. For patients with truncal gunshot wounds, posteroanterior and lateral radiographs of the chest and abdomen are warranted. It is helpful to mark the entrance and exit sites of penetrating wounds with metallic clips or staples so that the trajectory of the missile or blade can be estimated.

Many trauma patients cannot provide specific information about the nature of their injury mechanism. Emergency medical personnel and police are trained to evaluate an injury scene and should be questioned. For automobile accidents the speed of the accident, the angle of impact (if any), the use of restraints, airbag deployment, condition of the steering wheel and windshield, the amount of intrusion, whether the patient was ejected from the vehicle, and whether anyone was dead at the scene should all be ascertained. The patient's physiologic condition in the field also is important. Vital signs and mental status in the emergency room can be compared with those at the scene; improvement or deterioration provide critical prognostic information.

Mechanisms and Patterns of Injury

Evaluation and decision making are far more difficult in blunt trauma than in penetrating trauma. More energy is transferred over a wider area during blunt trauma than from a gunshot wound or a stab wound. As a result, blunt trauma is associated with multiple, widely distributed injuries, whereas in penetrating injuries the damage is localized to the path of the bullet or knife in penetrating wounds. Patients who have sustained blunt trauma are separated into categories according to their risk for multiple injuries, high energy transfer and low energy transfer. Injuries involving high energy transfer include auto-pedestrian accidents, motor vehicle accidents in which the car's change of speed exceeds 20 mph or in which the patient has been ejected, motorcycle accidents, and falls from heights greater than 20 feet. The greatest risk factors reflecting magnitude of injury from the field associated with life-threatening injuries are death of another occupant in the vehicle and an extrication time greater than 20 min.

Patients who have sustained high-energy-transfer trauma have certain patterns of injury related to the mechanism, e.g., when unrestrained drivers suffer frontal impacts, their heads strike the windshield, their chests and upper abdomens hit the steering column, and their legs or knees contact the dashboard. The resultant injuries frequently include facial fractures, cervical spine fractures, laceration of the thoracic aorta, myocardial contusion, injury to the spleen and liver, and fractures of the pelvis and lower extremities. The discovery of one of these injuries should prompt a search for others.

Low-energy trauma, such as being struck with a club or falling from a bicycle, usually does not result in widely distributed injuries, but potentially lethal lacerations of internal organs can still occur because the net energy transfer to that location may be substantial.

Penetrating injuries are classified according to the wounding agent, i.e., stab wounds, gunshot wounds, or shotgun wounds. Gunshot wounds are subdivided further into high- and low-velocity injuries because the speed of the bullet is much more important than its weight in determining kinetic energy. Experience in urban trauma centers indicates that high-velocity gunshot wounds (bullet speed greater than 2000 ft/s) are rare in the civilian setting. Shotgun injuries are divided into close-range (< 7 meters) and long-range wounds. Close-range shotgun wounds are comparable to high-velocity wounds because the entire energy of the load is delivered to a small area, often with devastating results. Long-range shotgun wounds result in a diffuse pellet pattern in which many pellets miss the victim, and those that do strike are dispersed and of comparatively low energy.

Regional Assessment and Special Diagnostic Tests

Additional diagnostic studies are often indicated on the basis of mechanism of injury, location of injuries, screening x-rays, and the patient's overall condition. The patient is in constant jeopardy when undergoing special diagnostic testing. The surgeon should be in attendance and be prepared to alter plans as circumstances demand. Hemodynamic, respiratory, and mental statuses determine the most appropriate course of action.

Head

A score based on the *Glasgow Coma Scale (GCS)* should be determined for all injured patients (Table 6-2). It is calculated by adding the scores of the best motor response, best verbal response, and eye opening. Scores range from 3 (the lowest) to 15 (normal). Scores of 13 to 15 indicate mild head injury, 9 to 12, moderate injury, and less than 9, a severe injury. The GCS is useful for triage and prognosis.

Examination of the head should focus on potentially treatable neurologic injuries. The presence of lateralizing findings are important, e.g., a unilateral dilated pupil unreactive to light, asymmetric movement of the extremities either spontaneously or in response to noxious stimuli, or a unilateral Babinski's reflex suggest a treatable intracranial mass lesion or major structural damage. Stroke syndromes should prompt a search for carotid dissection or thrombosis using duplex scanning or angiography. Otorrhea, rhinorrhea, "raccoon eyes," and Battle's sign (ecchymosis behind the ear) can be seen with basilar skull fractures. While not necessarily requiring treatment, these fractures carry an increased risk of meningitis in the postinjury period. The head and face should be systematically palpated for fractures. Patients with a significant closed head injury (GCS less than 14) should have a CT scan performed. For penetrating injuries plain skull films should be obtained as well, as they can provide information that CT does not.

Cerebral pathologic lesions from blunt trauma include hematomas, contusions, hemorrhage into ventricular and subarachnoid spaces, and diffuse axonal injury (DAI). Hematomas are further classified according to location. Epidural hematomas occur when blood accumulates between the skull and the dura and are caused by disruption of the middle meningeal artery or other small arteries in that potential space from a skull fracture (Fig. 6-10). Subdural hematomas occur between the dura and the cerebral cortex and are caused by venous disruption or laceration of the parenchyma of the brain (Fig. 6-11). Because of the underlying brain injury, prognosis is much worse with subdural hematomas. Intraparenchymal hematomas and contusions can occur anywhere within the brain. Hemorrhage may occur into the ventricles, and though usually not massive, this blood may cause postinjury hydrocephalus. Diffuse hemorrhage into the subarachnoid space may cause vasospasm and reduce cerebral blood flow. DAI results from high- speed deceleration injury and represents direct axonal damage. On CT a blurring of the gray/white matter interface may be seen, with multiple, small, punctate hemorrhages. While prognosis is difficult to predict, early evidence of DAI on CT scan is associated with a poor outcome. Magnetic resonance imaging (MRI) can often identify DAI with greater precision than CT.

Significant penetrating injuries usually are produced by bullets from handguns, but an array of other weapons or instruments can injure the cerebrum via the orbit or through the thinner temporal region of the skull. While the diagnosis usually is obvious, in some instances wounds in the auditory canal, mouth, and nose can be elusive. Prognosis is variable, but most supratentorial wounds that injure both hemispheres are fatal.

Neck

In evaluating the neck of a blunt trauma victim, attention should be focused on signs and symptoms of an occult cervical spine injury. Because of the devastating consequences of quadriplegia, all patients should be assumed to have cervical spine injuries until proven otherwise. The presence of posterior midline pain or tenderness should provoke a thorough radiologic evaluation. There is no perfect test to detect all injuries. A cervical spine series including lateral view with visualization of C7–T1, anteroposterior view, and transoral odontoid view is sufficient to detect most significant fractures and subluxations. If pain or tenderness persists in spite of normal appearance on plain x-ray films, a CT scan should be done. CT identifies most fractures but can miss some subluxations. A combination of plain film and CT imaging can identify virtually all injuries. An exception to this is a purely ligamentous injury. These rare and dangerous injuries may not be visible with standard imaging techniques. Flexion and extension views can be performed and may reveal opening of the intervertebral space. This should only be done in the presence of an experienced surgeon: patients with injuries have become permanently quadriplegic when flexed and extended by inexperienced individuals (Fig. 6-12). A safer method may be to instruct the patient to carefully move his or her head without assistance from the surgeon; patients will not pith themselves.

Spinal cord injuries can be complete or partial. Complete injuries cause permanent quadriplegia or paraplegia, depending on the level of the injury. These patients have a complete loss of motor function and sensation two or more levels below the bony injury. Patients with high spinal cord disruption are at risk for spinal shock from physiologic disruption of sympathetic fibers. Significant neurologic recovery is rare. There are several partial or incomplete spinal cord injury syndromes. Central cord syndrome usually occurs in older persons who suffer hyperextension injuries. Motor function, pain, and temperature sensation are preserved in the lower extremities but diminished in the upper extremities. Some functional recovery usually occurs, but it is seldom a return to normal. Anterior cord syndrome is characterized by diminished motor function and pain and temperature sensation below the level of the injury. Position, vibratory, and crude touch sensation are maintained. Prognosis for recovery is poor. Brown-Séquard's syndrome usually is the result of a penetrating injury in which the right or left half of the spinal cord is transected. This rare lesion is characterized by the ipsilateral loss of motor function, proprioception, and vibratory sensation; pain and temperature sensation are lost on the contralateral side.

Penetrating injuries of the anterior neck that violate the platysma are considered significant because of the density of critical structures in this region. Mandatory exploration may be appropriate in some circumstances, but patients are now managed selectively in most centers (Fig. 6-13). Selective management is based on the neck's division into three zones (Fig. 6-14). Zone I is between the clavicles and the cricoid cartilage, and is also referred to as the thoracic outlet. Zone II is between the cricoid cartilage and the angle of the mandible, and Zone III is above the angle of mandible. The evaluation and management of visceral and vascular injuries in Zone I (the thoracic outlet) are complicated by the overlying ribs, sternum, and clavicles. Because the operative incision to be made may depend on the injured structures, a precise preoperative diagnosis is desirable. Patients with Zone I injuries should undergo angiography of the great vessels, soluble-contrast esophagram followed by barium esophagram, esophagoscopy, and bronchoscopy. Hemodynamically unstable patients should not undergo this extensive evaluation but should be taken directly to the operating room.

Patients with Zone II injuries are the easiest to evaluate. Unstable patients or those with evidence of airway compromise, an expanding hematoma, or significant external hemorrhage (including hemorrhage into the mouth) should be explored promptly. Stable patients without these findings can be evaluated selectively. Penetrating neck wounds in stable patients should be locally explored to determine the depth of penetration. Wounds that do not penetrate the platysma are insignificant and should be closed; these patients can be discharged. The vast majority of the remaining Zone II penetrating wounds are observed for 12 h. Patients with right-to-left transcervical gunshot wounds may require diagnostic studies. Carotid and vertebral angiography, direct laryngoscopy, tracheoscopy, esophagoscopy, and esophagram might be necessary, depending on the bullet's trajectory.

Patients with Zone III penetrating injuries require carotid and vertebral angiography if there is evidence of arterial bleeding. This is important for three reasons: (1) exposure of the distal internal carotid and vertebral arteries is difficult; (2) the internal carotid artery may have to be ligated, a maneuver associated with a high risk of stroke; and (3) active hemorrhage from the external carotid and vertebral arteries can be controlled by selective embolization. Associated injuries of the pharynx are inconsequential and require no special evaluation.

Chest

Blunt trauma to the chest may involve the chest wall, thoracic spine, heart, lungs, thoracic aorta and great vessels, and the esophagus. Most of these injuries are assessable by physical examination and chest x-ray. Patients with large air leaks after tube thoracostomy and those who are difficult to ventilate should undergo fiberoptic bronchoscopy to search for bronchial tears or foreign bodies.

The most threatening occult injury in trauma surgery is a tear of the descending thoracic aorta. Widening of the mediastinum on anteroposterior chest x-ray strongly suggests this injury. The widening is caused by the formation of a hematoma around the injured aorta that is temporarily contained by the mediastinal pleura. Posterior rib fractures and laceration of small vessels also can produce similar hematomas. Should the hematoma rupture into the chest with an aortic injury, the patient exsanguinates in seconds. Other findings suggestive of an aortic tear are noted in Table 6-3. This injury may be present with an entirely normal chest x-ray, although the incidence is approximately 2 percent. Because of the dire consequences of missing the diagnosis, CT and angiography are frequently performed after certain types of injury. Aortic tears occur when shearing forces are created in the chest. This is most often seen in high- energy-transfer deceleration motor vehicle accidents with frontal or lateral impact. It may occur after an ejection injury or fall. The tear usually occurs just distal to the left subclavian artery, where the aorta is tethered by the ligamentum arteriosum (Fig. 6-15). In 2 to 5 percent of cases the tear occurs in the ascending aorta, in the transverse arch, or at the diaphragm. Dynamic, spiral CT is an excellent screening test. Positive findings are a hematoma around the aorta or injury of the aorta. This test is highly sensitive, but its specificity is unknown. A clearly widened mediastinum on chest x-ray or abnormalities on CT are an absolute indication for emergent aortography.

Penetrating thoracic trauma is considerably easier to evaluate. Physical examination, plain posteroanterior and lateral chest x-rays with metallic markings of entrance and exit wounds, and CVP measurement disclose the vast majority of injuries. Injuries of the esophagus and trachea are exceptions. Depending on the estimated trajectory of the missile or blade, bronchoscopy should be performed to evaluate the trachea. Esophagoscopy can be performed to evaluate the esophagus, but injuries have been missed with the use of this technique alone. Patients at risk also should undergo a soluble contrast esophagram. If no extravasation of contrast medium is seen, a barium esophagram should be performed for greater detail. Failure to identify extant esophageal injuries leads to fulminant mediastinitis that is often fatal. As in the neck, right-to-left transmediastinal gunshot wounds frequently cause visceral or vascular injuries. Stable patients should be carefully evaluated for tracheal and esophageal injuries. Angiography occasionally is indicated.

Abdomen

With few exceptions, it is not necessary to determine which intraabdominal organs are injured, only whether an exploratory laparotomy is necessary. Physical examination of the abdomen is unreliable in making this determination, but most authorities agree that the presence of abdominal rigidity or gross abdominal distention in a patient with truncal trauma is an indication for prompt surgical exploration. For the majority of patients suffering blunt abdominal trauma, however, it is not clear whether exploration is needed. Serial examinations by the same surgeon can detect early peritoneal inflammation and the need for laparotomy before serious infections and hemorrhagic complications occur. Drugs, alcohol, or injuries of the head or spinal cord complicate physical examination. Laparotomy also may be impractical in patients who require general anesthesia for the treatment of other injuries. These patients require additional diagnostic testing.

The diagnostic approaches to penetrating and to blunt abdominal trauma differ substantially. Little preoperative evaluation is required for firearm injuries in which the peritoneal cavity is penetrated because the chance of internal injury is over 90 percent and laparotomy is mandatory. Anterior truncal gunshot wounds between the fourth intercostal space and the pubic symphysis whose trajectory as determined by x-ray or entrance/exit wound suggests peritoneal penetration should be operated on. Gunshot wounds to the back or flank are more difficult to evaluate because of the greater thickness of tissue between the skin and the abdominal organs. If in doubt, it is always safer to explore the abdomen than to equivocate when the depth of penetration is uncertain.

In contrast to gunshot wounds, stab wounds that penetrate the peritoneal cavity are less likely to injure intraabdominal organs. Anterior and lateral stab wounds to the trunk should be explored under local anesthesia in the emergency room to determine whether the peritoneum has been violated. Injuries that do not penetrate the peritoneal cavity do not require further evaluation. Stab wounds to the flank and back are more difficult to evaluate. Some authorities have recommended a triple contrast CT scan to detect occult retroperitoneal injuries of the colon, duodenum, and urinary tract. Because CT does not always identify enteric injuries, the authors have used soluble contrast radiographs of the colon and duodenum followed by barium if necessary. The larger final images may improve sensitivity. *Diagnostic peritoneal lavage (DPL)* remains the most sensitive test available for determining the presence of intraabdominal injury (Fig. 6-16). For stab wounds to the abdomen, its sensitivity for detecting intraabdominal injury exceeds 95 percent. The results of DPL are considered to be grossly positive if more than 10 mL of free blood can be aspirated after insertion of the catheter. If less than 10 mL is withdrawn, 1 L of normal saline solution is instilled and the patient is gently rocked from side to side and up and down. The effluent is withdrawn and sent to the laboratory for red blood cell count and determination of amylase and alkaline phosphatase levels. A red blood cell count greater than 100,000/mm³ is considered positive. The detection of bile, vegetable or fecal material, or the observation of effluent draining through a chest tube, a nasogastric tube, or a Foley catheter also constitutes a positive result. In equivocal cases, measurement of amylase and alkaline phosphatase levels can be helpful in identifying perforation of hollow viscera. The white blood cell count of the lavage effluent is not considered a valid indicator of intraperitoneal injury.

Stab wounds to the lower chest present a diagnostic opportunity. After the administration of adequate local anesthesia and extension of the wound as necessary, a finger is placed into the thoracic cavity to palpate the diaphragm. Confirmation of diaphragm penetration is an indication for laparotomy. When a hole is not palpable but risk of a diaphragmatic injury exists, a *DPL* should be performed. A red cell count in the effluent of more than 10,000/mm³ is considered positive when evaluating for a diaphragmatic injury. For red cell counts between 1,000 and 10,000/mm³, thoracoscopy should be considered.

Blunt abdominal trauma is evaluated by ultrasound imaging in most major trauma centers and, in selected cases, with CT scanning to refine the diagnosis. Ultrasonography performed by a surgeon or an emergency physician in the emergency room has largely replaced *DPL*. Evaluation of the entire abdomen is not the goal, but ultrasound is used in specific anatomic regions (e.g., Morison's pouch, the left upper quadrant, the pelvis) to identify free intraperitoneal fluid (Fig. 6-17). This method is exquisitely sensitive for detecting intraperitoneal fluid collections larger than 250 mL, but it is relatively poor for staging solid organ injuries. DPL is appropriate for patients whose condition cannot be explained with ultrasound imaging.

The use of CT scanning for the diagnosis of blunt abdominal trauma gained considerable popularity in the early 1980s. It was reported that injuries of the liver, spleen, and kidneys could be diagnosed with great precision using this method. Much of the initial enthusiasm has been tempered by the recognition of several limitations: (1) the need for high-quality radiographs, (2) the need for radiologists skilled in the interpretation of postinjury CT images, (3) the need for proper patient preparation, (4) poor sensitivity for intestinal injuries and acute pancreatic injuries, and (5) relatively poor correlation between splenic and hepatic CT images and the subsequent risk of bleeding requiring an operation. Despite these limitations, CT is an important diagnostic tool because of its specificity for hepatic, splenic, and renal injuries (Fig. 6-18). CT is indicated primarily for hemodynamically stable patients who are candidates for nonoperative therapy. CT also is indicated for hemodynamically stable patients who have unreliable physical examinations or other conditions (i.e., intracranial injury) requiring CT evaluation. The algorithm the authors use to evaluate blunt abdominal trauma is outlined in Fig. 6-19.

Because of the excellent view provided of the liver and anterior diaphragm, laparoscopy seems to be an ideal diagnostic tool for stable patients who have possible anterior upper abdominal injuries. One theoretic concern is carbon dioxide gas embolism through injuries of the hepatic veins, but this potential complication can be eliminated with gasless laparoscopy. The role of laparoscopy remains to be clarified, but it may expand with the availability of a smaller laparoscope that can be inserted under local anesthesia.

Pelvis

Blunt injury to the pelvis frequently produces complex fractures (Fig. 6-20). Plain x-rays reveal gross abnormalities, but CT scanning may be necessary to assess the pelvis for stability. Sharp spicules of bone can lacerate the rectum or vagina. The finding of gross blood on digital examination strongly suggests injury to these organs. Proctoscopy or speculum examination may reveal the injury. In questionable cases, soluble-contrast x-rays are diagnostic. The bladder can be lacerated by sharp fracture fragments, or, if the bladder is full, a direct blow to the hypogastrium can generate sufficient intravesicular pressure to cause rupture. Gross blood on urinalysis may not always occur, and a cystogram should be performed if more than a few red cells per high-power field are seen on urinalysis. Urethral injuries are suspected by the findings of blood at the meatus, scrotal or perineal hematomas, and a high-riding prostate on rectal examination. Urethrograms should be done in stable patients before placing the Foley catheter to avoid false passage and subsequent stricture.

Major vascular injuries are uncommon in blunt pelvic trauma; however, thrombosis or disruption of the arteries or veins in the iliofemoral system may occur. Angiography is indicated if thrombosis of the arterial system is suspected. Evaluation of penetrating injuries of the pelvis is similar to that for blunt injuries in stable patients. Visceral and vascular injuries are much more common, and laparotomy is often required. Life-threatening hemorrhage can be associated with pelvic fractures. The source may be the lower lumbar arteries and veins or branches of the internal iliac arteries and veins. These injuries are frequently not amenable to surgical repair and usually occur with disruption of the posterior elements of the pelvis.

Extremities

Injury of the extremities from any cause requires plain x-ray films to evaluate fractures. Ligamentous injuries, particularly those of the knee and shoulder when related to sports activities, can be imaged with MRI. The assessment of vascular injuries is somewhat controversial. Vascular diagnosis usually is limited to the arterial system unless there is uncontrolled external venous hemorrhage or venous injuries are uncovered during operative exploration. It is uncommon to see a patient with a venous complication related to trauma that was not identified and treated while an arterial injury was being evaluated.

Physical examination serves to identify and localize arterial injuries in many instances. Physical findings are classified as hard signs or soft signs (Table 6-4). Hard signs constitute indications for operative exploration, whereas soft signs are indications for observation or additional testing. Arteriography may be helpful in localizing the injury in some patients with penetrating injuries and hard signs. For example, a bullet that enters the lateral hip and exits below the knee medially, when there is also a femoral shaft fracture and no popliteal pulse, could have injured the femoral or popliteal artery anywhere. Arteriography would be useful to localize the injury and limit the dissection.

The controversy in vascular trauma is in the management of patients with soft signs of injury, particularly injuries that are in proximity to major vessels. It is known that some of these patients will be found to have arterial injuries that require repair. One approach has been to measure systolic blood pressures using Doppler ultrasonography and compare the injured side to the uninjured side. If the pressures are within 10 percent of each other, a significant injury is excluded and no further evaluation is performed. If the difference is greater than 10 percent, an arteriogram is indicated. Some argue that there are occult injuries, such as pseudoaneurysms or injuries of the profunda femoris or peroneal arteries, which may not be sampled with this technique. If hemorrhage occurs from these injuries, compartment syndrome and limb loss may occur. While trauma centers debate this issue, the surgeon who is treating the injured patient can perform angiography in selected patients who have soft signs.

TREATMENT

General Considerations

Seriously injured patients are more fragile than their age and physical condition imply. Procedures that are well tolerated in older patients, such as hepatic lobectomy for hepatoma, usually are lethal in the multiply injured patient. There has been a remarkable change in operative approach over the past 20 years. Faster techniques are used, and shorter serial operations have become common. For example, at the authors' institution virtually all suture lines are created with a running single layer. There is no evidence that this method is less secure than interrupted multilayer techniques, and it is clearly faster. Drains, once considered mandatory for many parenchymal injuries and some anastomoses, have virtually disappeared. Fluid collections that accumulate in a delayed fashion are now effectively managed by interventional radiologists. Injuries once thought to mandate resection, such as splenic injuries, are now managed with suture repair or even nonoperatively. The treatment of colonic injuries by primary repair is another example. These conceptual changes have significantly improved survival in trauma patients, and all have been developed through the extensive experience of major urban trauma centers and the forums for the free exchange of ideas provided by the American College of Surgeons Committee on Trauma, the American Association for the Surgery of Trauma, the International Association of Trauma and Surgical Intensive Care, the Pan-American Trauma Congress, and other surgical organizations.

The management of patients with multiple injuries requires the early establishment of therapeutic priorities. While the concept of life over limb and limb over cosmesis seems obvious, decision making can be subtle. Many combinations of injuries and physiologic states can be anticipated that have an impact on decision making. It is the trauma surgeon's responsibility to assess the probable outcomes of different therapeutic strategies and choose which is in the patient's best interest.

Transfusion

Because fresh whole blood, the optimal replacement material for shed blood, is no longer available, whole blood must be recreated from its component parts: *packed red blood cells (pRBC)*, *fresh-frozen plasma (FFP)*, and platelet packs. Not all trauma patients requiring transfusions receive all three components. Most trauma patients receive between 1 and 5 units of pRBC and no other components, but major trauma centers have the capability of transfusing tremendous quantities of blood components. It is not unusual for 100 component units to be transfused during one procedure. Red cell transfusion rates of 20 to 40 units of pRBC per hour are common in severely injured patients.

Transfusion practices in trauma require the surgeon to identify the insidious signs of coagulopathy, such as excessive bleeding from the cut edges of skin, fascia, and peritoneum that were previously controlled. While the local volume of coagulopathic hemorrhage in one visual field seems low compared to that of a hole in the aorta or venae cavae, blood loss from the entire area of dissection can lead to exsanguination. The usual measurements of coagulation capability, i.e., prothrombin time (PT), partial thromboplastin time (PTT), and platelet count have a turnaround time of more than 30 min in most institutions. These tests are of limited value in patients who have lost two or three blood volumes while waiting for test results. Under such conditions, transfusion must be empiric and based on the surgeon's observations. At the first sign of coagulopathic hemorrhage, the previously lost plasma proteins and platelets must be restored with *FFP* and platelet packs. Additional transfusions should be administered with equal ratios of *pRBC*, FFP, and platelets.

The causal relationship of core hypothermia metabolic, acidosis, and postinjury coagulopathy has been observed in a number of studies. The pathophysiology is multifactorial and includes inhibition of temperature-dependent enzyme-activated coagulation cascades, platelet dysfunction, endothelial abnormalities, and a poorly understood fibrinolytic activity. The role of metabolic acidosis in the pathogenesis of a coagulopathy is unclear. Experiments have demonstrated impaired hemostasis at a pH of 7.20; others have suggested that pH directly affects platelet function. Other series implicated acidosis in the propagation of disseminated intravascular coagulation with the secondary consumption of clotting factors. Hypothermia and metabolic acidosis have adverse effects on myocardial performance and tissue perfusion.

Primary hemostasis relies on platelet adherence and aggregation to injured endothelium, resulting in the formation of the platelet plug. A platelet count of 50,000/mm³ is considered adequate for tissue hemostasis if the platelets are normal. However, platelet dysfunction is a well-documented complication of massive transfusion that is aggravated by associated hypothermia. Consequently, the recommended target of more than 100,000/mm³ for platelet transfusion in other high-risk patients should be extended to the severely injured.

Blood typing and, to a lesser extent, crossmatching is essential to avoid life-threatening intravascular hemolytic transfusion reactions. A complete type and crossmatch requires 20 to 45 min to complete and reduces the risk of an intravascular hemolysis to approximately 0.004 percent. If 20 units of *pRBC* are needed within an hour, an army of technicians would be required to perform this service. Twenty to 45 min is too long for a patient with an exsanguinating hemorrhage to wait. Therefore, trauma patients requiring emergency transfusions are given type O, type-specific, or biologically compatible red blood cells. As a cross-check for ABO compatibility, a saline crossmatch is often performed.

The administrative and laboratory time required is approximately 5 min, and the risk of intravascular hemolysis is about 0.05 percent. The risk increases to 1.0 percent with a history of previous transfusions or pregnancy, and up to 3.0 percent with both. This increased risk of transfusion reaction is a result of the presence of irregular antibodies (e.g., Kell, Duffy, Kidd, etc.) in the patient's plasma that occur in about 1/1000 patients. Intravascular hemolysis can occur with ABO-compatible *pRBC* if the patient has an irregular antibody. It usually is not as severe as ABO incompatible hemolytic reactions, and the time required to detect the antibodies biochemically or by crossmatch makes the increased risk of hemolytic reaction a reasonable trade for rapid availability. Preformed antibodies are rapidly depleted by hemorrhage and are produced slowly, diminishing the severity of intravascular hemolysis if it occurs. An alternative strategy for those patients who are consistently stable and do not have serious injuries is to perform a type and screen as a cost-saving measure. If blood is subsequently needed urgently, low-titer, type-specific red cells can be administered with the same risk of intravascular hemolysis as with fully typed and crossmatched blood, provided the screen for irregular antibodies is negative. Unstable patients should receive O-negative, O-positive, or type-specific red cells, depending on the patient's age and sex and the availability of blood cell types. Other components should be type specific or biologically compatible.

Prophylaxis

All injured patients undergoing an operation should receive preemptive antibiotic therapy. The authors use second-generation cephalosporins for laparotomies and first-generation cephalosporins for all other operations. Additional doses should be administered during the procedure on the basis of blood loss and the half-life of the antibiotic. The role of postoperative antibiotic therapy in trauma patients remains to be defined, but the trend has been to reduce the duration. Tetanus prophylaxis is administered to all patients according to the American College of Surgeons guidelines (see Chap. 5).

Deep venous thrombosis and other venous complications occur more often in injured patients than is generally believed. This is particularly true for patients with major fractures of the pelvis and lower extremities, those with spinal cord injury or in a coma, and those with injury of the large veins in the abdomen and lower extremities. The authors use pulsatile compression stockings in all injured patients and selectively place inferior vena caval filters for those at very high risk. The role of inferior vena caval filters may expand in the future when removable devices become commercially available. Low-molecular-weight heparins have been demonstrated to be safe and effective in patients with orthopaedic injuries. Their use in patients with other injuries remains to be elucidated.

Another prophylactic measure is thermal protection. Hemorrhagic shock impairs perfusion and metabolic activity throughout the body. With declining metabolism, heat production and body temperature decrease. The injured patient receives a second thermal insult with the removal of insulating clothing. As a result, trauma patients can become seriously hypothermic, with temperatures as low as 34°C by the time they reach the operating room. Hypothermia impairs coagulation and myocardial contractility and increases myocardial irritability. Intentional hypothermia has protective features for patients with massive head injuries, but most authorities agree that the deleterious effects outweigh the potential benefits. Injured patients whose intraoperative core temperature drops below 32°C are at risk for fatal arrhythmias and defective coagulation. Thermal prophylaxis should begin in the emergency room by maintaining the ambient temperature comfortable for an exposed patient. Fluids should be stored at body temperature and blood products should be administered through rapid-warming devices. When examination is completed, the patient should be kept scrupulously covered with warm blankets or other devices until body temperature returns to normal.

Vascular Repair

The initial control of vascular injuries should be accomplished digitally by applying enough pressure directly on the bleeding site to stop the hemorrhage. Some bleeding vessels may need to be gently pinched between the thumb and index finger. These maneuvers, along with suction, usually create a dry enough field to safely permit the dissection necessary to define the injury. Sharp dissection with fine scissors is preferable to blunt dissection because the latter can aggravate the injury. When a sufficient length of vessel is available, a vascular thumb forceps is used to grasp the vessel. If the vessel is not transected, forceps can be placed directly across the injury. This minimizes or eliminates bleeding while the dissection necessary for clamping is completed. If the vessel is transected (or nearly so) digital control is maintained on one side while the other is occluded with a thumb forceps. The vessel is then sharply mobilized to allow an appropriate vascular clamp to be applied. When definitive control of all injuries is achieved, heparinized saline is injected into the proximal and distal ends of the injured vessel to prevent thrombosis. The exposed intima and media at the site of the injury are highly thrombogenic, and small clots often form. These clots should be carefully removed to prevent thrombosis or embolism when the clamps are removed. Because of the frequency that embolism occurs, routine balloon catheter exploration of the distal vessel has been recommended. Ragged edges of the injury site should be judiciously debrided using sharp dissection.

Injuries of the large veins such as the venae cavae, or the innominate and iliac veins pose a special problem for hemostasis. Numerous large tributaries make adequate hemostasis difficult to achieve, and their thin walls render them susceptible to additional iatrogenic injury. When a large-vessel injury is encountered, tamponade with a folded laparotomy pad held directly over the bleeding site usually establishes hemostasis sufficient to prevent exsanguination. If hemostasis is not adequate to expose the vessel proximal and distal to the injury, sponge sticks can be placed strategically on either side of the injury and carefully adjusted to improve hemostasis. This maneuver requires skill and discipline to maintain a dry field. The operative field is sometimes sufficient to delineate and repair the injury. It is often difficult for the assistant to maintain complete control of hemorrhage with sponge sticks. In this situation, the vessel can be exposed on either side of the sponge stick and a vascular clamp applied. The clamp can then be sequentially advanced toward the injury until hemostasis is complete.

Options for the treatment of vascular injuries are listed in Table 6-5. Some arteries and most veins can be ligated without significant sequelae. Arteries for which repair should always be attempted include the aorta and the carotid, innominate, brachial, superior mesenteric, proper hepatic, renal, iliac, femoral, and popliteal arteries. In the forearm and lower leg at least one of the two palpable vessels should be salvaged. The list of veins for which repair should be attempted is short: the superior vena cava, the inferior vena cava proximal to the renal veins, and the portal vein. There are notable vessels for which repair is not necessary, e.g., the subclavian artery and the superior mesenteric vein. The portal vein can be ligated successfully provided adequate fluid is administered to compensate for the dramatic but transient edema that occurs in the bowel. Ligation of some vessels, such as the popliteal vein and the left or right branch of the portal vein, can result in morbidity for the patient that is not life threatening. The authors attempt to repair all arteries larger than 3 mm and all veins larger than 10 mm in diameter, depending on the patient's physiologic condition.

Some arterial injuries have been treated by observation without subsequent complications. These include small pseudoaneurysms, intimal dissections, small intimal flaps and arteriovenous fistulas in the extremities, and occlusions of small (<2 mm) arteries. Follow-up angiography is obtained within 2 to 4 weeks to ensure that healing has occurred.

Lateral suture is appropriate for small arterial injuries with little or no loss of tissue. End-to-end anastomosis is used if the vessel is transected or nearly so. The severed ends of the vessel are mobilized, and small branches are ligated and divided as necessary to obtain the desired length. Arterial defects of 1 to 2 cm usually can be bridged. The surgeon should not be reluctant to divide small branches to obtain additional length because most injured patients have normal vasculature and the preservation of potential collateral flow is not as important as in atherosclerotic surgery. To avoid postoperative stenosis, particularly in smaller arteries, some technique such as beveling or spatulation should be used so that the

completed anastomosis is slightly larger in diameter than the native artery (Fig. 6-21).

Interposition grafts are used when end-to-end anastomosis cannot be accomplished without tension despite mobilization. For vessels less than 6 mm in diameter, autogenous saphenous vein from the groin should be used because *polytetrafluoroethylene (PTFE)* grafts less than 6 mm in diameter have a prohibitive rate of thrombosis. Injuries of the brachial, popliteal, and internal carotid arteries require the saphenous vein for interposition grafting. When the saphenous vein is harvested for treating an arterial injury in the lower extremity, it should be taken from the contralateral extremity. Because the status of the ipsilateral venous system is unknown, the saphenous vein on that side may become an important tributary. Larger arteries must be bridged by artificial grafts. Some authorities advocate the use of free internal iliac artery grafts because of the greater thickness and strength of its wall compared to the saphenous vein. The authors believe that this vessel is overly tedious to remove and has no advantage over the saphenous vein.

Transposition procedures can be used when an artery has a bifurcation of which one vessel can safely be ligated. Injuries of the proximal internal carotid can be treated by mobilizing the adjacent external carotid, dividing it distal to the internal injury and performing an end-to-end anastomosis between it and the distal internal carotid (Fig. 6-22). The proximal stump of the internal carotid is oversewn in such a way as to avoid a blind pocket where clot may form. Injuries of the ipsilateral external and contralateral common iliac arteries can be handled in a similar fashion provided flow is maintained in at least one internal iliac artery (Fig. 6-23).

Arterial injuries are often grossly contaminated from enteric or external sources, in which case many surgeons are reluctant to place artificial grafts in situ. This situation arises most often in injuries to the aortic or iliac artery when the colon also is injured. For the aorta there are few options. Ligation of the aorta with unilateral or bilateral axillofemoral bypass can be performed. These are lengthy procedures that are prone to thrombosis and infection. Most patients who require an aortic graft cannot tolerate surgery for the amount of time required to perform an axillofemoral bypass. Therefore, even in the presence of fecal contamination, it is common practice to use *PTFE* or Dacron in situ for aortic injuries. Every effort is made to remove and control contamination after the control of hemorrhage but before the graft is brought into the operative field. This includes copious irrigation of the abdominal cavity and changing of drapes, gowns, gloves, and instruments. After placement of the graft, it is covered with peritoneum or omentum before definitive treatment of the enteric injuries. Graft infection is rare in these instances. A similar approach can be used for injuries to the iliac artery, but in most cases this can be avoided by the innovative use of transposition procedures.

Suture selection for arterial injuries is based on the diameter of the vessel being repaired (Table 6-6). The use of progressively finer suture for smaller- diameter vessels encourages the inclusion of less tissue with more closely placed sutures, which is necessary for successful repair. When performing anastomoses in which the vessels are tethered, e.g., the thoracic artery and the abdominal aorta, the authors use the parachute technique to ensure precise placement of the posterior suture line (Fig. 6-24). If this technique is used, traction on both ends of the sutures must be maintained or leakage from the posterior aspect of the suture line is probable. A single temporary suture 180 degrees from the posterior row is used to maintain alignment.

Venous injuries are more difficult to repair successfully because of their propensity to thrombose. Small injuries without loss of tissue can be treated with lateral suture. More complex repairs often fail. Thrombosis does not occur acutely but rather gradually over 1 to 2 weeks. Adequate collateral circulation, sufficient to avoid acute venous hypertensive complications, usually develops within several days. Therefore it is reasonable to use *PTFE* for venous interposition grafting and accept a gradual but eventual thrombosis while waiting for collateral circulation to develop. Conversely, chronic venous hypertensive complications in the lower extremities often can be avoided with any level of ligation by (1) elastic bandages carefully applied in the operating room at the end of the procedure, and (2) continuous elevation of the lower extremities to 30 degrees. These measures should be maintained for 1 week, after which the patient is ambulated. If no edema occurs with the bandages removed, elevation is no longer necessary. It is a reasonable precaution to have the patient wear compressive stockings up to the knee for a few months afterward.

There are several circumstances in which a more aggressive approach should be considered. Ligation of the superior vena cava has been associated with sudden blindness resulting from compression of the optic nerve from venous hypertension. Ligation of the suprarenal inferior vena cava is believed to be associated with acute renal failure from venous hypertension. Chronic venous insufficiency of the lower extremities may be caused by ligation of the infrarenal vena cava or any in-line vein below that level, particularly the popliteal vein. Interposition grafting can be considered in these situations, but the choice of material is problematic. One option is to use artificial material because it is rapidly available in hemodynamically correct sizes. The drawback is that thrombosis is inevitable when such grafts are placed below the renal veins. Artificial grafts have performed satisfactorily in cases of suprarenal inferior vena caval and superior vena caval replacement. The jugular vein can be used to replace vessels of similar size, e.g., the portal or femoral vein. The saphenous vein is too small to replace any important vein. Panel grafts and spiral grafts constructed around a mandrel (chest tube) using saphenous vein have occasionally been performed, but these procedures are extremely tedious and have no apparent advantage over ligation in most instances.

The technology used by interventional radiologists is advancing rapidly. They have the ability to cannulate virtually any artery in the body and dilate it, place an intraluminal filter, stent, or graft in it, or occlude it. Their services are most valuable for treating arterial or venous injuries that are surgically inaccessible, such as stent placement in the internal carotid artery near or in the base of the skull, or controlling hemorrhage in hepatic injuries or pelvic fractures (Figs. 6-25, 6-26, and 6-27).

Staged Operations

The most common causes of death for trauma patients are head injury, exsanguination from cardiovascular injuries, and sepsis with multiple organ failure. Another cause of death has become apparent as the capability of delivering massive quantities of red blood cells and other components has developed. Surgeons are able to operate on the most severely injured patients until a constellation of metabolic derangements develops. These are characterized by the triad of an obvious coagulopathy, profound hypothermia, and metabolic acidosis. Hypothermia from evaporative and conductive heat loss and diminished heat production occurs in spite of warming blankets and blood warmers. The metabolic acidosis of shock is exacerbated by aortic clamping, vasopressors, massive transfusions, and impaired myocardial performance. Coagulopathy is caused by dilution, hypothermia, and acidosis. Each of these factors reinforces the others, resulting in a critically ill patient who is at high risk for a fatal arrhythmia. This downward spiral has been referred to as “the bloody vicious cycle” (Fig. 6-28).

Heat loss appears to be the central event because neither of the other components can be corrected until core temperature returns toward normal. Laboratory and mathematical heat exchange models have demonstrated that evaporative heat loss from an open abdomen is by far the greatest source. A concomitant open thoracic cavity greatly accelerates the rate of the patient's deterioration and can cause the syndrome by itself. This is the rationale for the immediate abdominal closure and the reason it has been successful.

Staged operations are indicated when a coagulopathy develops and core temperature drops below 34°C. A refractory acidosis is almost always present. Several unorthodox techniques can be used to expedite wound closure. Bleeding raw surfaces, often of the liver, are packed with laparotomy pads. Small enteric injuries are closed with staples, and large ones are stapled on both sides with the GIA stapler and the damaged segment removed. Clamps may be left on unrepaired vascular injuries, or the vessels may be ligated. Injuries of the pancreas and kidneys are not treated if they are not bleeding. No drains are placed, and the abdomen is closed with sharp towel clips placed 2 cm apart, which include only the skin (Fig. 6-29). Towel clips are used because they do not cause bleeding as needles do, and they can be applied very rapidly, usually in 60 to 90 seconds. The closure of just the skin allows for the abdominal or thoracic cavity to accommodate a greater volume without increased pressure. The clips are covered with a towel, and a plastic adhesive sheet is placed over the towel to prevent excessive fluid from draining onto the patient's bedding. Cold wet drapes are removed, and the patient is covered from head to toe with layers of warm blankets. Some of the unorthodox treatments used, including the creation of closed-loop bowel obstructions and unrepaired renal injuries, are not compatible with survival; however, reoperation is planned within 2 to 24 h, and the treatments are tolerated well within that time frame. The goal is to complete the procedure as soon as possible, or the patient will die. If the surgeon believes that the patient's metabolic problems can be corrected in a short time (2 h or less), the patient can remain in the operating room while additional blood products are administered and rewarming measures are instituted. Patients who are in very poor condition and require several hours for metabolic corrections should be transferred to the surgical intensive care unit. If the patient's condition improves as evidenced by normalization of coagulation studies, the correction of acid/base imbalance, and a core temperature of at least 36°C, the patient should be returned to the operating room for removal of packs and definitive treatment of injuries.

There are several complications associated with this treatment. Failure to identify noncoagulopathic hemorrhage can lead to exsanguination. Most patients with coagulopathic hemorrhage have a gradual decrease in the need for *pRBC*, *FFP*, and platelets and an improvement in coagulation studies as temperature rises. In the case of vascular hemorrhage coagulopathy does not correct itself, and these patients must be returned to the operating room for reexploration.

A second complication is referred to as the abdominal or thoracic compartment syndrome, which are caused by an acute increase in intracavitary pressure. In the abdomen the compliance of the abdominal wall and the diaphragm permit the accumulation of many liters of fluid before *intraabdominal pressure (IAP)* increases. There are primarily two sources for this fluid, blood, and edema. Blood accumulates as a result of the coagulopathy or missed vascular injury described above. The cause of edema is multifactorial. Ischemia and reperfusion cause capillary leakage, loss of oncotic pressure occurs, and in the case of the small bowel, which is often eviscerated, prolongation and narrowing of veins and lymphatics caused by traction impairs venous and lymphatic drainage.

The resulting edema may be dramatic (Fig. 6-30). Similar phenomena occur in the chest. As fluid continues to accumulate, the compliant limit of the abdominal cavity is eventually exceeded, and *IAP* increases. When *IAP* exceeds 15 mmHg, serious physiologic changes begin to occur. The lungs are compressed by the upward displacement of the diaphragm. This causes a decrease in functional residual capacity, increased airway pressure, and, ultimately, hypoxia. Cardiac output decreases as a consequence of diminished venous return to the heart and increased afterload. Blood flow to every intraabdominal organ is reduced because of increased venous resistance. As *IAP* exceeds 25 to 30 mmHg, life-threatening hypoxia and anuric renal failure occur. Cardiac output is further reduced but can be returned toward normal with volume expansion and inotropic support.

The only method for treating hypoxia and renal failure is to decompress the abdominal cavity by opening the incision. This results in an immediate diuresis and a resolution of hypoxia. Failure to decompress the abdominal cavity eventually causes lethal hypoxia or organ failure. There have been a few reports of sudden hypotension when the abdomen is opened, but volume loading to enhance cardiac output has largely eliminated this problem. *IAP* is measured using the Foley catheter. Because the bladder is a passive reservoir at low volumes (50 to 100 mL), it imparts no intrinsic pressure but can transmit *IAP*. Fifty mL saline solution is injected into the aspiration port of the urinary drainage tube with an occlusive clamp placed across the tube just distal to the port. The saline is used to create a standing column of fluid between the bladder and port that can transmit *IAP* to a recording device. The needle in the port is connected to a *CVP* manometer using a three-way stopcock. The manometer is filled with saline and opened to the drainage tube. *IAP* is read at the meniscus with manometer zeroed at the pubic symphysis. Bladder pressures measured in this fashion are reliable and consistent. Pressures less than 15 mmHg do not require decompression. Table 6-7 lists recommendations according to *IAP*.

In the chest similar phenomena occur. Edema of the heart and lungs develops, and the heart also may dilate. Blood accumulation is rarely a problem because of the use of chest tubes. The diagnosis usually is apparent in the operating room because the heart tolerates compression poorly. Attempts to close the chest in this setting are associated with profound hypotension, and an alternative method of closure is necessary. The most popular material used to accommodate the addition of volume in the chest or abdomen is a 3-liter plastic urologic irrigation bag that has been cut open and sterilized. The bag is sewn to the skin or fascia using No. 2 nylon suture with a simple running technique (Fig. 6-31). As many as four bags may need to be sewn together to cover a large defect. Closed- suction drains are placed beneath the plastic to remove blood and serous fluid that inevitably accumulate. The entire closure is covered with an iodinated plastic adhesive sheet to simplify nursing care. Patients whose renal function has not been impaired will have a

remarkable diuresis. Exogenous fluids are held to a minimum to facilitate the resolution of edema. Definitive wound closure can usually be performed in 48 to 72 h.

In the case of patients who develop sepsis and multiple organ failure (MOF), edema does not resolve until sepsis and MOF have resolved. This may require several weeks. The bags have been left in place up to 3 weeks with the patient surviving. The authors make every effort to close the skin over the viscera to decrease protein and heat loss and to inhibit infection. If these attempts are unsuccessful and the abdomen remains open with granulating tissue exposed, lateral traction forces of the abdominal wall eventually cause an enteric fistula. The risk of developing a fistula increases rapidly after 2 weeks with an open abdomen. These problems are extremely difficult to treat. Several approaches have been used to avoid this catastrophic complication, including polyglycolic acid or polypropylene mesh sewn to the fascia, split-thickness skin grafts placed directly on the bowel, musculocutaneous flaps, and traction devices. Of these options, skin grafts have the greatest success rates, although the abdominal wall hernia eventually requires reconstruction.

Nonoperative Management

Nonoperative treatment for blunt injuries of the liver, spleen, and kidneys is now the rule rather than the exception. Up to 90 percent of children and 50 percent of adults are treated in this manner. As interventional radiology continues to advance, these numbers will increase. The primary requirement for this therapy is hemodynamic stability. The extent of the patient's injuries should be delineated by CT scanning. Recurrent hemorrhage from the liver and kidneys has been infrequent, but delayed hemorrhage or rupture of the spleen is an important consideration in the decision to pursue nonoperative management. The patient should be monitored in the intensive care unit for the first 24 h. Because CT misses some enteric injuries, frequent abdominal examination should be performed. Usually the fall in hematocrit level stabilizes within 24 h. If the hematocrit level continues to fall, angiography with embolization of bleeding sites should be considered, particularly for hepatic and renal injuries. CT scanning usually is repeated at least once during the hospitalization to assess major hepatic or splenic lesions requiring transfusion. Gradually increasing activity is permitted after discharge. Patients involved in contact sports should have complete healing of the injury documented radiographically before resuming participation. This can take several months.

Complications of nonoperative treatment include continuing hemorrhage, delayed hemorrhage, necrosis of liver, spleen, or kidney from embolization, abscess, biloma, and urinoma. Hemorrhage may be treated by interventional radiology, though open operative control often is necessary. Most infectious complications can be treated by percutaneous drainage. Bilomas usually are resorbed.

Head

General principles for the management of cerebral injuries have changed in recent years. Attention is now focused on maintaining or enhancing cerebral perfusion rather than merely lowering intracranial pressure (ICP). Hyperventilation to a pCO₂ below 30 mmHg to induce cerebral vasoconstriction exacerbates cerebral ischemia in spite of decreasing ICP. These secondary iatrogenic cerebral injuries cause more harm than previously appreciated. Other treatments or conditions that must be avoided include decreased cardiac output because of the excessive use of osmotic diuretics, sedatives, or barbiturates, and hypoxia. Nevertheless, the measurement of ICP is important and is efficiently accomplished with a ventriculostomy tube. The tube also permits the withdrawal of cerebrospinal fluid, which is the safest method for lowering ICP. Although an ICP of 10 mmHg is believed to be the upper limit of normal, therapy is not usually initiated until the ICP reaches 20 mmHg. *Cerebral perfusion pressure (CPP)*, which is equal to the mean arterial pressure (MAP) minus the ICP, is an important measurement that is used to monitor therapy. The lowest acceptable CPP is 60 mmHg. This figure can be adjusted by lowering ICP or raising MAP. Induced paralysis, sedation, osmotic diuresis, and barbiturate- induced coma are used. The goal of fluid therapy is to achieve a euvolemic state, and arbitrary fluid restriction is avoided. It is unclear whether outcome is improved by boosting MAP with pressors or inotropes in patients with an elevated ICP resistant to treatment.

Indications for operative intervention for space-occupying hematomas are based on the amount of midline shift, the location of the clot, and the patient's ICP. A shift of more than 5 mm usually is considered an indication for evacuation. This is not an absolute rule, however. Smaller hematomas causing less shift in treacherous locations, such as the posterior fossa, can require drainage because of the threat of brainstem compression or herniation. Removal of small hematomas also may improve ICP and *CPP* in patients with an elevated ICP that is refractory to medical therapy.

The treatment of diffuse axonal injury includes the control of cerebral edema and general supportive care. The authors frequently use percutaneous tracheostomy for airway control and percutaneous endoscopic gastrostomy for enteral access in head-injured patients whose recovery is unlikely or prolonged. Prognosis is related to Glasgow Coma Scale score. Serious head injuries, GCS 3–8, have a poor prognosis, and an institutional existence is almost a certainty. Mild brain injuries, GCS 13–15, have a good prognosis; independent living is probable, but neuropsychiatric testing often reveals significant abnormalities.

General surgeons in small or rural communities without emergency neurosurgical coverage may be required to drill a burr hole in one life- saving circumstance: in a patient with an epidural hematoma. As blood from a torn vessel, usually the middle meningeal artery, accumulates, the temporal lobe is forced medially, which compresses the third cranial nerve and eventually the brainstem. The typical course is: (1) initial loss of consciousness; (2) awakening and a lucid interval; (3) recurrent loss of consciousness with a unilaterally fixed, dilated pupil; and (4) cardiac arrest. These patients usually do not have a serious underlying cortical injury, and complete recovery often is possible. The burr hole should be made on the same side as the dilated pupil, as shown in Fig. 6-32. The goal of the procedure is not to control the hemorrhage but to decompress the intracranial space. A craniotomy is required for the control of hemorrhage. The patient's head should be loosely wrapped with a thick layer of gauze to absorb the bleeding, and the patient should be transferred to a facility with emergency neurosurgical capability for a craniotomy.

Neck

Blunt Injury Cervical Spine

Treatment of injuries to the cervical spine is based on the level of injury, the stability of the spine, the presence of subluxation, the extent of angulation, and the extent of neurologic deficit. Cautious axial traction in line with the mastoid process is used to reduce subluxations. A halo-vest combination can accomplish this and also provide rigid external fixation for definitive treatment when left in place for 3 to 6 months. This device is the treatment of choice for many cervical spine injuries. Surgical fusion usually is reserved for those with neurologic deficit, those who demonstrate angulation greater than 11 degrees on flexion and extension x-rays, or those who are unstable after external fixation.

Spinal Cord

Injuries of the spinal cord, particularly complete injuries, are essentially untreatable. Approximately 3 percent of patients who present with flaccid quadriplegia have concussive injuries, and these patients represent the very few who seem to have miraculous recoveries. A prospective randomized study comparing methylprednisolone with placebo demonstrated a significant improvement in outcome (usually one or two spinal levels) for those who received the corticosteroid within 8 h of injury. The standard dosage is 30 mg/kg given as an intravenous bolus followed by a 5.4 mg/kg infusion administered over the next 23 h.

Larynx

The larynx may be fractured by a direct blow, which can result in airway compromise. A hoarse voice in a trauma patient is highly suggestive of laryngeal fracture. In cases of severe fracture a cricothyroidotomy or tracheostomy should be performed to protect the airway. The larynx is repaired with fine wires and sutures. If direct repair of internal laryngeal structures is necessary, the thyroid cartilage is split longitudinally in the midline and opened like a book. This is referred to as a laryngeal fissure.

Carotid and Vertebral Arteries

Blunt injury to the carotid or vertebral arteries may cause dissection, thrombosis, or pseudoaneurysm. More than half the patients with such injuries have a delayed diagnosis. Facial contact resulting in hyperextension and rotation appears to be the mechanism of injury. To reduce delayed recognition, the authors use CT angiography in patients at risk to identify these injuries before neurologic symptoms develop. The injuries frequently occur at or extend into the base of the skull and usually are not surgically accessible. Accepted treatment for thrombosis and dissection is anticoagulation therapy with heparin followed by warfarin sodium (Coumadin) for 3 months. Pseudoaneurysms also occur near the base of the skull. If they are small, they can be followed with repeat angiography. If enlargement occurs, consideration should be given to the placement of a stent across the aneurysm by an interventional radiologist. Another possibility is to approach the intracranial portion of the carotid artery by removing the overlying bone and performing a direct repair. This method has only recently been described and has been performed in a limited number of patients.

Venous Injuries

Thrombosis of the internal jugular veins caused by blunt trauma can occur unilaterally or bilaterally. These injuries usually are discovered incidentally and are generally asymptomatic. Bilateral thrombosis can aggravate cerebral edema in patients with serious head injuries. Stent placement should be considered in such patients if their ICP remains elevated. Laryngeal edema resulting in airway compromise also can occur.

Penetrating Injuries

Penetrating injuries in Zone II or III that require operative intervention are explored using an incision along the anterior border of the sternocleidomastoid muscle. If bilateral exploration is necessary, the inferior end of the incision can be extended to the opposite side. Midline wounds or significant bilateral injuries can be exposed via a large collar incision at the appropriate level. Alternatively, bilateral anterior sternocleidomastoid incisions can be used.

Carotid and Vertebral Arteries

Exposure of the distal internal carotid artery in Zone III is difficult (Fig. 6- 33). The first step is to divide the ansa cervicalis and mobilize the hypoglossal nerve. Next, the portion of the posterior belly of the digastric muscle that overlies the internal carotid artery is resected. The glossopharyngeal and vagus nerves are mobilized and retracted. If accessible, the styloid process and attached muscles are removed. At this point anterior displacement of the mandible may be helpful, and various methods for accomplishing this have been devised. Some authorities have advocated division and elevation of the vertical ramus, but two remaining structures still prevent exposure of the internal carotid to the base of the skull: the parotid gland and the facial nerve. Excessive anterior traction on the mandible or parotid may damage the facial nerve, particularly the mandibular branch. Unless the surgeon is willing to resect the parotid and divide the facial nerve, division of the ramus is seldom helpful.

Penetrating carotid artery injuries, regardless of the patient's neurologic status, usually require repair, except in comatose patients. Inaccessible carotid artery injuries near the base of the skull can be treated by interventional radiologists with a stent if the anatomy of the injury is favorable. Otherwise the artery will need to be thrombosed or ligated. If ligation is necessary, the patient should be given anticoagulation therapy with heparin followed by warfarin sodium (Coumadin) for 3 months. This treatment may prevent a stroke by inhibiting the generation of thrombi from the surface of the clot at the circle of Willis while the endothelium heals. Without anticoagulation therapy the risk of stroke with ligation has been approximately 20 to 30 percent, and most strokes occur a few days after ligation. Tangential wounds of the internal jugular vein should be repaired by lateral venorrhaphy, but extensive wounds are efficiently attended to by ligation.

Vertebral artery injuries usually result from penetrating trauma, although thrombosis and pseudoaneurysms can occur from blunt injury. The diagnosis is made by angiography or when significant hemorrhage is noted posterior to the carotid sheath during neck exploration. Exposure of the vertebral artery above the C6 vertebra where it enters its bony canal is complicated by the overlying anterior elements of the canal and the tough fascia covering the artery between the elements. The artery is approached through an anterior neck

incision by retracting the contents of the carotid sheath laterally (Fig. 6-34). The muscular attachments to the anterior elements are removed. Care must be taken to avoid injury to the cervical spinal nerves that are located directly behind and lateral to the bony canal. Some authorities have recommended using a high-speed burr to remove the anterior aspect of the canal, thereby avoiding the venous plexus between the elements. The authors have not found this to be a problem and have often excised the fascia between the elements and lifted the artery out of its canal with a tissue forceps.

The treatment for vertebral artery injuries is ligation proximal and distal to the injury. There is rarely, if ever, an indication for repair. Neurologic complications are uncommon. Exposure of the vertebral artery above C2 is extremely difficult. Rather than using a direct operative approach, the authors expose the vessel below C5, outside the bony canal, clamp the artery proximally, and insert a No. 3 balloon-tipped catheter. The catheter is advanced to the level of the injury or distal to it, and the balloon is inflated with saline solution until back bleeding stops. The tube to the catheter is crimped over on itself and secured in this position with several heavy silk sutures. The catheter is trimmed so that it can be left in the wound under the skin. The proximal end of the artery is ligated. One week later the catheter is removed under local anesthesia. Rebleeding has not occurred in our experience.

The same approach can be used for the distal internal carotid artery. An alternative approach is to have the interventional radiologist place coils to induce thrombosis proximal and distal to the injury if the lesion is diagnosed by angiography. Not all vertebral artery injuries can be treated by this method. Injuries of the proximal vertebral artery can be exposed by a median sternotomy with a neck extension.

Trachea and Esophagus

Injuries of the trachea are repaired with a running 3-0 absorbable monofilament suture. Tracheostomy is not required in most patients. Esophageal injuries are repaired in a similar fashion. If an esophageal wound is large, or if tissue is missing, a sternocleidomastoid muscle pedicle flap is warranted, and a closed-suction drain is a reasonable precaution. The drain should be near but not in contact with the esophageal or any other suture line. It can be removed in 7 to 10 days if the suture line remains secure. Care must be taken when exploring the trachea and esophagus to avoid iatrogenic injury to the recurrent laryngeal nerves.

Penetrating injuries of the neck often create wounds in adjacent hollow structures, e.g., the trachea and esophagus or the carotid artery and esophagus. If, after repair, these adjacent suture lines are in contact, the stage is set for devastating postoperative fistulous complications. To avoid these complications, viable tissue should routinely be interposed between adjacent suture lines. Viable strips of the sternocleidomastoid muscle or strap muscles are useful for this purpose.

Thoracic Outlet

Great Vessels

Most injuries of the great vessels of the thoracic outlet (Zone I) are caused by penetrating trauma, although the innominate and subclavian arteries are occasionally injured from blunt trauma. Angiography is desirable for planning the incision. If this is not possible because of hemodynamic instability, a reasonable approach can be inferred from the chest x-ray and the location of the wounds. If the patient has a left hemothorax, a left third or fourth interspace anterolateral thoracotomy should be performed because the proximal left subclavian artery may be injured. Hemorrhage can be controlled digitally until the vascular injury is delineated. Additional incisions or extensions are often required. A third or fourth interspace right anterolateral thoracotomy may be used for thoracic outlet injury presenting with hemodynamic instability and a right hemothorax. A median sternotomy with a right clavicular extension also can be used. Unstable patients with injuries near the sternal notch may have a large mediastinal hematoma or have lost blood directly to the outside. These patients should be explored via a median sternotomy.

If angiography has identified an arterial injury, a more direct approach can be used. Fig. 6-35 shows the various incisions that are used depending on the location of the arterial injury. A median sternotomy is used for exposure of the innominate, proximal right carotid and subclavian, and proximal left carotid arteries.

The proximal left subclavian artery presents a unique challenge. Because it arises from the aortic arch far posteriorly, it is not readily approached via a median sternotomy. A posterolateral thoracotomy provides excellent exposure but severely limits access to other structures and is not recommended. The best option is to create a full-thickness flap of the upper chest wall. This is accomplished with a third or fourth interspace anterolateral thoracotomy for proximal control, a supraclavicular incision with a resection of the medial third of the clavicle, and a median sternotomy, which links the two horizontal incisions. The ribs can be cut laterally for additional exposure, which allows the flap to be folded laterally with little effort. This incision has been referred to as a book or trapdoor thoracotomy (Fig. 6-36). The midportion of the subclavian artery is accessible by removing the proximal third of either clavicle, with the skin incision made directly over the clavicle. Muscular attachments are stripped away, and the clavicle is divided with a Gigli's wire saw. The medial remnant of the clavicle is forcibly elevated. The periosteum is dissected from the posterior aspect of the bone until the sternoclavicular joint is reached. The capsular attachments are cut with a heavy scissors or knife, and the bone is discarded. The periosteum and underlying fascia are very tough and must be sharply incised along the direction of the vessel. The subclavian vein is mobilized, and the artery is directly underneath. The anterior scalene muscle is divided for injuries just proximal to the thyrocervical trunk; the relatively small phrenic nerve should be identified on its anterior aspect and spared. Iatrogenic injury to cords of the brachial plexus can occur.

The great vessels are fragile and easily torn during dissection or crushed with a clamp. Some advocate oversewing proximal injuries of the artery on the side of the aortic arch and sewing a graft onto a new location on the arch. The graft is then sewn to the artery without tension. The authors have not found this necessary, provided the vessels are handled with care.

Trachea and Esophagus

The trachea and esophagus are difficult to approach at the thoracic outlet. The combination of a neck incision and a high anterolateral thoracotomy may be used. Alternatively, these structures can be approached via a median sternotomy, provided the left innominate vein and artery are divided. Temporary division of the innominate artery is tolerated well in otherwise healthy people, but the vessel should be repaired after treatment of the tracheal or esophageal injury. The vein does not need to be repaired. As in the neck, adjacent suture lines should be separated by viable tissue. A portion of the sternocleidomastoid can be rotated down for this purpose.

Chest

The most common life-threatening complications from blunt and penetrating thoracic injury are hemothorax, pneumothorax, or a combination of the two. Approximately 85 percent of these patients can be treated definitively with a chest tube. Because of the viscosity of blood at various stages of coagulation, a 36F or larger chest tube should be used. If one tube fails to completely evacuate the hemothorax (a "caked hemothorax"), a second tube should be placed (Fig. 6-37). If the second chest tube does not remove the blood, a thoracotomy should be performed because of the risk of life-threatening hemorrhage. Common sources of blood loss include intercostal vessels, internal thoracic artery, pulmonary parenchyma, and the heart. Less common sources are the great vessels, aortic arch, azygos vein, superior vena cava, and inferior vena cava. Blood may also enter the chest from an abdominal injury through a perforation or tear in the diaphragm. Indications for operative treatment of penetrating thoracic injuries are listed in Table 6-8.

The indications for thoracotomy in blunt trauma are based on specific preoperative diagnoses. These include pericardial tamponade, tear of the descending thoracic aorta, rupture of a main bronchus, and rupture of the esophagus. Thoracotomy for hemothorax in the absence of the above diagnoses is rarely indicated. A shattered chest wall that produces a hemothorax is better treated by the interventional radiologist with embolization.

Thoracic Incisions

The selection of incision is important and depends on the organs being treated. For exploratory thoracotomy for hemorrhage, the patient is supine and an anterolateral thoracotomy is performed. Depending on findings, the incision can be extended across the sternum or even farther for a bilateral anterolateral thoracotomy. The fifth interspace usually is preferred unless the surgeon has a precise knowledge of which organs are injured and knows that exposure would be enhanced by selecting a different interspace. The heart, lungs, aortic arch, great vessels, and esophagus are accessible with these incisions. Care should be taken to ligate the internal thoracic artery and veins if they are transected. This step often is overlooked, resulting in continuous blood loss that obscures the field and endangers the patient.

The heart also can be approached via a median sternotomy. Because little else can be done in the chest through this incision, it usually is reserved for stab wounds of the anterior chest in patients who present with pericardial tamponade. Posterolateral thoracotomies rarely are used since ventilation is impaired in the dependent lung, and the incision cannot be extended. There are two specific exceptions. Injuries of the posterior aspect of the trachea or main bronchi near the carina tracheae are inaccessible from the left or from the front. The only possible approach is through the right chest using a posterolateral thoracotomy. A tear of the descending thoracic aorta can be repaired only through a left posterolateral thoracotomy. Because the authors use left heart bypass for these procedures, the patient's hips and legs are rotated toward the supine position to gain access to the left groin for femoral artery cannulation. It is also helpful for optimal exposure to resect the fourth rib and enter the chest through its bed.

Heart

Most cardiac injuries are the result of penetrating trauma, and any part of the heart is susceptible. Control of hemorrhage while the heart is being repaired is crucial, and several techniques can be used. The atria can be clamped with a Satinsky vascular clamp. Digital control and suturing beneath the finger is possible anywhere in the heart, though the technique requires skill and a long, curved cardiovascular needle. However, the reality of blood-borne viral infections raises the question of whether this method should be used. If the hole is small, a "peanut" sponge clamped in the tip of a hemostat can be placed into the wound, or the blood loss may be accepted while sutures are being placed. For larger holes a 16F Foley catheter with a 30 mL balloon can be inflated with 10 mL of saline solution. Gentle traction on the catheter controls hemorrhage from any cardiac wound because wounds too large for balloon tamponade are incompatible with survival. Suture placement with the balloon inflated is problematic. Usually the ends of the wound are closed progressively toward the middle until the amount of blood loss is acceptable with the balloon removed. The use of skin staples for the temporary control of hemorrhage has become popular, particularly when emergency room thoracotomy has been performed. The use of staples has the advantages of reducing the risk of needle-stick injury to the surgeon and of not demanding the attention required by a balloon catheter. In most instances, hemostasis is neither perfect nor definitive. Inflow occlusion of the heart by clamping the superior and inferior venae cavae can be performed for short periods, and this may be essential for the treatment of extensive or multiple wounds as well as for those that are difficult to expose.

Immediate repair of valvular damage or acute septal defects rarely is necessary and requires total cardiopulmonary bypass, which has a high mortality in this situation. Most patients who survive to make it to the hospital do well with only external repair. After recovery, the heart can be thoroughly evaluated, and, if necessary, secondary repair can be performed under more controlled conditions. Coronary artery injuries also pose difficult problems. Ligation leads to acute infarction distal to the tie, but reconstruction requires bypass. The right coronary artery can be ligated anywhere, but the resultant arrhythmias may be extremely resistant to treatment. The left anterior descending and circumflex arteries cannot be ligated proximally without causing a large infarct. These injuries are rare and usually produce death in the field.

Lungs

Pulmonary injuries requiring operative intervention usually result from penetrating injury. Formerly the entrance and exit wounds were oversewn to control hemorrhage. This set the

stage for air embolism, which occasionally caused sudden death in the operating room or in the immediate postoperative period. Pulmonary tractotomy has been used to reduce this problem as well as the need for pulmonary resection. Linear stapling devices are inserted directly into the injury tract and positioned to cause the least degree of devascularization (Fig. 6-38). Two staple lines are created and the lung is divided between. This allows direct access to the bleeding vessels and leaking bronchi. No effort is made to close the defect. Lobectomy or pneumonectomy rarely is necessary. Lobectomy is indicated only for a completely devascularized or destroyed lobe. Parenchymal injuries severe enough to require pneumonectomy rarely are survivable, and major pulmonary hilar injuries necessitating pneumonectomy usually are lethal in the field.

Trachea and Esophagus

Injuries of the trachea and esophagus are managed in the same fashion as described above for lung injuries. Because exposure can be difficult, provisions should be made to deflate the lung on the operative side by using a double-lumen endotracheal tube (a double-lumen tube is seldom needed for cardiac or pulmonary injury). Repair of injuries of the main bronchi and the trachea near the carina tracheae can result in a complete loss of ventilation when the overlying pleura is opened, even if a double-lumen tube is used. Gases from the ventilator preferentially escape from the injury and neither lung will be ventilated. Digital occlusion of the injury can control air loss if the injury is small. Larger injuries are an imminent threat to life. To avoid this catastrophe, a 6 or 7 mm cuffed endotracheal tube should be on the operative field and a second ventilator available. If ventilation is inadequate, the surgeon can insert and inflate the endotracheal tube into the main bronchus on the opposite side through the injury to permit ventilation of one lung while the injury is repaired. Eventually, the tube will have to be removed to close the defect, but the remaining hole can be controlled digitally. Alternatively, it may be possible for the anesthesiologist to cannulate the opposite bronchus.

Descending Thoracic Aorta

The occurrence of paraplegia from ischemic injury of the spinal cord has been a concern in injuries to the descending thoracic aorta. Conceptually, two techniques have been advocated. The simpler technique, often referred to as “clamp and sew,” is accomplished with the application of vascular clamps proximal and distal to the injury and repair or replacement of the damaged portion of the aorta. This method results in transient hypoperfusion of the spinal cord distal to the clamps as well as all abdominal organs. Large doses of vasodilators also are required to reduce afterload and avoid acute left heart failure. If the clamping time is short, less than 30 min, paraplegia is uncommon. Longer clamping times have been associated with paraplegia in approximately 10 percent of patients. Clamping times of less than 30 min are difficult to achieve where there are many tears requiring complex repair. An alternative approach is to provide some method for maintaining a reasonable degree of perfusion for organs distal to the clamps. Two techniques have been used to accomplish this goal. The first is with the use of a shunt, a temporary extraanatomic route around the clamps. A heparin-impregnated tube, the Gott shunt, has been designed specifically for this purpose, but the volume of blood flow to the distal aorta is marginal. The second method is to use left heart bypass. With this method a volume of oxygenated blood is siphoned from the left heart and pumped into the distal aorta. Flow rates of 2 to 3 L/min appear to provide adequate protection by maintaining a distal perfusion pressure higher than 65 mmHg. This is the preferred method. The left superior pulmonary vein, rather than the left atrium, is cannulated to remove blood from the heart because the vein is tougher and less prone to tearing (Fig. 6-39). The left femoral artery is cannulated to return the blood to the distal aorta. A centrifugal pump is used because it is not as thrombogenic as a roller pump and, strictly speaking, heparinization is not required. This can be a significant benefit in patients with multiple injuries, particularly in those with intracranial hemorrhage. Occasional small cerebral infarcts have occurred, and 5,000 to 10,000 units of heparin usually is administered unless contraindicated by associated injuries.

Once bypass is initiated, the proximal vascular clamp is applied between the left common carotid and left subclavian arteries, and the distal clamp is placed distal to the injury. The left subclavian artery is clamped separately. The hematoma is entered and the injury evaluated. In most patients a short gelatin-sealed Dacron graft is placed, usually 18 to 22 mm in diameter. Primary repair without a graft is possible in some patients. For the anastomoses or suture lines, 3-0 polypropylene suture is used. Air and clot are flushed from the aorta between two clamps and the subclavian artery before tying the final suture. After completion of the repair the clamps are removed and the patient is weaned from the pump. The cannulae are removed, and the vessels are repaired. Meta-analysis comparing the clamp-and-sew and left heart bypass methods revealed a significantly lower incidence of paraplegia when the pump is used.

Injuries of the transverse aortic arch do occur from blunt trauma. The proximal clamp usually can be placed between the innominate and left carotid arteries without cerebral infarction. The proximal clamp, however, cannot be placed proximal to the innominate artery. A possible approach to injuries in which the clamps completely exclude the cerebral circulation is to use profound hypothermia and circulatory arrest.

Small intimal flaps of the thoracic aorta without hematomas can be treated nonoperatively. Intraluminal mediastinal stents also may provide a solution, but their role remains to be defined. Penetrating injuries of the thoracic aorta are rare and do not afford enough time to set up the pump. There is no choice but to use the clamp-and-sew technique with partially occluding clamps, if possible.

Abdomen

All abdominal explorations in adults are performed using a long midline incision because of its versatility. For children under the age of 6 years, a transverse incision may be advantageous. If the patient has been in shock or is currently unstable, no attempt should be made to control bleeding from the abdominal wall until major sources of hemorrhage have been identified and controlled. The incision should be made with a scalpel rather than with an electrosurgical unit, because it is faster. Liquid and clotted blood are rapidly evacuated with multiple laparotomy pads and suction. Additional pads are placed in each quadrant to localize hemorrhage, and the aorta is palpated to estimate blood pressure.

If exsanguinating hemorrhage is encountered on opening the abdomen, it usually is caused by injury to the liver, aorta, inferior vena cava, or iliac vessels. If the liver is the source, the hepatic pedicle should be immediately clamped (a Pringle maneuver) and the liver compressed posteriorly by tightly packing several laparotomy pads between the hepatic injury and the underside of the right anterior chest wall (Figs. 6-40, 6-41). This combination of maneuvers temporarily controls the hemorrhage from most survivable hepatic injuries.

If exsanguinating hemorrhage originates near the midline in the retroperitoneum, direct manual pressure is applied with a laparotomy pad, and the aorta is exposed at the diaphragmatic hiatus and clamped. The same approach is used in the pelvis except that the infrarenal aorta can be clamped, which is easier and safer because splanchnic and renal ischemia are avoided. Injuries of the iliac vessels pose a particular problem for emergency vascular control. Because there are so many large vessels in proximity, multiple vascular injuries are common. Venous injuries are not controlled with aortic clamping. A helpful maneuver in these instances is pelvic vascular isolation (Fig. 6-42). For stable patients with large midline hematomas, clamping the aorta proximal to the hematoma also is a wise precaution. Many surgeons take a few moments, once overt hemorrhage has been controlled, to identify obvious sources of enteric contamination and minimize further spillage. This can be accomplished with a running suture or with Babcock clamps.

Any organ can be injured by blunt or penetrating trauma, but certain organs are injured more often, depending on the mechanism. In blunt trauma, organs that cannot yield to impact by elastic deformation are most likely to be injured. The solid organs—liver, spleen, and kidneys—are representative of this group. For penetrating trauma, organs with the largest anterior surface area are most prone to injury, i.e., the small bowel, liver, and colon. Bullets and knives usually follow straight lines, and adjacent structures are commonly injured, e.g., the pancreas and duodenum. Penetrating trauma is not limited by the elastic properties of the tissue, and vascular injuries are far more common. While these general principles simplify the localization of injuries, unless the patient has exsanguinating hemorrhage, a methodical exploration always should be performed.

Abdominal organs are systematically examined by visualization or palpation. Missed injuries are a serious problem with often fatal results. In penetrating trauma missed injuries can occur if wound tracks are not followed their entire course. Injuries also can be missed if the surgeon fails to explore retroperitoneal structures such as the ascending and descending colon, the second and third portion of the duodenum, and the ureters. Injuries of the aorta or venae cavae may be temporarily tamponaded by overlying structures. If the retroperitoneum is opened and the injury overlooked, delayed massive hemorrhage can occur after abdominal closure. Blunt abdominal injuries usually are obvious, but injuries of the pancreas, duodenum, bladder, and even the aorta can be overlooked.

Vascular Injuries

Injury to the major arteries and veins in the abdomen are a technical challenge to the surgeon and often are fatal. All vessels are susceptible to injury in penetrating trauma. Vascular injuries in blunt trauma are far less common and usually involve the renal arteries and veins, though all other vessels, including the aorta, can be injured. Several vessels are difficult to expose: the retrohepatic vena cava, the suprarenal aorta, the celiac axis, the proximal superior mesenteric artery, the junction of the superior mesenteric, splenic, and portal veins, and the bifurcation of the vena cava. Techniques to aid in the exposure of these vessels have been described. The suprarenal aorta, the celiac axis, and the proximal superior mesenteric and left renal arteries can be exposed by left medial visceral rotation (Fig. 6-43). This is accomplished by incising the left lateral peritoneal reflection beginning at the distal descending colon and extending the incision past the splenic flexure, around the posterior aspect of the spleen, behind the gastric fundus, and ending at the esophagus. This incision permits the left colon, spleen, pancreas, and stomach to be rotated toward the midline. Division of the left crus of the diaphragm permits access to the aorta well above the celiac axis. In contrast, mobilization of the right colon and a Kocher maneuver exposes the entire inferior vena cava except the retrohepatic portion, and it is technically simple. This is referred to as a right medial visceral rotation (Fig. 6-44). The kidney can be left in situ or mobilized with the remaining viscera with right and left medial rotations.

The junction of the superior mesenteric, splenic, and portal veins can be exposed in elective surgery by dissecting the vessels from the pancreas, as required when performing a distal splenorenal shunt. In the presence of massive bleeding from a venous injury, this may be impossible. Therefore, the neck of the pancreas is divided without hesitation. This provides excellent exposure of this difficult area.

The bifurcation of the vena cava is obscured by the right common iliac artery. This vessel should be divided to expose extensive vena caval injuries of this area (Fig. 6-45). The artery must be repaired after the venous injury is treated. Amputation occurs in approximately 50 percent of patients in whom the vessels are not repaired.

Liver

The lower costal margins impair visualization and a direct approach to the liver. Exposure of the right lobe can be improved by elevating the right costal margin with a large Richardson retractor. The right lobe can be mobilized by dividing the right triangular and coronary ligaments. After division of the right triangular ligament, the dissection is continued medially, dividing the superior and inferior coronary ligaments. The right lobe then can be rotated medially into the surgical field. Mobilization of the left lobe is accomplished in the same fashion. Care must be taken when dividing any of the coronary ligaments because of their proximity to the hepatic veins and the retrohepatic vena cava. On occasion it may be necessary to extend the midline abdominal incision into the chest. This is best accomplished with a median sternotomy. The pericardium and diaphragm can be divided toward the center of the inferior vena cava. The combination of incisions provides outstanding exposure of the hepatic veins and retrohepatic vena cava while avoiding injury to the phrenic nerves.

The Pringle maneuver is one of the most useful techniques for evaluating the extent of hepatic injuries (see Fig. 6-40). In patients with extensive hepatic injuries, the Pringle maneuver differentiates between hemorrhage from the hepatic artery and portal vein, which ceases when the clamp is applied, and hemorrhage from the hepatic veins and retrohepatic vena cava, which does not. The authors prefer to manually tear the lesser omentum and place the clamp from the left side while guiding the posterior blade of the clamp through the foramen of Winslow with the aid of the left index finger. This approach has the advantage of avoiding injury to the structures within the hepatic pedicle, assuring

that the clamp will be placed properly the first time, and including any anomalous or accessory left hepatic arteries between the blades of the clamp.

Techniques for the temporary control of hemorrhage from the liver are necessary when dealing with an extensive injury to provide the anesthesiologist with sufficient time to restore circulating blood volume before proceeding, and because it is not possible to control hemorrhage from more than one location in the abdomen simultaneously. The temporary hemostatic techniques that have proved most useful are hepatic compression, the Pringle maneuver, and perihepatic packing. Manual compression of a bleeding hepatic injury may be a lifesaving maneuver (Fig. 6-46). The addition of laparotomy pads on the surface of the liver distributes digital forces and lessens the chance of aggravating the injury. If the lacerated edges of the liver are carefully opposed and the proper forces applied, hemorrhage from almost any hepatic injury can be controlled. The obvious drawback is that considerable skill is required and that little else can be done while the liver is being compressed. Manual compression is best suited for immediate attempts to prevent exsanguination and for periodic control during a complex procedure.

Perihepatic packing also is capable of controlling hemorrhage from most hepatic injuries, and it has the advantage of freeing the surgeon's hands. The laparotomy pads, two or three stacked together, should remain folded. The right costal margin is elevated, and the pads are strategically placed over and around the bleeding site (see Fig. 6-41). Additional pads should be placed between the liver, diaphragm, and anterior chest wall until the bleeding has been controlled. Ten to 15 pads may be required to control the hemorrhage from an extensive right lobar injury. The effectiveness of packing may be enhanced by downward pressure on the right costal margin by an assistant. Packing of injuries of the left lobe is not as effective because there is insufficient abdominal and thoracic wall anterior to the left lobe to provide adequate compression with the abdomen open. Hemorrhage from the left lobe usually can be controlled by mobilizing the lobe and compressing it between the surgeon's hands.

Two complications might be caused by packing hepatic injuries. Tight packing can compress the inferior vena cava and reduce cardiac filling, and the right diaphragm will be forced cephalad, increasing airway pressure and decreasing tidal volume and functional residual capacity. The surgeon must decide whether these complications outweigh the risk of additional blood loss.

Perihepatic packing will not reliably control hemorrhage from larger branches of the hepatic artery. The Pringle maneuver often is used as an adjunct to packing for the temporary control of the arterial hemorrhage. Properly applied, a Pringle maneuver eliminates all hepatopetal flow. The length of time that a Pringle maneuver can remain in place without causing irreversible ischemic damage to the liver is unknown. Several authors have documented a Pringle maneuver applied for over 1 h without appreciable hepatic damage; this is a reasonable figure. Another option for temporary control of hepatic hemorrhage is to use a tourniquet. After mobilization of the bleeding lobe, a 1-inch Penrose drain is wrapped around the liver near the anatomic division between the left and right lobes. The drain is cinched until hemorrhage ceases; tension is maintained by placing a clamp on the drain. Tourniquets are difficult to use, however, because they often slip off or even tear through the parenchyma. An alternative is to use the Lin liver clamp, though it has the same shortcomings as the tourniquet. If successful, the occluding device is removed in 24 h and nonviable tissue is resected.

Special techniques have been developed for controlling hemorrhage from juxtahepatic venous injuries. These formidable procedures include hepatic vascular isolation with clamps, the atriocaval shunt, and the Moore-Pilcher balloon. Hepatic vascular isolation with clamps is accomplished by the application of a Pringle maneuver, clamping the aorta at the diaphragm, and clamping of the suprarenal and suprahepatic vena cava. Although this technique has success in elective procedures, its use in trauma patients has had mixed results because patients in profound hemorrhagic shock do not tolerate the precipitous loss of venous return to the heart.

The atriocaval shunt was designed to achieve hepatic vascular isolation while permitting venous blood to enter the heart from below the diaphragm. Enthusiasm for the shunt has declined as mortality rates with its use range from 50 to 80 percent. The shunt must be precisely constructed and properly positioned on the first attempt because patients with juxtahepatic venous injuries do not tolerate the continuing blood loss associated with repeated unsuccessful attempts to position the shunt correctly. A variation of the original atriocaval shunt has been the substitution of a 9-mm endotracheal tube for the usual large chest tube (Fig. 6-47). While this change may seem trivial, surrounding the suprarenal vena cava for a snare tourniquet is extremely difficult because exsanguinating hemorrhage must be controlled by posterior compression of the liver, which severely restricts access to that segment of the vena cava.

An alternative to the atriocaval shunt is the Moore-Pilcher balloon. This device is inserted through the femoral vein and advanced into the retrohepatic vena cava. When the balloon is inflated, the hepatic veins and vena cava are occluded, thereby achieving vascular isolation. The catheter itself is hollow, and holes placed below the balloon permit blood to flow into the right atrium from the inferior vena cava.

Surgeons attempting hepatic vascular isolation should be aware that none of the techniques provides complete hemostasis. The residual bleeding after successful vascular isolation can be removed readily with suction. Regardless of the technique used, a Pringle maneuver should always be used. Because of the technical challenge and high mortality of hepatic vascular isolation, there has been a trend toward avoiding a direct operative approach to the injured vessels. If massive venous hemorrhage is seen from behind the liver, and, if hemostasis can be achieved with perihepatic packing, the patient can be transferred to the interventional radiology suite, where hemorrhage from arterial sources are embolized and stents are placed to bridge venous injuries (see Fig. 6-26).

Numerous methods for the definitive control of hepatic hemorrhage have been developed. Minor lacerations may be controlled with manual compression applied directly to the injury site. For similar injuries that do not respond to compression, topical hemostatic techniques have been successful. Small bleeding vessels may be controlled with electrocautery, although the power output of the machine may have to be increased. Bleeding surfaces immune to electrocautery may respond to the argon beam coagulator. Microcrystalline collagen can be used. The powder is placed on a clean 4 × 4 sponge and applied directly to the oozing surface. Pressure is maintained for 5 to 10 min. Topical thrombin also can be applied to minor bleeding injuries by saturating a gelatin foam sponge or a microcrystalline collagen pad and applying it to the bleeding site.

Fibrin glue has been used for superficial and deep lacerations and is an effective topical agent. Fibrin glue is made by mixing concentrated human fibrinogen (cryoprecipitate) with bovine thrombin and calcium. Because the coagulum forms quickly, the fibrinogen and thrombin-calcium solution are placed in separate syringes joined with a Y connector. Spray-on applicators also have been used. Enthusiasm has been tempered by reports of fatal anaphylactic reactions and idiopathic hypotension related to an antigenic response to the bovine component.

Suturing of the hepatic parenchyma is an effective hemostatic technique. This treatment has been maligned as a cause of hepatic necrosis, but hepatic sutures often are used for persistently bleeding lacerations less than 3 cm in depth. It also is an appropriate alternative for deeper lacerations if the patient will not tolerate further hemorrhage. The preferred suture is 2-0 or 0 chromic attached to a large, curved, blunt needle. The large diameter of the suture helps to prevent it from pulling through Glisson's capsule. A simple running technique is used to approximate the edges of shallow lacerations. Deeper lacerations can be managed with interrupted horizontal mattress sutures placed parallel to the edge of the laceration. When tying the suture, adequate tension exists when visible hemorrhage ceases or the liver blanches around the suture.

Most sources of venous hemorrhage within the liver can be managed with parenchymal sutures, and even injuries of the retrohepatic vena cava and hepatic veins have been successfully tamponaded by closing the hepatic parenchyma over the bleeding vessel. Venous hemorrhage resulting from penetrating wounds that traverse the central portion of the liver can be managed by suturing the entrance and exit wounds with horizontal mattress sutures. Intrahepatic hematomas might form, which can become infected, though this may be preferable to intracaval shunt or deep hepatotomy. Suturing of the hepatic parenchyma is not always successful in controlling the hemorrhage, particularly when the hemorrhage is of arterial origin.

Hepatotomy with selective ligation of bleeding vessels is an important technique usually reserved for transhepatic penetrating wounds. Hepatotomy is performed using the finger fracture technique. The dissection continues until the bleeding vessels are identified and controlled. Considerable blood loss may be incurred because the division of additional viable hepatic tissue is often required to reach the bleeding vessels. An alternative to suturing the entrance and exit wounds of a transhepatic injury or extensive hepatotomy is the use of an intrahepatic balloon. Our method is to tie a large Penrose drain to a hollow catheter and ligate the opposite end of the drain (Fig. 6-48). The balloon is then inserted into the bleeding wound and inflated with soluble contrast medium. If control of the hemorrhage is successful, a stopcock or clamp is used to occlude the catheter and maintain inflation. The catheter is left in the abdomen and removed at an operation 24 to 48 h later. Recurrent hemorrhage may occur when the balloon is deflated but usually is amenable to selective embolization.

Hepatic arterial ligation may be appropriate for patients with recalcitrant arterial hemorrhage from deep within the liver. Its utility is limited because hemorrhage from the portal and hepatic venous systems continues. Its primary role is in transhepatic injuries when application of the Pringle maneuver results in the cessation of arterial hemorrhage. Arterial ligation is a reasonable alternative to a deep hepatotomy, particularly in unstable patients. While ligation of the right or left hepatic artery is well tolerated, the fate of dearterialized lobe is unpredictable. Lobar necrosis requiring anatomic lobectomy after arterial ligation has been described. Ligation of the proper hepatic artery may not be tolerated.

An uncommon, perplexing hepatic injury is the subcapsular hematoma. This lesion occurs when the parenchyma of the liver is disrupted by blunt trauma, but Glisson's capsule remains intact. The hematoma may be recognized at the time of the surgery or preoperatively if CT is performed, and subsequent decision making is often difficult. Subcapsular hematomas discovered during an exploratory laparotomy that involve less than 50 percent of the surface of the liver and are not expanding or ruptured should be left alone or packed. Hematomas that are expanding during an operation may require exploration. These lesions often are caused by uncontrolled arterial hemorrhage, and packing alone may not be successful. An alternative strategy is to pack the liver to control venous hemorrhage, close the abdomen, and transport the patient to the angiographic suite for hepatic arteriography and embolization of the bleeding vessel. Ruptured hematomas require exploration and selective ligation, with or without packing.

Resectional debridement is indicated for the removal of peripheral portions of nonviable hepatic parenchyma. The mass of tissue removed should rarely exceed 25 percent of the liver. Because additional blood loss may occur, it should be reserved for patients who are in good metabolic condition and who will tolerate additional blood loss. Resectional debridement is performed by finger fracture. An alternative for patients with extensive unilobar injuries is anatomic hepatic resection, but the mortality rate for trauma patients exceeds 50 percent in most series. It has largely been replaced by perihepatic packing, resectional debridement, and hepatotomy with selective ligation and usually is not indicated in the acute setting. There are two circumstances, however, in which anatomic resections are appropriate. The first is when there are extensive injuries of the lateral segment of the left lobe. Because hemorrhage can be easily controlled with bimanual compression, uncontrolled blood loss is not as problematic as with the left or right anatomic lobectomies. Another indication for anatomic lobectomy occurs in patients whose hemorrhage has been controlled by perihepatic packing or arterial ligation but whose left or right lobe is nonviable. The mass of the remaining necrotic liver is large and the risk of subsequent infection high, and it should be removed as soon as the patient's condition permits.

Several centers have reported patients with devastating hepatic injuries or necrosis of the entire liver who have undergone successful hepatic transplantation. The patient must have all other injuries delineated, particularly of the central nervous system, and have an excellent chance of survival excluding the hepatic injury. Cost and donor availability limit such procedures, but it is probable that hepatic transplantation for trauma will continue to be performed in rare circumstances.

Omentum has been used to fill large defects in the liver, with the rationale that it provides an excellent source for macrophages and that it fills a potential dead space with viable tissue. The omentum also can provide some additional support for parenchymal sutures and often is strong enough to prevent them from cutting through Glisson's capsule.

Several prospective and retrospective studies have demonstrated that the use of Penrose or sump drains is associated with a greater risk of intraabdominal sepsis than the use of closed-suction drains or no drains. Drains are not necessary for minor lacerations. They should be used if bile is seen oozing from the liver and in most patients with deep central injuries.

The complications after significant hepatic trauma include hemorrhage, infection, and various fistulas. Postoperative hemorrhage can be expected in a considerable percentage of patients treated with perihepatic packing. The source may be persistent coagulopathy or missed vascular injury. In most instances in which postoperative hemorrhage is suspected, the patient is best served by returning to the operating room. Arteriography with embolization can be considered in selected patients.

Infections within and around the liver occur in about 3 percent of injured patients. Perihepatic infections develop more often in victims of penetrating trauma than blunt trauma, presumably because of the greater frequency of enteric contamination of the former. Persistent elevation of temperature and white blood cell count after the third or fourth postoperative day should prompt a search for intraabdominal infection. In the absence of pneumonia, line sepsis, or urinary tract infection, an abdominal CT scan with intravenous and upper gastrointestinal contrast should be obtained. Many perihepatic infections can be treated with CT-guided drainage. Infected hematomas and infected necrotic liver cannot be expected to respond to percutaneous drainage. Right twelfth rib resection remains an excellent approach for posterior infections and allows superior drainage.

Bilomas are loculated collections of bile that may or may not be infected. If infected, the biloma is essentially an abscess and should be treated as such. If sterile, it will eventually be reabsorbed. Biliary ascites is caused by disruption of a major bile duct. Reoperation with the establishment of appropriate drainage is the prudent course. Even if the source of bile leakage can be identified, primary repair of the injured duct is unlikely to be successful. It is best to wait until a firm fistulous communication is established with adequate drainage.

Biliary fistulas occur in approximately 3 percent of patients with hepatic injuries. They usually are of little consequence and most will close without specific treatment. Rarely, a fistulous communication with intrathoracic structures forms in patients with associated diaphragm injuries and results in a bronchobiliary or pleurobiliary fistula. As a result of the pressure differential between the biliary tract and thoracic cavity, most of these fistulas require operative closure, but the authors have treated a pleurobiliary fistula by endoscopic sphincterotomy with stent placement, which then closed spontaneously.

Hemorrhage from hepatic injuries often is treated without identifying and controlling each individual bleeding vessel; arterial pseudoaneurysms may develop. If the pseudoaneurysm enlarges, it eventually ruptures into the parenchyma of the liver, a bile duct, or an adjacent portal venous branch. Rupture into a bile duct results in hemobilia, which is characterized by intermittent episodes of right upper quadrant pain, upper gastrointestinal hemorrhage, and jaundice. If the aneurysm ruptures into a portal vein, portal venous hypertension with bleeding esophageal varices can occur. These complications are exceedingly rare and are best managed with hepatic arteriography and embolization. Biliovenous fistulas also have been reported. Serum bilirubin rises very rapidly, and extremely high values are common. Sphincterotomy of the papilla of Vater may hasten closure.

Gallbladder and Extrahepatic Bile Ducts

Injuries of the gallbladder are treated by lateral suture or cholecystectomy, whichever is easier. If lateral suture is performed, absorbable suture should be used to prevent the formation of calculi. Injuries of the extrahepatic bile ducts are a challenge. Because of the proximity of the portal vein, hepatic artery, and vena cava, associated vascular injuries are common and the patient's physiologic status is often poor. The ducts are of normal size and texture, i.e., small in diameter and thin-walled. These factors usually preclude primary repairs except for the smallest lacerations with no loss of tissue. These injuries can be treated by the insertion of a T tube through the wound or by lateral suture using 4-0 to 6-0 monofilament absorbable suture. Most transections and any injury associated with significant tissue loss require a Roux-en-Y choledochojejunostomy. The anastomosis is performed using a single-layer interrupted technique, as it is almost impossible to do a running stitch, using 4-0 or 5-0 monofilament absorbable suture. A round patch of seromuscular tissue the size of the common duct is removed from the jejunum at the site of the anastomosis to inhibit wound contraction. The mucosa and submucosa are punctured but not resected. Full-thickness bites of the duct and jejunum are taken. Because of the small size of the duct, only six to eight stitches can be used. T tubes are not placed. The jejunum is then sutured to the areolar tissue of the hepatic pedicle or porta hepatis to relieve tension from the anastomosis.

Injuries of the hepatic ducts are almost impossible to repair satisfactorily under emergency circumstances. One approach is to intubate the duct for external drainage and attempt a repair when the patient recovers. Alternatively, the duct can be ligated if the opposite lobe is normal and uninjured. For patients who are critically ill, the common duct also can be treated by intubation with external drainage.

Spleen

Splenic injuries are treated by splenic repair (splenorrhaphy), partial splenectomy, resection, or nonoperatively, depending on the extent of the injury and the condition of the patient. Enthusiasm for splenic salvage has been driven by the evolving trend toward nonoperative management of solid organ injuries and the rare, but often fatal, complication of overwhelming postsplenectomy infection (OPSI). These infections are caused by encapsulated bacteria, e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, and are very resistant to treatment. OPSI occurs most often in young children and immunocompromised adults. It is uncommon in otherwise healthy adults.

To repair or remove the spleen safely, it should be mobilized to the extent that it can be brought to the surface of the abdominal wall without tension. This requires division of the attachments between the spleen and splenic flexure of the colon. An incision is made in the peritoneum and endoabdominal fascia beginning at the inferior pole, 1 or 2 cm from the spleen, and continuing posteriorly and superiorly until the esophagus is encountered; this is similar to a left medial visceral rotation (Fig. 6-49). Care must be taken not to pull on the posterior aspect of the spleen or it will tear at the peritoneal reflection, causing significant hemorrhage. The spleen should be rotated counterclockwise with posterior pressure applied to expose the peritoneal reflection. It is often helpful to rotate the operating table 20 degrees to the patient's right so that the weight of abdominal viscera aids in their own retraction. A plane can then be established between the spleen and pancreas and the renal fascia (Gerota's fascia) that can be extended to the aorta. This completes mobilization and permits repair or removal of the spleen without struggle for exposure.

Hilar injuries or a pulverized splenic parenchyma usually are treated by splenectomy. The authors have selectively reimplanted six pieces of the spleen (40 × 40 × 3 mm) within the leafs of the omentum. Technetium scans have confirmed their viability. IgM levels have normalized. The patient's response to an antigenic challenge has not been evaluated. Splenectomy also is indicated for lesser splenic injuries in patients with multiple abdominal injuries who have developed a coagulopathy; it usually is necessary in patients with failed splenic salvage attempts. Partial splenectomy can be used in patients in whom only a portion of the spleen has been destroyed, usually the superior or inferior half. After removal of the damaged portion, the same methods used to control hemorrhage from hepatic parenchyma can be used for the spleen. When placing horizontal mattress sutures across a raw edge, gentle compression of the parenchyma by an assistant facilitates hemostasis (Fig. 6-50). After ligation of the sutures and releasing compression, the spleen expands slightly and further tightens the sutures. Drains are never used after completion of the repair or resection. If splenectomy is performed, vaccines against the encapsulated bacteria are administered. The pneumococcal vaccine is routinely given, and those effective against *Haemophilus influenzae* and *Neisseria meningitidis* should be used.

Diaphragm

In blunt trauma the diaphragm is injured on the left in 75 percent of cases, presumably because the liver diffuses some of the energy on the right side. For blunt and penetrating trauma the diagnosis is suggested by an abnormality of the diaphragmatic shadow on chest x-ray. Many of these are subtle, particularly with penetrating injuries, and additional diagnostic evaluation may be warranted. The typical diaphragmatic injury from blunt trauma is a tear in the central tendon that may be large. Acute injuries are repaired through an abdominal incision. The laceration is closed with No. 1 monofilament permanent suture using a simple running technique. Occasionally, large avulsions or shotgun wounds with extensive tissue loss require polypropylene mesh to bridge the defect.

Duodenum

Duodenal hematomas are caused by a direct blow to the abdomen, and they occur more often in children than adults. Blood accumulates between the seromuscular and submucosal layers, eventually causing obstruction. The diagnosis is suspected by the onset of vomiting after blunt abdominal trauma; barium x-ray examination of the duodenum reveals the coiled- spring sign of obstruction. Most duodenal hematomas in children can be managed nonoperatively with nasogastric suction and parenteral nutrition. Resolution of the obstruction occurs in the majority of patients if this therapy is continued for 7 to 14 days. If surgical intervention is necessary, evacuation of the hematoma is associated with equal success and fewer complications than bypass procedures. Despite a lack of existing data on adults, there is no reason to believe that their hematomas should be treated differently from those of children. A new approach is laparoscopic evacuation if the obstruction persists more than 7 days.

Duodenal perforations can be caused by blunt and penetrating trauma (Fig. 6-51). Blunt injuries are difficult to diagnose because the contents of the duodenum have a neutral pH and few bacteria and are often contained by the retroperitoneum. Mortality can exceed 30 percent if the lesion is not identified and treated within 24 h. The perforations are not reliably identified by initial oral contrast CT examinations; therefore, the authors often obtain contrast x-rays with soluble contrast medium followed with barium if necessary. Most perforations of the duodenum can be treated by primary repair. The authors prefer to use a running, single-layer suture of 3-0 monofilament. The wound should be closed in a direction that results in the largest residual lumen. Occasionally, penetrating injuries damage only the pancreatic aspect of the second or third portion. Because the duodenum cannot be adequately mobilized to repair the injury directly, the wound should be extended laterally or the duodenum divided so that the pancreatic aspect can be sutured from the inside. Duodenal repairs or anastomoses do not benefit from adjunctive external drainage.

Challenges arise when there is a substantial loss of duodenal tissue. Extensive injuries of the first portion of the duodenum can be repaired by debridement and anastomosis because of the mobility and rich blood supply of the distal gastric antrum and pylorus. In contrast, the second portion is tethered to the head of the pancreas by its blood supply and the pancreatic and accessory pancreatic ducts (ducts of Wirsung and Santorini) so that the length of duodenum that can be mobilized from the pancreas is limited to approximately 1 cm. Unlike the jejunum, ileum, or colon, this mobilization yields little additional tissue to alleviate tension on suture line. As a result, suture repair of the second portion when tissue is lost often results in an unacceptably narrow lumen, and an end-to-end anastomosis is almost impossible, requiring more sophisticated repairs. For extensive injuries proximal to the accessory papilla, debridement and end-to-end anastomosis are appropriate. For lesions between the accessory papilla and the papilla of Vater, a vascularized jejunal graft, either a patch or a tubular interposition graft, may be required. Experience with these procedures is limited. Duodenal injuries with tissue loss distal to the papilla of Vater and proximal to the superior mesenteric vessels are best treated by Roux-en-Y duodenojejunostomy (Fig. 6-52). The distal portion of the duodenum is oversewn; the jejunum is sutured end-to-end to the proximal duodenum, and the defunctionalized distal duodenum and proximal jejunum are drained into the jejunum. Alternatively, the short defunctionalized duodenum can be resected. This is a rather tedious dissection behind the superior mesenteric vessels that may not be tolerated by a patient who has been in protracted shock.

Injuries to the third and fourth portions of the duodenum with tissue loss pose other problems. Because of the short mesentery of the third and fourth portions of the duodenum, the risk of ischemia limits mobilization. While end-to-end duodenojejunal anastomoses are possible in these regions, the technique used must resemble that of a hand-sewn, low anterior rectal anastomosis with a posterior row of interrupted sutures placed while the ends of the bowel are far apart. The jejunum is then parachuted down to the duodenum, and the anterior row is completed. Duodenal fistulas are common when this method is used. Resection of the third and fourth portions and a duodenojejunostomy on the right side of the superior mesenteric vessels is recommended.

An important adjunct for high-risk or complex duodenal repairs is the pyloric exclusion technique (Fig. 6-53). By occluding the pylorus and performing a gastrojejunostomy, the gastrointestinal stream can be diverted away from the duodenal repair. If a fistula does develop, it is functionally an end fistula, which is easier to manage and more likely to close than a lateral fistula, and the patient can take food by mouth to maintain nutritional status. To perform a pyloric exclusion, a gastrostomy is made on the greater curvature as close to the pylorus as possible. The pylorus is then grasped with a Babcock clamp via the gastrostomy and oversewn with a 0 polypropylene suture. A gastrojejunostomy restores gastrointestinal continuity. Vagotomy is not necessary because marginal ulceration occurs at the same frequency (approximately 3 percent) as duodenal ulceration occurs in the same patient population. Absorbable sutures do not last long enough to be effective, and even heavy polypropylene will give way in 3 to 4 weeks in most patients. A linear staple line across the outside of the pylorus provides the most enduring pyloric closure.

Pancreas

Blunt pancreatic transection at the neck of the pancreas can occur with a direct blow to the abdomen. As an isolated injury, it is more difficult to detect than blunt duodenal rupture, but a missed pancreatic injury is more benign. Because the main pancreatic duct is transected, the patient develops a pseudocyst or pancreatic ascites; there is minimal inflammation because the pancreatic enzymes remain inactivated. The diagnosis occasionally can be made with CT using fine slices through the pancreas. CT will not identify a significant number of transections if performed within 6 h of injury.

Optimal management of pancreatic trauma is determined by the location of the injury and whether or not the main pancreatic duct is injured. Pancreatic injuries in which the pancreatic duct is not injured may be treated by drainage or left alone. In contrast, pancreatic injuries associated with a ductal injury always require treatment to prevent pancreatic ascites or a major external fistula. Direct exploration of perforations or lacerations confirms the diagnosis of a ductal injury in most instances. This leaves a small but significant percentage of patients whom the diagnosis is in doubt and in whom more invasive investigations may be required. One recommendation has been to perform operative pancreatography. This procedure requires direct access to the duct by way of a duodenotomy or after resection of the tail of the pancreas. The duct is cannulated with a 5F pediatric feeding tube, and 2 to 4 mL of full-strength contrast medium is slowly injected; injuries are identified by obstruction or extravasation. Care must be taken to avoid overdistention of the duct with contrast medium, which can produce pancreatitis. The obvious shortcoming of this approach is the creation of a duodenal wound that must heal in a less than optimal environment. While those who advocate transduodenal pancreatography have had few duodenal fistulas, some have occurred. The problems associated with lateral duodenal fistulas are sufficient to dampen enthusiasm for this approach. If the patient already has a duodenal wound in the second portion, the above objections to pancreatography are mitigated.

An expeditious alternative to pancreatography is to pass a 1.5 to 2.0 mm coronary artery dilator into the main duct via the papilla and observe the pancreatic wound. If the dilator is seen in the wound, a ductal injury is confirmed. When inserted through the papilla of Vater, care must be taken to ensure that the dilator enters the pancreatic duct and not the bile duct. This can be determined by palpation of the hepatic pedicle. The limitations of this approach are the same as those for pancreatography.

A third method for identifying pancreatic ductal injuries is the use of *endoscopic retrograde pancreatography (ERP)*. This technique may be difficult to perform in an anesthetized patient in the operating room, but the surgeon can assist by manipulating the duodenum or occluding the distal portion to facilitate air insufflation. ERP is very helpful in the delayed diagnosis of a ductal injury or in those patients who are too sick to explore adequately during the initial operation.

No ideal method exists for identifying pancreatic ductal injuries that cannot be ruled out by direct exploration. This dilemma tends to encourage aggressive local exploration, which may create a ductal injury where none existed. For injuries involving the neck, body, or tail of the pancreas, this is of minor consequence because a simple resection distal to the injury cures the lesion. This is not the case for injuries to the head of the pancreas, which cannot be treated with a simple resection. Rather than accepting the risks of pancreatography or aggressive local exploration, a final option for identifying ductal injuries in the head of the pancreas is to do nothing other than drain the pancreas (Fig. 6-54). If a pancreatic fistula or pseudocyst develops, the diagnosis is confirmed. The majority of pancreatic fistulas close spontaneously with only supportive care. The authors prefer this approach to operative pancreatography when the diagnosis of ductal injury in the head of the pancreas is not apparent and *ERP* is not promptly available.

Several options are available for treating injuries of the neck, body, and tail of the pancreas when the main duct is transected. Distal pancreatectomy with splenectomy has been the preferred approach, but increasing interest in splenic preservation has stimulated the use of the splenic-preserving distal pancreatectomy. This procedure is performed by dissecting the pancreas from the splenic vein. Another method for splenic preservation is to bury the distal transected end of the pancreas in a Roux-en-Y limb. This technique also conserves the distal pancreas but is seldom performed because of the added complexity of the Roux-en-Y and the risks of pancreatojejunostomy.

For injuries to the head of the pancreas that involve the main pancreatic duct but not the intrapancreatic bile duct, there are few options. Distal pancreatectomy is rarely indicated because the risk of pancreatic insufficiency is significant if more than 85 to 90 percent of the gland is resected. A more limited resection from the site of the injury to the neck of the pancreas, with preservation of the pancreaticoduodenal vessels and common duct, allows closure of the injured proximal pancreatic duct. Pancreatic function can then be preserved by a Roux-en-Y pancreatojejunostomy with the distal pancreas (Fig. 6-55).

In contrast to injuries of the pancreatic duct, diagnosis of injuries to the intrapancreatic common bile duct is simple. The first method is to squeeze the gallbladder and observe the pancreatic wound. If bile is seen leaking from the pancreatic wound, the presence of an injury is established. Operative cholangiography is diagnostic in questionable cases. If a patient with an intrapancreatic bile duct injury is critically ill from hemorrhage, external drainage can be used until the patient is fit for definitive treatment. Small tangential perforations of the intrapancreatic bile duct may heal with this treatment, but it is seldom recommended. Most authorities advocate division of the common bile duct superior to the first portion of the duodenum, ligation of the distal common duct, and reconstruction with a Roux-en-Y choledochojejunostomy.

The use of drains has played an important role in the management of pancreatic injuries. Many authorities advocate routine drainage of all pancreatic injuries, but the authors do not drain contusions, lacerations in which the probability of a major ductal injury is small, or pancreatic anastomoses. Pancreatic injuries should be drained when there is a possible unidentified major ductal injury. If a drain is desirable, prospective studies have demonstrated that closed-suction devices are associated with fewer infectious complications than sump or Penrose drains. Almost all pancreatic fistulas close spontaneously. Nutritional support is important, and electrolyte replacement may be necessary.

Pancreaticoduodenal Injuries

Because the pancreas and duodenum are in physical contact, combined pancreaticoduodenal injuries are not uncommon, particularly in penetrating trauma. These lesions are dangerous because of the risk of duodenal suture line dehiscence and the development of a lateral duodenal fistula. The simplest treatment is to repair the duodenal injury and drain the pancreatic injury. This method is appropriate for combined injuries without major duodenal tissue loss and without pancreatic or biliary ductal injuries. With more extensive injuries, consideration should be given to providing additional protection for the duodenal suture line. The authors prefer pyloric exclusion to other alternatives.

While most pancreatic and duodenal injuries can be treated with relatively simple procedures, a few require extensive operations, such as pancreatoduodenectomy (Fig. 6-56). Examples of such injuries include transection of the intrapancreatic bile duct and the main pancreatic duct in the head of the pancreas, avulsion of the papilla of Vater from the duodenum, and destruction of the entire second portion of the duodenum. Most injuries of that nature are caused by higher-energy gunshot wounds. In patients with a pancreaticoduodenal injury who also have an intrapancreatic bile duct injury, it is possible to use the combination of a pyloric exclusion and Roux-en-Y choledochojejunostomy to avoid a pancreatoduodenectomy. The complexity and unpredictable physiology of the combined procedures makes the pancreatoduodenectomy more attractive.

Colon

There are three conceptually different methods for treating colonic injuries: primary repair, colostomy, and exteriorized repair. Primary repairs include lateral suture of perforations and resection of the damaged colon with reconstruction by ileocolostomy or colocolostomy. The advantage of primary repairs is that definitive treatment is carried out at the initial operation. The disadvantage is that suture lines are created in suboptimal conditions, and leakage may occur. Several different styles of colostomies are used to manage colonic injuries. In some instances, the injured colon can be exteriorized like a loop colostomy. The injured area can be resected and an end colostomy or ileostomy performed; the distal colon can be brought to the abdominal wall as a mucous fistula or oversewn and left in the abdominal cavity. A loop colostomy can be created proximal to a suture line that is left in the abdominal cavity.

The advantage of colostomy is that it avoids an unprotected suture line in the abdomen. The disadvantage is that a second operation is required to close the colostomy. Often overlooked disadvantages are the complications associated with the creation of a colostomy, some of which may be fatal. Exteriorized repairs are created by the suspending of a repaired perforation or anastomosis on the abdominal wall with an appliance after the fashion of a loop colostomy. If after 10 days the suture line does not leak, it can be returned to the abdominal cavity under local anesthesia without subsequent risk of leakage. If the repair breaks down before 10 days, it is treated as a loop colostomy. Healing is successful in 50 to 60 percent of cases. The advantage is avoidance of an intraperitoneal suture line when it is at risk of leakage, and the disadvantage is that 40 to 50 percent of patients require colostomy closure. Stomal complications similar to those of colostomies also can occur with the exteriorization.

Numerous large retrospective and several prospective studies have demonstrated that primary repair is safe and effective in the majority of patients with penetrating injuries. Colostomy is appropriate in a few patients but the current dilemma is how to select them. Exteriorized repair is no longer indicated because most patients who were once candidates for this treatment are successfully managed by primary repair. Two methods have been advocated that result in 75 to 90 percent of penetrating colonic injuries being safely treated by primary repair. The first is to repair all perforations that do not require resection. If resection is required because of the local extent of the injury and it is proximal to the middle colic artery, the proximal portion of the right colon up to and including the injury is resected and an ileocolostomy performed. If resection is required distal to the middle colic artery, an end colostomy is created and the distal colon oversewn and left within the abdomen. Ileocolostomy heals more reliably than colocolostomy because, in the trauma patient who has suffered shock and may be hypovolemic, assessing the adequacy of the blood supply of the colon is much less reliable than in elective procedures. The blood supply of the terminal ileum is never a problem. Another approach is to repair all injuries regardless of the extent and location (including colocolostomy) and reserve colostomy for patients with protracted shock and extensive contamination. Systemic factors are more important than local factors in determining whether a suture line heals. Both of these approaches are reasonable and result in the majority of patients being treated by primary repairs. When a colostomy is required, performing a loop colostomy proximal to a distal repair should be avoided because a proximal colostomy does not protect a distal suture line. All suture lines and anastomoses are performed with the running single-layer technique described in Fig. 6-57.

Complications related to the colonic injury and its treatment may include intraabdominal abscess, fecal fistula, wound infection, and stomal complications. Intraabdominal abscess occurs in approximately 10 percent of patients, and most are managed with percutaneous drainage. Fistulas occur in 1 to 3 percent of patients and usually present as an abscess or wound infection, which, after drainage, is followed by continuous fecal output. Most colonic fistulas heal spontaneously. Wound infection can be effectively avoided by leaving the skin and subcutaneous tissue open and relying on healing by secondary intention. The skin can be closed primarily in approximately 60 percent of patients without developing an infection. This treatment should be reserved for injuries with little contamination and in patients with minimal blood loss and little subcutaneous fat.

Stomal complications include necrosis, stenosis, obstruction, and prolapse. Taken together they occur in approximately 5 percent of patients, and most require reoperation. Necrosis is a serious complication that must be recognized and treated promptly. Failure to do so can result in life-threatening septic complications, including necrotizing fasciitis.

Rectum

Rectal injuries are similar to colonic injuries with respect to the ecology of the luminal contents, the structures and blood supply of the wall, and the nature and frequency of complications. They differ in two important ways: mechanisms of injury and accessibility. The rectum is often injured by gunshot wound, rarely by stab wound, and frequently by acts of autoeroticism and sexual misadventure. The rectum also is subject to high-pressure injuries that can be caused by air guns or water under high pressure, as used in golf course irrigation systems. The second difference is limited access to the rectum because of the surrounding bony pelvis.

The diagnosis is suggested by the course of projectiles, the presence of blood on digital examination of the rectum, and history. Patients in whom a rectal injury is suspected should undergo proctoscopy. Hematomas, contusions, lacerations, and gross blood may be seen. If the diagnosis is in question, x-ray examinations with soluble contrast medium enemas are indicated. It may be difficult to determine whether an injury is present. These patients should be treated as though an injury were present.

The portion of the rectum proximal to the peritoneal reflection is referred to as the intraperitoneal segment, and that portion distal to the reflection as the extraperitoneal segment. This distinction is blurred somewhat because the broad posterior aspect of the intraperitoneal portion could be considered as either. Injuries of the intraperitoneal portion (including its posterior aspect) are treated as previously outlined in the section on colonic injuries. Access to extraperitoneal injuries is so restricted, especially in the narrow male pelvis, that indirect treatment usually is required. While colostomies proximal to a suture line are avoided in patients with colonic injuries, there is often no option in patients with extraperitoneal injuries; sigmoid colostomies are appropriate for most patients. Properly constructed loop colostomies are preferred because they are quick and easy to fashion, and they provide total fecal diversion. Essential elements include: (1) adequate mobilization of the sigmoid colon so that the loop rests on the abdominal wall without tension; (2) maintenance of the spur of the colostomy (the common wall of the proximal and distal limbs after maturation) above the level of the skin with a 1 cm nylon rod or similar device; (3) longitudinal incision in the taeniae coli; and (4) immediate maturation in the operating room using 3-0 braided absorbable suture (Fig. 6-58). A staple line can be applied across the distal limit to ensure complete diversion, but it is not necessary, and it complicates closure of the colostomy. A mucous fistula is never required and should be avoided because of the risk of necrosis if the inferior mesenteric or superior rectal arteries were injured or otherwise ligated.

If a perforation is inadvertently uncovered during dissection, it should be repaired as described previously. Otherwise, it is not necessary to explore the extraperitoneal rectum to repair perforation. It may be extremely difficult or impossible to accomplish exploration. If the injury is so extensive that it must be repaired, the rectum is divided at the level of injury, the distal rectum is oversewn or stapled, and an end colostomy is created (Hartmann's procedure). In rare instances in which the anal sphincters have been destroyed, an abdominoperineal resection may be necessary.

Extraperitoneal injuries of the rectum should be drained via a retroanal incision (see Fig. 6-58). Waldeyer's fascia is particularly tough at this level and may need to be sharply incised. The drains, Penrose or closed-suction, should be placed close to the perforation or suture line and left until they fall out spontaneously or drainage diminishes, which usually occurs within 7 to 10 days. Irrigation of the distal rectum with various solutions is advocated by some authorities; this has not been determined to be helpful or harmful in retrospective studies, but it may be of benefit in a patient whose rectum is full of feces. If it is done, the irrigation solution should be isotonic and the anus should be mechanically dilated to avoid building up pressure that might force feces out of an unrepaired perforation. If the patient has a concomitant bladder injury and adjacent suture lines are created, a flap of viable omentum should be placed between them to reduce the risk of a rectovesical fistula.

There have been reports of treating small extraperitoneal rectal injuries by suture or drainage alone. The outcomes have been acceptable, and colostomies have been avoided. There is insufficient experience to recommend this approach because pelvic sepsis associated with rectal injury is highly lethal.

Complications of rectal injuries are similar in nature and frequency to those of colonic injuries. Pelvic osteomyelitis also may occur. Bone biopsy and bacteriology should be performed to secure the diagnosis. Culture-specific intravenous antibiotics should be administered for 2 to 3 months. Debridement might be necessary.

Stomach and Small Intestine

Injuries of the stomach and small bowel pose no special problems or controversies. Gastric injuries can be missed occasionally if a wound is located within the mesentery of the lesser curvature or high in the posterior fundus. The stomach should be clamped at the pylorus and inflated with air or methylene-blue-colored saline solution if there is any question. Patients with injuries that damage the nerves of Latarjet or both vagus nerves should have a drainage procedure. If the distal antrum or pylorus is severely damaged it can be reconstructed with a Billroth I or II procedure. A running two-layer suture line is preferred for the stomach because of its rich blood supply and because postoperative hemorrhage has occurred when the single-layer technique has been used in the stomach.

There are no special issues in treating injuries of the small bowel. Wounds of the mesenteric border can be missed if the exploration is not comprehensive. Most injuries are treated with a lateral single-layer running suture. Multiple penetrating injuries often occur close together. Rather than performing many lateral repairs, judicious resections with end-to-end anastomosis can save considerable time.

Kidneys

Three imaging techniques—CT, *intravenous pyelography (IVP)*, and arteriography—can be used to evaluate accurately the extent of renal injury. The contrast medium required for each is nephrotoxic and limits the number of studies that can be performed. The fact that there are two identical organs makes the sacrifice of one a viable therapeutic option. Nearly 95 percent of all blunt renal injuries are treated nonoperatively. The diagnosis is suspected by the finding of microscopic or gross hematuria and confirmed by CT or IVP. Most cases of urinary extravasation and hematuria resolve in a few days with bed rest. Persistent gross hematuria can be treated by embolization. Persistent urinomas can be drained percutaneously. Operative treatment is necessary occasionally for similar lesions that do not respond to these less invasive measures.

If a perinephric hematoma is encountered during laparotomy from blunt trauma, exploration is indicated if it is expanding or pulsatile. Very large hematomas should be explored because of the risk of a major vascular injury. Vascular control at the junction of the renal vessels with the aorta and vena cava is not always necessary before entering the hematoma. If emergent vascular control is needed, a large curved vascular clamp can be placed easily across the hilum from below with the clamp parallel to the vena cava and aorta.

Hemostatic and reconstructive techniques used to treat blunt renal injuries are similar to those used to treat the liver and spleen. The collecting system should be closed separately and the renal capsule preserved to close over the repair of the collecting system (Fig. 6-59). Permanent sutures should be avoided because of the risk of calculus formation. The authors prefer absorbable monofilament sutures because of their lack of abrasiveness. If nephrectomy is being considered and the status of the opposite kidney is unknown, the latter should be palpated. The presence of a palpably normal opposite kidney is assurance that the patient will not be rendered anephric by a unilateral nephrectomy. Unilateral renal agenesis occurs in 1/1000 patients.

The renal arteries and veins are uniquely susceptible to traction injury caused by blunt trauma. As the artery is stretched, the inelastic intima and media may rupture. This causes thrombus formation, resulting in high-grade stenosis or thrombosis. The injury can be detected by CT, *IVP*, or duplex scanning. If the patient does not have more urgent injuries and treatment and repair can be accomplished within 3 h of admission, it should be attempted. Successful renal artery repair in a patient who presents with complete thrombosis is rare. If repair is not possible within this time frame, leaving the kidney in situ to resorb does not necessarily lead to hypertension or abscess formation. Isolated renal vein injuries can occur from blunt trauma. The vein may be torn or avulsed from the vena cava, and a large hematoma develops that often leads to an operation and nephrectomy.

All penetrating wounds to kidneys are explored. Bleeding perforations and lacerations are treated using the same hemostatic techniques described above. Renal vascular injuries are common after penetrating trauma, and they may be deceptively tamponaded and result in delayed hemorrhage. Injuries involving the collecting system should be closed separately if they are large. Small perforations that penetrate the collecting system can be controlled by suture of the capsule and parenchyma. Perforations of the renal pelvis should be meticulously repaired with fine sutures.

Ureters

Injuries of the ureters from external trauma are rare. They occur in a few patients with pelvic fractures and are uncommon in penetrating trauma because the silhouette they present is so small. The diagnosis in blunt trauma may be made by CT, *IVP*, or retrograde ureterography. The injury often is not identified until a complication, e.g., a urinoma, is apparent. In penetrating trauma, ureteral injuries are discovered during the exploration of the retroperitoneum, although missed injuries also are not unusual. If an injury is suspected but not identified, methylene blue or indigo carmine is administered intravenously. Staining of the tissue adjacent to the injury can facilitate identification of the injury site. Most injuries can be repaired primarily using the same technique as that described earlier for small arteries, using 5-0 absorbable monofilament suture. When the ureter is mobilized, the dissection should be at least 1 cm lateral and medial to the ureter to avoid injury to its delicate vascular plexus. The kidney also can be mobilized to increase ureteral mobility. Injuries of the distal ureter can be treated by reimplantation. The psoas hitch and Boari flap may be helpful in selected distal ureteral injuries (Fig. 6-60). If the patient is critically ill and being considered for a staged laparotomy or if the surgeon is uncomfortable with ureteral repair, the ureter can be ligated on both sides of the injury and a nephrostomy performed (Fig. 6-61).

Bladder

Bladder injuries are diagnosed by cystography, CT, or during laparotomy. A postvoid view enhances the accuracy of cystography. Blunt ruptures of the intraperitoneal portion are closed with a running single-layer closure using 3-0 absorbable monofilament suture. Blunt extraperitoneal rupture is treated with a Foley catheter; direct operative repair is not necessary. Cystograms can be used to determine when the catheter can be removed, which is usually in 10 to 14 days. Penetrating bladder injuries are treated in the same fashion, although injuries near the trigone should be repaired through an incision in the dome so that iatrogenic injury to the intravesicular ureter is avoided by direct visualization.

Urethra

Blunt disruption of the posterior urethra is managed by bridging the defect with a Foley catheter. This usually requires passing catheters through the urethral meatus and through an incision in the bladder. Once the catheter bridges the defect, healing occurs as the intervening hematoma resorbs. Strictures are not uncommon but can be managed electively. Penetrating injuries are treated by direct repair.

Gynecologic Injuries

Gynecologic injuries are rare. Occasionally, the vagina is lacerated by a sharp bone fragment from a pelvic fracture. Penetrating injuries to the vagina, uterus, fallopian tubes, and ovaries also are uncommon. The usual hemostatic techniques are used to control bleeding, and suture repair is used to close defects that communicate with a lumen. Repair of a transected fallopian tube can be attempted but probably is unjustified; a suboptimal repair increases the risk of tubal pregnancy. Transection at the injury site with proximal ligation

and distal salpingectomy is a more prudent approach.

Trauma in pregnancy also is rare. Blunt trauma can cause uterine rupture, which almost always results in fetal demise. The outcome of penetrating uterine injuries is more variable and is dependent on penetration of the uterine cavity, damage to the placenta, and fetal injury. Spontaneous abortion is a frequent outcome. On occasion, a mother presents with life-threatening injuries, including severe head injury or cardiac arrest from hemorrhagic shock. If the fetus is viable by dates or examination, an emergency cesarean section should be considered whether or not the mother's life can be saved. This occurs more often with severe head injury than cardiac arrest from hemorrhagic shock.

Completion of the Laparotomy and Postoperative Considerations

After repair of all injuries, the abdomen is irrigated with saline warmed to body temperature. This will not eliminate all bacteria, but an effort should be made to remove blood clots, food particles, and gross enteric and fecal contamination.

Patients with moderate to severe injuries are at risk for multiple organ failure and nosocomial infection. The integrity of the gut has a pivotal role in the severity and outcome of these complications. Needle-catheter jejunostomies are placed in all such patients before abdominal closure (Fig. [6-62](#)). Enteric feedings are initiated as soon as the patient arrives in the intensive care unit and are advanced to full strength within 72 h. Total parenteral nutrition might be necessary in some patients, but it causes mucosal atrophy, which may impair the barrier function of the mucosa.

The abdominal incision is closed with a running No. 2 nylon suture that includes at least 1.5 cm of fascia. Tension of the suture should be just enough to approximate the fascia but no more. Subcutaneous sutures are never used. The skin is closed selectively, depending on the amount of contamination and subcutaneous tissue. The greater the degree of contamination and subcutaneous fat, the more frequently the skin and subcutaneous tissue should be left open. Patients initially treated with staged laparotomy should have the skin and subcutaneous tissue left open.

Pelvis

Pelvic fractures can cause exsanguinating retroperitoneal hemorrhage without associated major vascular injury; branches of the internal iliac vessels and the lower lumbar arteries are often responsible. Hemorrhage also comes from small veins and from the cancellous portion of the fractured bones. A direct surgical approach is rarely effective because many of the sources of hemorrhage are outside of the surgical field. Most pelvic fractures that cause life-threatening hemorrhage involve disruption of the posterior elements, i.e., the sacroiliac joints and associated ligaments, and are often biomechanically unstable.

A hemodynamically unstable patient with an unstable pelvic fracture may be bleeding from sources other than the pelvis, such as the spleen. Large retroperitoneal hematomas also can cause a hemoperitoneum, particularly if overlying peritoneum ruptures. Determining the source of hemorrhage poses a therapeutic problem because it is desirable not to operate for a retroperitoneal hematoma, whereas a laparotomy may be essential to deal with hemorrhage from the spleen or liver. Ultrasonography and *DPL* have been used to aid in this decision. If 10 mL or more of free blood can be aspirated from the peritoneal cavity, or if the ultrasound scan is unequivocally positive, then the blood is assumed to be coming from an injury unrelated to the pelvic fracture, and a laparotomy is performed. If the DPL is positive by laboratory analysis or if it is negative, attention is directed toward treating the pelvic fracture. The decision to operate or not may prove to have been the wrong course, and the plan may need to be altered accordingly.

Several methods have been used to control hemorrhage associated with pelvic fractures. These include immediate external fixation, medical antishock trousers (MAST), angiography with embolization, and pelvic packing. No single technique is effective for treating all fractures, and there is little agreement among specialists as to which should be used. Anterior external fixation is not intended to provide definitive fracture stabilization in most instances. Its advocates intend for the device to decrease pelvic volume, to tamponade bleeding, and to prevent secondary hemorrhage that may occur if the fractured bones shift. Many orthopaedic surgeons are unconvinced of the efficacy of external fixation for grossly unstable posterior fractures. Antishock trousers can provide some stability for the fracture and probably tamponade venous hemorrhage. The disadvantages are the loss of access to the abdomen and the risk of lower-extremity compartment syndrome. Angiography with embolization is very effective for controlling arterial hemorrhage, but arterial hemorrhage occurs in only 10 to 20 percent of patients with active hemorrhage from pelvic fractures. Pelvic packing may control venous hemorrhage. The only reason to consider its use is when a pelvic hematoma is inadvertently entered or if it has ruptured. An algorithm for managing patients is shown in Fig. [6-63](#).

Another challenge is the open pelvic fracture. In many instances the wounds are located in the perineum, and the risk of pelvic sepsis and osteomyelitis is high. To reduce the risk of infection, a sigmoid colostomy is recommended. The pelvic wound is manually debrided and irrigated daily with a high-pressure pulsatile irrigation system until granulation tissue covers the wound. The wound is then left to heal by secondary intention. This approach has been highly successful.

Extremities

Vascular Injuries with Fractures

Vascular injuries associated with fractures are rare, occurring in only 0.5 to 3 percent of all patients with extremity fractures. They also are more severe than isolated vascular injuries or fractures, and amputation rates of more than 50 percent have been noted. These injuries can be caused by blunt and penetrating trauma. Particular fractures and dislocations are more likely to be associated with vascular injury than others. In the upper extremity, a fracture of the clavicle or the first rib may lacerate the distal subclavian artery. The axillary artery may be injured in patients with dislocations of the shoulder or proximal humeral fractures. Supracondylar fractures of the distal humerus and dislocations of the elbow are known for their association with brachial artery injuries. In all these fractures and dislocations, vascular injuries are uncommon and occur in only a small fraction of patients.

In the lower extremity, the orthopaedic injury most commonly associated with vascular injury is dislocation of the knee, in which the popliteal artery or vein may be injured in as many as 30 percent of patients. The popliteal vessels also may be injured in patients with supracondylar fractures of the femur or tibial plateau fractures. Vascular injury can occur in patients with combined fractures of the tibia and fibula.

The importance of a careful neurologic examination in these patients is critical. Three distinctly different mechanisms can produce paralysis and numbness in an injured extremity: ischemia, nerve injury, and compartment syndrome. As a result, failure to accurately perform and document the neuromuscular function of the injured extremity can lead to missed injuries, improper treatment, and unrealistic expectations on the part of the patient.

Perhaps the greatest controversy in the treatment of patients with combined orthopaedic and vascular injuries is the order in which the procedures are to be performed. Advocates of initial fracture treatment argue that it is difficult to judge the length of a vascular graft (or whether one is required) when the ends of the fractured bone are overriding or if angulation is present. Also, extensive orthopaedic manipulation can easily disrupt delicate vascular repairs. Opponents of this approach argue that the length of time required to stabilize the fracture may cause further ischemic damage of the limb. The use of temporary intravascular shunts has been recommended as a compromise to avoid ischemia during fracture treatment.

A rational approach is to consider all the above options in light of the condition of the patient's injured extremity. If the extremity is clearly viable and there is no hemorrhage from the vascular injury, the fracture should be treated first. If the limb is at risk from ischemia, prompt revascularization is required. When little or no fracture manipulation is anticipated, definitive vascular repair is performed first. If extensive manipulation is required in an ischemic extremity, temporary shunts can be placed and vascular repair performed after the fracture has been treated (Fig. [6-64](#)).

The extent of injury causing combined orthopaedic and vascular injuries frequently results in open fractures, and the use of external fixation devices for these injuries has become common. These devices may significantly hinder vascular repair because of their location and bulk. Preoperative planning between the vascular and orthopaedic surgeon should serve to avoid this technical problem.

Because of the severity of combined orthopaedic and vascular injuries, the need for immediate amputation might arise. Primary amputation should be strongly considered when the primary nerve is transected in addition to a fracture and arterial injury—such as when the popliteal nerve is transected along with injuries to the popliteal artery and the distal femur. This difficult decision is best reached through a collaborative effort involving the trauma surgeon, the orthopaedic surgeon, and, in certain cases, the neurosurgeon. Prolonged rehabilitation resulting in a paralyzed, anesthetic extremity prone to ulceration is hardly better than the prompt fitting of a good prosthesis.

Compartment Syndrome

A compartment syndrome can occur anywhere in the extremities, including the thighs, buttocks, arms, and hands. The pathophysiology is an acute increase in pressure in a closed space that impairs blood flow to the structures within. The causes of extremity compartment syndrome include arterial hemorrhage into a compartment, venous ligation or thrombosis, crush injuries, infections, crotalid envenomation, and ischemia/reperfusion. In conscious patients, pain is the prominent symptom. Active or passive motion of involved muscles increases the pain. Progression to paralysis can occur. The most frequent site is in the anterior compartment of the leg; a well-described early sign is paresthesia or numbness between the first and second toes caused by pressure on the deep peroneal nerve.

In comatose or obtunded patients, the diagnosis is more difficult to secure. A compatible history, firmness of the compartment to palpation, and diminished mobility of the joint are suggestive. The presence or absence of a pulse distal to the affected compartment is notoriously unreliable in the diagnosis of a compartment syndrome. A frozen joint and myoglobinuria are late signs and suggest a poor prognosis. Compartment pressure can be measured. The small, hand-held Stryker manometer is a convenient tool for this purpose. Pressures greater than 45 mmHg usually require operative intervention. Pressures between 30 and 45 mmHg should be carefully evaluated and watched closely.

Treatment consists of measures to reduce compartment pressure, including elevation of the extremity, evacuation of hematomas, and fasciotomy. As long as neurologic and muscular function are intact, elevation and observation are sufficient. The evacuation of hematomas as a consequence of arterial injury almost always results in a fasciotomy, because the compartment must be opened to treat the vascular injury. Because the lower extremity is most frequently involved, the two-incision, four-compartment fasciotomy is shown in Fig. [6-65](#). Note that the soleus muscle must be detached from the tibia to decompress the deep flexor compartment.

Prognosis is related to the severity, duration, and cause of the compartment syndrome. The best results are obtained in patients with arterial hemorrhage and venous ligation or thrombosis who undergo early fasciotomy. Those who develop compartment syndrome from crush injuries, crotalid envenomation, and particularly ischemia/reperfusion have a poor prognosis because of the preexisting muscle and nerve damage caused by the original insult. Fasciotomy should be attempted, although infection and amputation are a frequent outcome.

Prognosis and Outcome Evaluation

Prognosis and outcome evaluation for various injuries began during World War I. At that time, mortality was calculated according to the organ injured. For example, all patients who

suffered an injury to the colon were determined to have lived or died. Accordingly, frequency of death was assigned to that particular organ, and it was assumed that any patient with a colonic injury had the same probability of dying. Because no other factors such as associated injuries or physiologic condition were considered, it is not surprising that any abdominal visceral injury was associated with a mortality rate of 50 to 60 percent. This practice continued during World War II and resulted in some remarkable conclusions that were subsequently shown to be incorrect. Perhaps the best example of this was the conclusion that performing colostomies for all colonic injuries during World War II resulted in a reduction of mortality for patients so treated from 60 percent during the first World War I to 30 percent in World War II. Civilian literature in the second half of this century recognized that the number of injured organs, major fractures, blood loss, and the presence of shock were all predictive of outcome but only in the crudest fashion. The quality of the local EMS system is another confounding factor. Regions with rapid response and transport are more likely to bring severely injured patients to the emergency room with signs of life than less efficient systems. As a result, mortality is paradoxically greater in regions with better EMS systems.

Today there are anatomic and physiologic grading systems. The anatomic systems are derived from the Abbreviated Injury Scale (AIS), which was developed during the 1950s. The AIS is a list that assigns a number from 1 (minor injury) to 6 (always fatal) for the various spectra of organ injuries. The AIS evaluates only solitary injuries; it cannot reflect the additional impact of multiple injuries. The Injury Severity Score (ISS) was devised to supplement this shortcoming. The ISS is calculated by squaring the AIS from the worst injured of three body compartments (head and neck, face, chest, abdomen and pelvis, pelvic girdle, and extremities) and adding them together. With the always-fatal score of 6 excluded, scores can range from 1 to 75. ISS is further characterized according to the mechanism of injury (blunt versus penetrating) and age (less than 55 years versus 55 years or greater). The ISS, however, suffers from the inability to consider multiple injuries in one compartment, the assumption that all compartments are of equal significance, and the lack of recognition of the patient's physiologic status. Several physiologic scoring systems have been developed. The Revised Trauma Score (RTS) is most commonly used. It is calculated from the Glasgow Coma Scale, blood pressure, and respiratory rate, with the GCS being most heavily weighted. The RTS is a purely physiologic score that is compromised by the relative insensitivity of these common clinical measurements. The TRISS method (Trauma and Injury Severity Score) was developed to incorporate the RTS and ISS, thereby combining physiologic and anatomic score and enhancing the importance of head injury. TRISS remains fundamentally flawed because of the limitations of RTS and ISS. Newer versions of the TRISS concept, such as ASCOT (A Severity Characterization of Trauma), also have failed to improve the prediction of postinjury mortality. Perhaps more important than mortality, outcome assessment must include the critical issues of total medical resource consumption (complications, hospital length of stay, cost for medical care, etc.) and capacity to return to preinjury functional status. Several functional outcome scales have been developed, but a standard has yet to be established.

BITES AND STINGS OF ANIMALS AND INSECTS

Rabies

In 1950 approximately 5000 cases of rabies were reported among dogs and 18 were reported in humans. Only 160 cases of rabies in dogs were reported in 1989. In 1991 there were three patients in the United States who died from rabies. Wild animals, therefore, constitute the most important potential source of infection for humans and domestic animals in the United States; however, the exposure that results from frequent contact between domestic dogs and humans continues to be the basis of most antirabies treatment.

Approximately 10,000 patients receive postexposure prophylaxis for rabies annually. Rabies among wild animals, especially skunks, foxes, raccoons, and bats, account for more than 85 percent of known cases of animal rabies. Although any mammal may carry rabies, rodents are seldom found to be infected with rabies and have not been known to cause rabies in human beings in the United States. Woodchucks accounted for 70 percent of rabies among rodents reported to the Centers for Disease Control and Prevention (CDC). In all cases involving rodents, the state or local health department should be consulted before a decision is made to initiate postexposure antirabies prophylaxis. Many of the cases of human rabies reported in the past 10 years have resulted from exposure outside of the United States; in much of the rest of the world the dog is the major species with rabies and the major source of rabies among human beings.

Circumstances surrounding the attack frequently furnish vital information as to whether or not vaccination is indicated. Most domestic animal bites are provoked attacks; if this history is obtained, rabies vaccine usually can be withheld if the animal appears healthy. Children are frequently bitten while attempting to separate fighting animals or while teasing or accidentally hurting the animal. Bites during attempts to feed or handle an apparently healthy animal are generally regarded as provoked. Postexposure prophylaxis combining local wound treatment, passive immunization, and vaccination is over 90 percent effective when appropriately applied. An unprovoked attack by a domestic animal is more likely than a provoked attack to indicate that the animal is rabid. A fully vaccinated dog or cat is unlikely to become infected with rabies, although rare cases have been reported.

Any penetration of the skin by teeth constitutes a bite exposure. Bites to the face and hands carry the highest risk, but the site of the bite should not influence the decision to begin treatment. Nonbites include scratches, abrasions, open wounds, or mucous membranes contaminated with saliva. If the material containing the virus is dry, the virus can be considered noninfectious. Other contact by itself, such as petting a rabid animal and contact with the blood, urine, or feces of a rabid animal, does not constitute an exposure and is not an indication for prophylaxis.

Most animal bites sustained by human beings are caused by dogs and cats, and in most instances it is possible to observe the biting animal for the development of rabies. Domestic animals that bite a person should be captured and observed for symptoms of rabies for 10 days. If none develop, the animal may be assumed to be nonrabid. If the animal dies or is killed, the head is sent promptly to a public health laboratory for examination. The tissue requires refrigeration, but not freezing, and transportation to the laboratory after the animal's death must be rapid. Clinical signs of rabies in wild animals cannot be interpreted reliably; therefore, any wild animal that bites or scratches a person should be killed at once (without unnecessary damage to the head) and the brain examined for evidence of rabies. Travelers to Asia, Africa, and Central and South America should be aware that more than 50 percent of the rabies cases among human beings in the United States result from exposure to dogs outside the United States (Table 6-9).

It is accepted that the incubation period for rabies in human beings ranges from 10 days to 1 year, with most cases occurring within 20 to 90 days of exposure. In cases of exposure of the head, neck, or upper extremities, the incubation period is potentially less than 30 days. Local care of the animal bite should consist of thorough irrigation, cleansing with soap solution, and debridement. Administration of tetanus toxoid and an antibiotic may be indicated.

Postexposure prophylaxis in addition to local wound treatment consists of *human rabies immune globulin (HRIG)* (Imogam Rabies) and vaccine. There are two rabies vaccines available in the United States: *human diploid cell rabies vaccine (HDCV)* or *rabies vaccine adsorbed (RVA)* (Imovax). Either is administered in conjunction with HRIG at the beginning of postexposure therapy. A regimen of five 1-mL doses of HDCV or RVA is given intramuscularly. The first dose of the five-dose course is given as soon as possible after exposure. Additional doses are given on days 3, 7, 14, and 28 after the first vaccination. For adults, the vaccine is always administered intramuscularly in the deltoid area. For children, the anterolateral aspect of the thigh also is acceptable. The gluteal area should never be used for HDCV or RVA injections because administration in this area results in lower neutralizing antibody titers.

Postexposure antirabies vaccinations should always include administration of passive antibody and vaccine, except for those who have previously received complete vaccine regimens with a cell culture vaccine or who have been vaccinated with other types of vaccines and have had documented rabies antibody titers; these persons should receive only vaccine. Because the antibody response after the recommended postexposure vaccination regimen has been satisfactory, routine postvaccination serologic testing is not recommended unless the patient is known to be immunosuppressed. The state health department can be contacted for recommendations.

HRIG is administered only once to provide immediate antibodies until the patient responds to the vaccine by actively producing antibodies. If HRIG was not given when vaccination was begun, it can be given through the seventh day after administration of the first dose of vaccine. Beyond the seventh day, HRIG is not indicated because the antibody response to cell culture vaccine is presumed to have occurred. The recommended dosage of HRIG is 20 IU/kg body weight. This formula is applicable for all age groups, including children. If anatomically feasible, up to one-half the dose of HRIG should be thoroughly infiltrated in the area around the wound, and the rest should be administered intramuscularly in the gluteal area. HRIG should never be administered in the same syringe or into the same anatomic site as vaccine. Because HRIG may partially suppress active production of antibody, no more than the recommended dose should be given (Table 6-10).

Local reaction such as pain, erythema, and swelling or itching at the injection site has been reported in 30 to 75 percent of recipients. Headache, nausea, abdominal pain, muscle aches, and dizziness have been reported from 5 to 40 percent of recipients. Cases of neurologic illness resembling Guillain-Barré syndrome that resolved have been reported. Local pain and low-grade fever may follow injections of *HRIG*. There is no evidence that hepatitis B virus, human immunodeficiency virus, or other viruses have ever been transmitted by commercially available HRIG in the United States. Corticosteroids can interfere with the development of active immunity after vaccination and may predispose the patient to rabies. When rabies postexposure prophylaxis is administered to persons receiving steroids or other immunosuppressive therapy, it is especially important that a serum sample be tested for rabies antibody to ensure that an acceptable antibody response has developed. Because of the potential consequences of inadequately treated rabies exposure, and because there is no indication that fetal abnormalities have been associated with rabies vaccination, pregnancy is not considered a contraindication to postexposure prophylaxis.

Manifestations and Treatment of Rabies

Symptoms of rabies include a 2- to 4-day prodromal period in which the patient reaches the excited stage. Paresthesia in the region of the bite is an important early symptom. Other symptoms include headaches, vertigo, stiff neck, malaise, lethargy, and severe pulmonary, symptoms including wheezing, hyperventilation, and dyspnea. The patient may have spasm of the throat muscles with dysphagia. The outstanding symptom of rabies is related to swallowing. Drooling, maniacal behavior, and convulsions ensue and are followed by coma, paralysis, and death. Intensive respiratory supportive care is essentially the only treatment to offer. Phenytoin (Dilantin) can be used for seizures.

Snakes

In North America all the poisonous snakes of medical importance are pit vipers, of the family Crotalidae, and the coral snake, of the Elapidae family. The pit vipers include rattlesnakes, cottonmouth moccasin, and the copperhead. Approximately 8000 persons are bitten each year by poisonous snakes, with over 98 percent of bites occurring on the extremities. Rattlesnakes are responsible for approximately 70 percent of deaths from snakebites, while death from the bite of a copperhead is extremely rare.

Pit Vipers

Pit vipers are named for the characteristic pit, a highly sensitive heat-sensing organ that is located between the eye and the nostril on each side of the head. These snakes may be identified by their elliptical pupil, as opposed to the round pupil of harmless snakes. Nonpoisonous snakes do not have pits. However, the coral snake does have a round pupil and lacks the facial pit. Pit vipers have two well-developed fangs that protrude from the maxillae, whereas most nonpoisonous snakes have rows of teeth without fangs. Pit vipers also may be identified by turning the snake's belly upward and noting the single row of subcaudal plates (Fig. 6-66). The coral snake is a small, brightly colored snake with red, yellow, and black rings. This color combination also occurs in nonpoisonous snakes, but the alternation of colors is different. Only the coral snake has a red ring next to a yellow ring. The nose of the coral snake is black.

The venoms of poisonous snakes consist of enzymatic complex proteins that affect all soft tissues. Venoms have been shown to have neurotoxic, hemorrhagic, thrombogenic, hemolytic, cytotoxic, antifibrinolytic, and anticoagulant effects. Most venoms contain hyaluronidase, which enhances the rapid spread of venom by way of the superficial lymphatics.

There may be considerable variation in the venom effect. Neurotoxic features such as muscle cramping, fasciculation, weakness, and respiratory paralysis or hemolytic characteristics may predominate, depending on the snake.

Pain from the bite of a pit viper is excruciating and probably the symptom that most easily differentiates poisonous from nonpoisonous snakebites. Pit vipers characteristically produce one or two fang marks. Hypotension, weakness, sweating and chills, dizziness, nausea, and vomiting are other systemic symptoms. Local signs and symptoms can include swelling, tenderness, pain, and ecchymosis and may appear within minutes at the site of venom injection. If no edema or pain is present within 30 min after injury, the snake probably did not inject any venom. Swelling may continue to increase for 24 h. Hemorrhage vesications, bullae, and petechiae may appear between 8 and 36 h, with thrombosis of superficial vessels and eventual sloughing of tissues. Systemic symptoms include paresthesias and muscle fasciculations. Muscle fasciculations are most common after a rattlesnake bite and often in the perioral region. Fasciculations rarely follow a copperhead bite or a cottonmouth bite. They are often seen in the face muscles and over the neck, back, and the involved extremity and can occur within 10 min.

The venom from rattlesnakes produces deleterious changes in the blood cells, defects in blood coagulation, injuries to the intimal linings of vessels, damage to the heart muscles, alterations in respiration, and to a lesser extent, changes in neuromuscular conduction. Pulmonary edema is common in severe poisoning, and hemorrhage into the lungs, kidneys, heart, and peritoneum can occur. Hematemesis, melena, changes in salivation, and muscle fasciculations may be seen. Urinalysis may reveal hematuria, glycosuria, and proteinuria. Red blood cells and platelets can decrease, and bleeding and clotting times usually are prolonged. Total afibrinogenemia is a hallmark of severe envenomation.

Blood should be immediately drawn for typing and crossmatching because hemolysis may later make this difficult. Because hemolysis and injury to kidneys and liver may occur, it is important to follow alterations in clotting mechanism, renal and liver function, and electrolyte status.

Coral Snakes

The coral snake contributes to only 3 percent of all bites and 1.5 percent of all deaths from poisonous snakes. Bites by the coral snake occasionally provoke blurred vision, ptosis, drowsiness, increased salivation, and sweating. The patient may notice paresthesia about the mouth and throat, sometimes slurring of speech, nausea, and vomiting. Pain is not a constant complaint, nor is edema a constant finding. Coral snake venom causes more extensive changes in the nervous system, and death may occur from inadequate ventilation.

Management of Snake Bites

Application of a tourniquet, incision, and suction are appropriate if used within 1 h of the time of the bite. The snake injects venom into the subcutaneous tissue, which is absorbed by capillaries and lymphatics. The tourniquet should be applied loosely to obstruct only venous and lymphatic flow. The tourniquet is not released once applied and may be left in place during the 30 min that suction is applied. The tourniquet may be removed after definitive treatment has been instituted and the patient is not in shock.

Incision and suction for 30 min may be beneficial if accomplished within 30 minutes after snakebite. The incision should be longitudinal and not cruciate. When two fang marks are seen, the depth of the venom injection is generally considered to be one-third of the distance between the fang marks. Severe bites may result in envenomations deep to the fascia, and surgical exploration may be indicated. Incisions made proximal to the bite are contraindicated.

The average snakebite does not require surgical excision. This procedure is reserved for the most severe envenomations. It has been shown that wide excision of the entire area around the snakebite within 1 h of the time of injection can remove most of the venom. Excision of the fang marks including skin and subcutaneous tissue should be considered in severe bites and in patients known to be allergic to horse serum and who are seen within 1 h of the bite. Most fatalities from snakebites do not occur for 6 to 48 h after the bite, giving time to institute other measures.

The most important treatment for a snakebite is antivenin, although many patients do not require it. Copperhead envenomation rarely necessitates antivenin. Most snakebite fatalities in the United States during the past 20 years have involved either delay in obtaining treatment, no antivenin treatment, or inadequate dosage. Because antivenin contains horse serum, before its administration skin testing is required. Epinephrine 1/1000 in a syringe should be available before antivenin is given.

Because the rattlesnake, cottonmouth moccasin, and copperhead belong to the same biologic family, their bites can be treated by the same antivenin (antivenin Crotalidae polyvalent). The coral snakebite is rare, and the antivenin is different from that for the pit viper. A North American coral snake (*Micrurus fulvius*) antivenin has been developed. It effectively treats *Micrurus* snakebites but is not effective in treating bites of *Micruroides*, the genus native to Arizona and New Mexico. Coral snake antivenin can be obtained from state health departments.

Information concerning identification of a snake or the proper antivenin frequently can be obtained from the nearest zoo herpetarium. A major problem with bites by exotic poisonous snakes is the choice and availability of suitable antiserum. Physicians confronted with this situation may obtain advice from the local poison center or the Antivenin Index Center of Oklahoma Poison Information Center, Oklahoma City, Oklahoma (405-271- 5454).

Antivenin should be withheld until a physician can determine whether it is indicated. Approximately 30 percent of all poisonous snakebites in the United States result in no envenomation. The indication for antivenin is governed by the degree of envenomation. With frequent observations using the classification presented in Table 6-11, the severity of the bite is often found to increase with time, and thus change in grade is observed. Most bites will have reached a final staging within 12 h. Antivenin usually is not required for grade 0 or I envenomation. Grade II may require 3 or 4 ampules, and grade III usually requires 5 to 15 ampules. If symptoms increase, several ampules may be required during the first 2 h. Proper dosage can be estimated by observing the clinical signs and symptoms. If systemic manifestations are severe, antivenin should be given rapidly, by intravenous drip, in large doses. The injection of antivenin locally around the bite is not advised.

If antivenin is indicated, 3 to 5 ampules are given by intravenous drip in 500 mL normal saline solution or 5% glucose solution. If severe systemic symptoms are already present, 6 to 8 ampules are given in addition. The dose of intravenously administered antivenin can be more easily titrated with response to treatment, and the amount administered is based on improvement in signs and symptoms, not on the weight of the patient. Antivenin is administered until severe local or systemic symptoms improve. When it is obvious that antivenin therapy will be instituted, the tourniquet should be left in place until antivenin is started.

If too much time has elapsed for excision to be effective and the patient is allergic to horse serum, a slow infusion of 1 ampule of antivenin in 250 mL of 5% glucose solution may be given in a 90-min period with constant monitoring of the blood pressure and electrocardiogram, depending on the seriousness of the bite. This is accomplished in an active emergency department or an intensive care unit. If an immediate reaction occurs, the antivenin is stopped, and a vasopressor and epinephrine may be required.

The incidence of serum sickness is directly related to the volume of horse serum injected. Of patients receiving 100 to 200 mL of horse serum, 85 percent have some degree of sensitivity within 8 to 12 days after injection.

Intravenous fluids are frequently required to replace the decreased extracellular fluid volume resulting from edema. Fascial planes may become very tense with obstruction of venous and later arterial flow, requiring fasciotomy. Adequate antivenin treatment usually makes surgical intervention unnecessary. These patients may need blood, since anemia can develop from the hematologic effects of envenomation. As afibrinogenemia has been reported, fibrinogen may be required. Vitamin K also may also be required. Bleeding and clotting abnormalities are treated with antivenin in addition to blood components. Antibiotics are recommended to prevent secondary infection, although their benefit is unproved. Tetanus toxoid is administered. The most common species of bacteria isolated from rattlesnake venom are *Pseudomonas aeruginosa*, *Proteus* species, *Clostridium* species, and *Bacteroides fragilis*.

Stinging Insects and Animals

Hymenoptera

The most important insects that produce serious and possibly fatal anaphylactic reactions are arthropods of the order Hymenoptera. This group includes the honeybee, bumblebee, wasp, yellow and black hornet, and the fire ant. The venom of these stinging insects is just as potent as that of snakes and causes more deaths in the United States yearly than are caused by snakebites.

Hymenopterans, except the bee, retain their stinger and are able to sting repeatedly, each time injecting some portion of the venom sac contents. The worker honeybee sinks its barbed sting into the skin and it cannot be withdrawn. As the bee attempts to escape, it is disemboweled. The stinger with the bowel, muscles, and venom sac attached is left behind. The muscles controlling the venom sac, although separated from the bee, rhythmically contract for as long as 20 min, driving the stinger deeper and deeper into the skin and continuing to inject the venom.

Symptoms consist of one or more of the following: localized pain, swelling, generalized erythema, a feeling of intense heat throughout the body, headache, blurred vision, injected conjunctivae, swollen and tender joints, itching, apprehension, urticaria, petechial hemorrhages of the skin and mucous membranes, dizziness, weakness, sweating, severe nausea, abdominal cramps, dyspnea, constriction of the chest, asthma, angioneurotic edema, vascular collapse, and possible death from anaphylaxis. Fatal cases may manifest glottal and laryngeal edema, pulmonary and cerebral edema, visceral congestion, meningeal hyperemia, and intraventricular hemorrhage. Death results from a combination of shock, respiratory failure, and central nervous system changes. Most deaths from insect stings occur within 15 to 30 min.

Early application of a tourniquet may prevent rapid spread of the venom. Bitten persons should be taught to remove the venom sac if present, being careful not to squeeze the sac. It may be necessary for some patients to carry an emergency kit, which is commercially available. Patients should be taught to give themselves an epinephrine injection. Patients having severe reactions should first receive 0.3 to 0.5 mL of a 1:1000 solution of epinephrine intravenously.

Stingrays

Approximately 750 persons each year are stung by stingrays. As the spine, which is curved and has serrated edges, enters the flesh, the sheath surrounding the spine ruptures, and venom is released. As the spine is withdrawn, fragments of the sheath may remain in the wound. The wound edges are often jagged and bleed freely. Pain usually is immediate and severe, increasing to maximum intensity in 1 to 2 h and lasting for 12 to 48 h. Treatment consists of copious irrigation with water to wash out any toxin and fragments of the spine's integumentary sheath. Venom is inactivated when exposed to heat. The area of the bite should be placed in water as hot as the patient can stand without injury for 30 min to 1 h. After soaking, the wound may be further debrided and treated appropriately. Patients treated in this manner have rapid and uncomplicated healing of the wound. Patients not treated with heat have tissue necrosis with prolonged drainage and chronically infected wounds.

Portuguese Man-of-War

After a severe sting by a Portuguese man-of-war there may be almost immediate severe nausea, gastric cramping, and constriction and tightness of throat and chest with severe

muscle spasm. There is intense, burning pain with weakness and perhaps respiratory distress. The most important emergency treatment is to inactivate the nematocysts immediately to prevent their continuous firing of toxins. This is accomplished by applications of a substance of high alcohol content, such as rubbing alcohol, followed by application of a drying agent, such as flour, baking soda, talc, or shaving cream. The tentacles may then be removed by shaving. An alkaline agent such as baking soda is then applied in order to neutralize the toxins, which are acidic. Demerol and Benadryl may dramatically relieve the pain and symptoms. Aerosol corticosteroid- analgesic balm is helpful.

Spiders Black Widow Spider

The most common biting spider in the United States is the black widow (*Latrodectus mactans*) (Fig. 6-67). The female spider has a reddish orange hourglass-shaped marking on its ventral surface. *Latrodectus mactans* venom is primarily neurotoxic in action and centers on the spinal cord. After a bite by the black widow spider, the majority of patients experience pain within 30 min, and a small wheal with an area of erythema appears. Nausea and vomiting occur in approximately one-third of patients, headache in one-fourth, and dyspnea may develop. The time of onset of symptoms after the bite is 30 min to 6 h. The severe symptoms last from 24 to 48 h. Generalized muscle spasm is the most prominent physical finding. Cramping muscle spasms occur in the thighs, lumbar region, abdomen, or thorax. Priapism and ejaculation have been reported. Most patients recover within 24 h.

Treatment consists of narcotics for the relief of pain and a muscle relaxant for relief of spasm. Methocarbamol (Robaxin) or 10 mL of a 10% solution of calcium gluconate relieves the symptoms. It is believed that calcium acts by depressing the threshold for depolarization at the neuromuscular junctions. Calcium gluconate may give instant relief of muscular pain, and methocarbamol can be administered intravenously 10 mL over a 5-min period, with a second ampule started in a saline solution drip. Although *Latrodectus mactans* antivenin is available, it is rarely required. The manufacturer recommends its use for patients with underlying cardiovascular disease. The antivenin is prepared from horse serum and is administered intramuscularly after appropriate skin tests. Hospitalization may be required for the young, the elderly, patients with significant chronic diseases, or those with severe signs and symptoms of envenomation.

Brown Recluse Spider

The distinguishing mark of the *Loxosceles reclusa* is the darker violin- shaped band over the dorsal cephalothorax (Fig. 6-68). The spider is native to the south central United States. The body ranges from 7 mm to 12 mm; including the legs, the spider's size ranges from 2 to 3 cm.

The initial bite may go unnoticed or be accompanied by a mild stinging sensation. Pain may recur 6 to 8 h afterward. A mild envenomation is associated with local urticaria and erythema that usually resolve spontaneously. More severe bites result in progression to necrosis and sloughing of skin with residual ulcer formation. A generalized macular and erythematous rash may appear in 12 to 24 h. Erythema develops, with bleb or blister formation surrounded by an irregular area of ischemia. A zone of hemorrhage and induration and a surrounding halo of erythema may develop peripherally. The central ischemia turns dark, and eschar forms by day 7; by day 14 the area sloughs, leaving an open ulcer. Approximately 3 weeks is required for the lesion to heal. The pain may be out of proportion with the size of the area involved. The progression from blue to black gives the bite a necrotic appearance, and the more severe bites develop within a few hours to 2 days. Systemically, the patient may have fever, nausea, vomiting, weakness, arthralgia, malaise, and even petechiae. The two principal systemic effects, hemolysis and thrombocytopenia, have been responsible for deaths. Hemoglobinemia, hemoglobinuria, leukocytosis, and proteinuria also may occur, and there may be eventual renal failure. *Loxosceles reclusa* venom is chiefly cytotoxic in action. Laboratory studies are obtained in patients with severe envenomation, including prothrombin time, partial thromboplastin time, platelet count, and urinalysis. In the pathophysiology of this spider bite, intravascular coagulations and the formation of microthrombi occur within the capillary, leading to capillary occlusion, hemorrhage, and necrosis.

Treatment is conservative because of the difficulty in predicting the severity of the bite. Various treatments have been advocated in addition to early excision, including treatment with corticosteroids, heparin, phentolamine, dextran, and infusion, but clinical studies have failed to identify the benefit of these agents. The dose for steroids has varied from 30 to 80 mg methylprednisolone daily tapered over a period of several days. A leukocyte inhibitor, dapsone (used in leprosy) is effective in reducing inflammation at the site of the brown recluse venom injection. Treatment with dapsone is 100 mg daily for 14 days before surgical excision, if required. The incidence of scarring and deformity was found to be much less in a dapsone-treated group than in a group treated with observation and subsequent surgical excision. There are significant side effects associated with dapsone treatment, including dose-dependent hemolytic anemia, methemoglobinemia, and rash. Conservative therapy usually is the preferred treatment. Excision of the necrotic area with skin grafting may be required at a later date.

Scorpions

Of the numerous species of scorpions in the United States, only one, *Centruroides exilicauda* or the bark scorpion, is medically significant. It is found primarily in the desert Southwest. Ranging in length from 1 to 7 cm, it is usually yellowish brown in color and may have vertical bands on its dorsum. A tubercle at the base of the stinger distinguishes the bark scorpion from other species. The venom is neurotoxic and causes the release of neurotransmitters from the autonomic nervous system and the adrenal glands. It also causes the depolarization of neuromuscular junctions.

The sting causes intense pain with few other local symptoms. Hyperesthesia persists at the site so that a light tap will reproduce the intense pain. The tap test reinforces the diagnosis. In addition to pain, other symptoms reflect the neurotoxic nature of the venom, including anxiety, blurred vision or temporary blindness, wandering eye movements, dyspnea, wheezing, dysphagia, involuntary urination and defecation, and opisthotonos. Somatic muscular contractions resembling seizures, hypertension, supraventricular tachyarrhythmias, and fever also are seen.

These stings have been of little significance in adults and are satisfactorily treated with cold compresses. In contrast, infants and small children have died from scorpion envenomation, though not since 1968. Small children with signs of envenomation should be admitted to the hospital and monitored. No special diagnostic tests are indicated. Treatment consists of airway management for excessive secretions, sedation, and treatment of arrhythmias and hypertension if indicated. Calcium gluconate has been used to treat muscle spasms. Narcotics should not be used because they aggravate the neurotoxic effects of the venom. A goat-derived antivenin is available but only in the state of Arizona.

CHAPTER 7 - Burns

Glenn D. Warden
David M. Heimbach

INTRODUCTION

Thermal burns and related injury are a major cause of death and disability in the United States. The introduction of burn centers in 1945 heralded a rapid improvement in survival and reduction of morbidity of burn patients and provided the basis for regional specialty treatment centers in other disciplines. The interactive multidisciplinary team has proved to be the least expensive and most efficient method of treating major burn injury, a long- term disease of which the initial acute care is only a small part of the total treatment. Burn patients often require years of supervised rehabilitation, reconstruction, and psychosocial support. Omission of any step in the treatment regimen by any of the burn team members, including the burn surgeon, the nursing staff, and rehabilitation, nutrition, and psychosocial support staff, can result in less than optimal outcome.

EPIDEMIOLOGY

In the United States approximately 2 million individuals annually are burned seriously enough to seek health care; about 70,000 of these require hospitalization, and about 5000 die. More than 90 percent of burns are caused by carelessness or ignorance and are completely preventable; nearly half are smoking- or alcohol-related. While prevention of burns is still the long-term solution to burn care, advances in the care of burned patients during the past 20 years are among the most dramatic in medicine.

The annual federal expenditure for research in cancer, heart disease, and stroke exceeds by 15 times that for trauma and burns, despite the fact that trauma and burns account for a loss of productive person years from injury greater than cancer, heart disease, and stroke combined. The number of burn deaths in the United States has decreased from 15,000 in 1970 to 5000 in 1996. Over the same period the size of burn associated with a 50 percent survival rate has increased from 30 percent of the *total body surface area (TBSA)* to over 80 percent TBSA in otherwise healthy young adults. Hospital stay has been cut in half. Ninety-six percent of patients admitted to burn centers survive, and eighty percent of them return to their preburn physical and social situation within a year of the injury.

The quality of burn care is no longer measured only by survival, but also by long-term function and appearance. Although small burns are not usually life-threatening, they need the same attention as larger burns to achieve functional and cosmetic outcome; in the largest burn centers the average burn size is less than 15 percent TBSA. The physician's goal for any burn is well-healed, durable skin with normal function and near-normal appearance. Scarring, a virtual certainty with deep burns, can be minimized by appropriate early surgical intervention and long-term scar management. These goals require individualized patient care plans, based on burn characteristics and host factors.

As with other forms of trauma, burns frequently affect children and young adults. The hospital expenses and the social costs related to time away from work or school are staggering. Most burns are limited in extent, but a significant burn of the hand or foot may keep manual workers away from work for a year or more, or permanently. The eventual outcome for the burned patient is related to the severity of the injury, the individual physical characteristics of the patient, the motivation of the patient, and the quality of the treatment.

Etiology

Cutaneous burns are caused by the application of heat, cold, or caustic chemicals to the skin. When heat is applied to the skin, the depth of injury is proportionate to the temperature applied, the duration of contact, and the thickness of the skin.

Scald Burns

In civilian practice, scalds, usually from hot water, are the most common cause of burns. Water at 140°F (60°C) creates a deep dermal or full- thickness burn in 3 s. At 156°F (69°C) the same burn occurs in 1 s. Freshly brewed coffee from an automatic percolator generally is about 180°F (82°C); boiling water always causes deep burns, and thick soups and sauces, which remain in contact longer with the skin, also invariably cause deep burns. Exposed areas tend to be burned less deeply than areas covered with thin clothing. Clothing retains the heat and keeps the liquid in contact with the skin for a longer period. Immersion scalds are always deep, severe burns. The liquid causing an immersion scald may not be as hot as with a spill scald, but the duration of contact is longer and these burns frequently occur in small children or elderly patients with thin skin.

Deliberate scalds are the commonest form of reported child abuse and are responsible for about 5 percent of admissions of children to burn centers. The physician should note any discrepancy between the history provided by the care giver and the distribution and probable cause of the burn. A suspicious burn must be reported promptly.

Scald burns from grease or hot oil are usually deep dermal or full-thickness burns. Cooking oil and grease may be in the range of 400°F. Tar and asphalt burns are a special kind of scald. The “mother pot” at the back of a roofing truck maintains tar at a temperature of 400 to 500°F (204 to 260°C). Burns caused by tar directly from the “mother pot” are invariably full-thickness burns. By the time the tar has been spread on the roof or street, its temperature has been lowered to the point where most burns caused by it are deep dermal in nature. The tar should be removed by application of a petroleum-based ointment under a dressing. The dressing may be removed and the ointment reapplied every 2 to 4 h until the tar has dissolved. Only then can the extent of the injury and the depth of the burn be estimated accurately.

Flame Burns

Flame burns are the next most common. Although the incidence of injuries caused by house fires has decreased with the use of smoke detectors, smoking-related fires, improper use of flammable liquids, automobile accidents, and ignition of clothing from stoves or space heaters still exact their toll. Patients whose bedding or clothes have been on fire rarely escape without some full-thickness burns.

Flash Burns

Flash burns are next in frequency. Explosions of natural gas, propane, gasoline and other flammable liquids cause intense heat for a very brief time. Clothing, unless it ignites, is protective against flash burns. Flash burns generally have a distribution over all exposed skin, with the deepest areas facing the source of ignition. Flash burns are mostly dermal, their depth depending on the amount and kind of fuel that explodes. These burns generally heal without requiring extensive skin grafting, but they may cover a large skin area and be associated with significant thermal damage to the upper airway.

Contact Burns

These burns result from contact with hot metals, plastic, glass, or hot coals; they are usually limited in extent, but invariably very deep. It is common for patients involved in industrial accidents to have associated crush injuries because these accidents are commonly caused by contact with presses or other hot, heavy objects. Automobile accidents may leave victims in contact with hot engine parts. The exhaust pipes of motorcycles cause a characteristic burn of the medial leg that, although small, usually requires excision and grafting. Toddlers who touch or fall against irons, ovens, and wood-burning stoves with outstretched hands are likely to suffer deep burns of the palms. Contact burns are often fourth-degree burns, especially those in unconscious or postictal patients, and those caused by molten materials.

Burn Prevention

The number of burns occurring annually in the United States remains unknown despite an extensive government-funded study; however, a number of states have passed legislation making a burn a reportable disease, so more accurate information may be forthcoming. One-third of the victims are children under the age of 15. In children under 8 years of age, the most common burns are scalds, usually from the spilling of hot liquids; in older children and adults, the most common burns are flame- related, usually the result of house fires or the ill-advised use of flammable liquids for burning brush or trash, lighting barbecues, etc., or smoking- or alcohol-related. Industrial accidents are most often caused by chemicals or hot liquids, followed by electricity and then molten or hot metal.

More than 90 percent of all burns are preventable by using common sense and taking ordinary precautions. Over the past 20 years several critical legislative actions, such as that mandating flame-resistant sleepwear for children, have decreased burns and burn mortality. Smoke detectors are required in all rental units and new construction, and are probably the most significant factor in the major decrease in burn mortality during the past decade. Many states have initiated legislation mandating that the maximum temperature for home and public hot water heaters be set to below 140°F (60°C). Individual burn centers, the *American Burn Association (ABA)*, and the International Society for Burn Injury have all produced multiple television public service announcements regarding hot water, carburetor flashes, barbecue burns, scalds, etc. Numerous programs are directed to schools; for example, the “Stop Drop and Roll” sequence is known by most school children. “Change your clock, change your smoke detector battery” is a national program reminding everyone to keep their detector batteries fresh.

HOSPITAL ADMISSION AND BURN CENTER REFERRAL

The need for hospital admission and specialized care is dictated by the severity of symptoms from smoke inhalation and the magnitude of associated burns. Any patient who is symptomatic with smoke inhalation and has more than trivial burns should be admitted to a hospital. If the burns cover more than 15 percent TBSA, the patient should be referred to a special care unit. In the absence of burns, admission depends on the severity of symptoms, the presence of preexisting medical problems, and the social circumstances of the patient. Otherwise healthy patients with mild symptoms (only a few expiratory wheezes, minimal sputum production, CO level <10, and normal blood gases) who have a place to go and someone to stay with them can be observed for an hour or two and then discharged. Patients with preexisting cardiovascular or pulmonary disease who have any symptom related to smoke inhalation should be admitted for observation. Patients with moderate symptoms (generalized wheezing, mild hoarseness, moderate sputum, CO levels 5 to 10, and normal blood gases) are admitted to a medical-surgical unit for close observation and treatment. Patients with severe symptoms (air hunger, severe wheezing, copious [usually carbonaceous] sputum) should be admitted to an intensive care unit or, preferably, a burn unit.

Burn Severity and Classification

The severity of injury caused by burns is proportionate to the size of the total burn, the depth of the burn, the age of the patient, and associated medical problems or injuries. Burns have been classified by the American Burn Association and the American College of Surgeons Committee on Trauma as minor, moderate, and severe. Minor burns are superficial burns of less than 15 percent TBSA. *Moderate* burns are defined as superficial burns of 15 to 25 percent TBSA in adults or 10 to 20 percent in children; full-thickness burns of less than 10 percent TBSA, and burns not involving the eyes, ears, face, hands, feet, or perineum. Because of the significant cosmetic and functional risks associated with burns, all but very superficial burns of the face, hands, feet, and perineum should be treated by a physician with an interest in burn care in a facility that is accustomed to dealing with burns. Major burns, as described above, and most full- thickness burns in infants and elderly patients, or patients with associated diseases or injuries, should also be cared for in a specialized facility. Moderate burns can be cared for in a community hospital by a knowledgeable physician, as long as the other members of the health care team have the resources and knowledge to ensure a good result. Newer techniques of early wound closure have made burn care more complex, and an increasing number of patients with small but significant burns are being referred to specialized care facilities.

The criteria for hospital admission of patients with minor or moderate burns vary according to physician preference, the patient's social circumstances, and the ability to provide close follow-up. In some circumstances superficial burns as large as 15 percent can be successfully managed on an outpatient basis. In other circumstances, burns as small as 1 percent may require admission because of the patient's inability or unwillingness to care for the wound. The physician should have low- threshold criteria for admission of elderly patients and infants. Any patient (child or adult) with suspicion of abuse must be admitted.

Burn Center Referral Criteria

The ABA has identified the following injuries as those requiring referral to a burn center after initial assessment and stabilization at an emergency department.

- (1) Second- and third-degree burns greater than 10 percent TBSA in patients under 10 or over 50 years of age.
- (2) Second- and third-degree burns greater than 20 percent TBSA in other age groups.
- (3) Second- and third-degree burns involving the face, hands, feet, genitalia, perineum, and major joints.
- (4) Third-degree burns greater than 5 percent TBSA in any age group.
- (5) Electrical burns, including lightning injury.
- (6) Chemical burns.
- (7) Inhalation injury.
- (8) Burn injury in patients with preexisting medical disorders that could complicate management, prolong the recovery period, or affect mortality.
- (9) Any burn patients with concomitant trauma (e.g., fractures) where the burn injury poses the greatest risk of morbidity or mortality. If the trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable before being transferred to a burn center. The physician's decisions should be made with the regional medical control plan and triage protocols in mind.
- (10) Burn injury in children admitted to a hospital without qualified personnel or equipment for pediatric care.
- (11) Burn injury in patients requiring special social, emotional, and/or long-term rehabilitative support, including cases involving suspected child abuse, substance abuse, etc.

Transport and Transfer Protocols

Once an airway is established and resuscitation under way, burned patients are eminently suitable for transport. Resuscitation can continue en route because the patient will usually remain stable for several days. This was well demonstrated during the Viet Nam war: about 1000 burn victims were first transported from Viet Nam to Japan, and then from Japan to the military Burn Center in San Antonio, Texas; the transport was usually accomplished during the first 2 weeks postburn with very few complications.

Hospitals without specialized burn care facilities should have transfer agreements and treatment protocols with a burn center well in advance of the need for transfer. Definitive care begins at the initial hospital and continues without interruption during transport and at the burn center. Transfer should be from physician to physician, and contact should be established as soon as the patient arrives in the emergency room of the initial hospital.

The mode of transport depends on vehicle availability, local terrain, weather, and the distances involved. For distances of less than 50 miles (80 km), ground ambulance is usually satisfactory. Helicopter transport is often preferred when the distance is between 50 and 150 mi (80 and 240 km); however, patient monitoring, airway management, and effecting changes in therapy are very difficult to achieve in a helicopter. In all cases in which the time of transport will be long, it is the responsibility of the referring physician to ensure that the patient's condition will permit the transport. All patients transported by air should have a nasogastric tube inserted and placed on dependent drainage, because nausea and vomiting inevitably result during the flight. Two large-bore intravenous lines are mandatory.

For distances over 150 mi (240 km), fixed-wing aircraft are most satisfactory. Modern air ambulances are completely equipped intensive care units, and the personnel are usually well trained for critical care.

The airway must be secured. At 30,000 ft the planes are pressurized to an altitude of about 5500 ft. Supplemental oxygen can be given in flight, but if the patient's oxygenation is marginal, it may be best to intubate and place the patient on a ventilator for the transport. Intubation is difficult en route; if there is question of upper airway edema, the patient should be intubated prior to transport. Burned patients have difficulty maintaining body temperature, and they should be warmly wrapped prior to transport. Bulky dressings, a blanket, and a mylar sheet (usually available from the flight team) can help maintain body temperature. If the patient has any cardiac irregularities, the plane must be equipped with monitoring capability, because noise and vibrations in-flight make clinical monitoring difficult. If there is danger of compromised circulation due to circumferential full- thickness burns, escharotomies should be done at the referring hospital, unless the total hospital-to-hospital time will be less than 2 h.

Burn Center Verification and a National Burn Registry

In 1995, in conjunction with the American College of Surgeons Committee on Trauma (ACS-COT), the ABA initiated a program of Burn Center Verification. A resource document outlines the resources and process necessary to provide optimal care of the burn patient. Burn centers may be reviewed to verify that they provide state-of-the-art care for burn patients, a process involving a lengthy questionnaire, a site visit, a written report, and approval by the joint verification committees. By 1996, over 25 centers had gone through this process. A national burn registry is kept by U.S. burn centers to provide national statistics regarding incidence, epidemiology, and outcome of burn cases.

EMERGENCY CARE

Care at the Scene

Airway

Once flames are extinguished, initial attention must be directed to the airway. Immediate cardiopulmonary resuscitation is rarely necessary, except in electrical injuries that have induced cardiac arrest or in patients with severe carbon monoxide poisoning with hypoxic cardiac arrest. Any patient rescued from a burning building or exposed to a smoky fire should be placed on 100% oxygen by tight-fitting mask if there is any suspicion of smoke inhalation. If the patient is unconscious, and appropriately trained personnel are present, an endotracheal tube should be placed and attached to a source of 100% oxygen. If the airway has to be supported by a tight mask, there is a significant danger of aspiration of gastric contents, because air forced into the stomach will distend it and cause vomiting. The mask prevents expulsion of the fluid, and gastric contents can flood the tracheobronchial tree.

Other Injuries and Transport

Once an airway is secured, the patient is assessed for other injuries and then transported to the nearest hospital. If a burn center is within a 30- min drive and the burn is severe, the patient may be taken directly to that facility. Patients should be kept flat and warm and be given nothing by mouth. If appropriately trained, the emergency medical technicians should place an intravenous line and begin fluid administration of crystalloid solution at a rate of approximately 1 L/h. For transport, the patient should be wrapped in a clean sheet and blanket. Sterility is not required. Before or during transport, constricting clothing and jewelry should be removed from burned parts, because local swelling begins almost immediately. Constricting objects increase swelling, and removing tight jewelry in the presence of distal edema is time-consuming and difficult.

Cold Application

Smaller burns, particularly scalds, are treated with immediate application of cool water. It has been mathematically demonstrated that cooling cannot reduce skin temperature enough to prevent further tissue damage, and that histologic damage is similar with or without cooling, but there is evidence in animals that cooling delays edema formation, probably by reducing initial thromboxane production. After several minutes have elapsed, further cooling does not alter the pathologic process. Iced water should never be used even on the smallest of burns. If ice is used on larger burns, systemic hypothermia may follow, and the associated cutaneous vasoconstriction can extend the thermal damage.

Emergency Room Care

The primary rule for the emergency physician is, "Forget about the burn." As with any form of trauma the ABC protocol—airway, breathing, circulation—must be followed. Although a burn is a dramatic injury, a careful search for other life-threatening injuries is the first priority. Only after making an overall assessment of the patient's condition should attention be directed to the burns. The assessment of patients who have not been thermally injured is discussed in Chap. 6; the following sections apply specifically to problems encountered in the burn patient.

Emergency Assessment of Inhalation Injury

The history is important. Inhalation injury should be suspected in anyone with a flame burn, and assumed, until proved otherwise, in anyone burned in an enclosed space. The acrid smell of smoke on a victim's clothes should raise suspicion. The rescuers are the most important historians and should be questioned carefully before they leave the emergency facility.

Careful inspection of the mouth and pharynx should be done early. Hoarseness and expiratory wheezes are signs of potentially serious airway edema or smoke poisoning. Copious mucus production and carbonaceous sputum are sure signs, but their absence does not rule airway injury out. Carboxyhemoglobin levels should be obtained; elevated carboxyhemoglobin levels or any symptoms of carbon monoxide poisoning are presumptive evidence of associated smoke poisoning.

A decreased P/F ratio, the ratio of arterial P_{o2} to percentage of inspired oxygen (Fi_{o2}) in arterial blood gases is one of the earliest indicators of smoke inhalation. A ratio of 400 to 500 is normal; patients with impending pulmonary problems have a ratio of less than 300 (e.g., a Pa_{o2} of less than 120 with an Fi_{o2} of 0.40). A ratio of less than 250 is an indication

for aggressive pulmonary support rather than for increasing the inspired oxygen concentration.

Fiberoptic bronchoscopy is inexpensive, is quickly performed in experienced hands, and is very useful for accurately assessing edema of the upper airway. Although bronchoscopy documents tracheal erythema, it does not materially influence the treatment of pulmonary injury.

Fluid Resuscitation in the Emergency Room

As burns approach 20 percent TBSA, local inflammatory cytokines escape into the circulation and result in a systemic inflammatory response. The capillary leak, permitting loss of fluid and protein from the intravascular compartment into the extravascular compartment, becomes generalized. Cardiac output decreases as a result of marked increased peripheral resistance, hypovolemia secondary to the capillary leak, and the accompanying increase in blood viscosity. The resulting intense sympathetic response leads to decreased perfusion to the skin and viscera. Decreased flow to the skin may convert the zone of stasis to one of coagulation, thereby increasing the depth of burn. Decreased cardiac output may depress CNS function, and, in extreme cases, lead to severe cardiac depression with eventual cardiac failure in healthy patients, or to myocardial infarction in patients with preexisting coronary artery atherosclerosis. Impairment in CNS function manifests as restlessness, followed by lethargy, and finally by coma. If resuscitation is inadequate, burns of 30 percent TBSA frequently leads to acute renal failure, which, in the case of severe burn, almost invariably results in a fatal outcome.

Resuscitation begins by starting intravenous Ringer's lactate solution at a rate of 1000 mL/h in adults and 20 mL/kg in children. Burn patients requiring intravenous resuscitation (generally those with burns over 20 percent TBSA) should have a Foley catheter placed and urine output monitored hourly.

Patients with burns less than 50 percent TBSA can usually be resuscitated with a single large-bore peripheral intravenous line. Because of the high incidence of septic thrombophlebitis lower extremities should not be used as portals for intravenous lines. Upper extremities are preferable, even if the intravenous line must pass through burned skin. Patients with burns over 50 percent TBSA, who have associated medical problems, who are very young or very old, or who have concomitant smoke inhalation should have additional central venous pressure monitoring. Because of the hemodynamic instability in patients with burns over 65 percent TBSA, these patients should be transferred as quickly as possible so they can be monitored in an intensive care setting where Swan-Ganz catheters for measuring pulmonary wedge pressures and cardiac outputs can be placed.

Tetanus

Burns are tetanus-prone wounds. The need for tetanus prophylaxis is determined by the patient's current immunization status. Previous immunization within 5 years requires no treatment, immunization within 10 years a tetanus toxoid booster, and unknown immunization status hyperimmune serum (Hyper-Tet).

Gastric Decompression

Many burn centers begin tube feeding on admission, to protect the stomach from stress ulceration and the patient from a paralytic ileus and decreasing catabolism. If the patient is to be transported, the safest course is usually to decompress the stomach with a nasogastric tube.

Pain Control

During the shock phase of burn care, medications should be given intravenously. Subcutaneous and intramuscular injections are absorbed variably depending on perfusion and should be avoided. Pain control is best managed with small intravenous doses of morphine, usually 2 to 5 mg, given until pain control is adequate, without affecting blood pressure.

Psychosocial Care

Psychosocial care should begin immediately. The patient and family must be comforted and given a realistic assessment regarding the prognosis of the burns. In house fires, patients' loved ones, pets, and possessions may have been destroyed. If the family is not available, some member of the team, usually the social worker, should determine the extent of the damage. If the patient is a child, and if the circumstances of the burn are suspicious, physicians in all states are required by law to report any suspected case of child abuse to local authorities.

Care of the Burn Wound

After all other assessments are complete, attention should be directed to the burn. If the patient is to be transferred during the first postburn day, which is almost always the case, the burn wounds can be left alone. However, the size of the burn should be calculated to establish the proper level of fluid resuscitation, and pulses distal to circumferential full-thickness burns should be monitored. The patient can be wrapped in a clean sheet and kept warm until arriving at the definitive care center.

Escharotomy and Fasciotomy

Chest Escharotomy

The adequacy of respiration must be monitored continuously throughout the resuscitation period. Early respiratory distress may be due to compromise of the ventilatory function caused by a cuirass effect related to a deep circumferential burn wound of the chest. Pressures required by ventilation increase and arterial P_{co2} rises. Inhalation injury, pneumothorax, or other causes may also result in respiratory distress.

When escharotomy is required in a patient with a circumferential chest wall burn, it is performed in the anterior axillary line bilaterally. If there is significant extension of the burn onto the adjacent abdominal wall, the escharotomy incisions should be extended to this area and should be connected by a transverse incision along the costal margin (Fig. 7-1).

Escharotomy of Extremities

Edema formation in the tissues under the tight unyielding eschar of a circumferential burn of an extremity may produce significant vascular compromise that, if unrecognized and untreated, will lead to permanent, serious neurologic and vascular deficits. All rings, watches, and other jewelry must be removed from injured limbs to avoid distal vascular ischemia. Skin color, sensation, capillary refill, and peripheral pulses must be assessed hourly in any extremity with a circumferential burn. The occurrence of any of the following signs or symptoms may indicate poor perfusion of the distal extremity: cyanosis, deep tissue pain, progressive paresthesia (loss of sensation), progressive decrease or absence of pulse, or sensation of cold extremities. An ultrasonic flowmeter is a reliable means for assessing arterial blood flow, and the need for an escharotomy, and can also be used to assess adequacy of circulation after an escharotomy.

Direct monitoring of intramuscular compartment pressure provides objective evidence for adequacy of circulation. It is useful for assessing not only the need for, but also the adequacy of, escharotomy and/or fasciotomy. An 18-gauge needle is attached to the transducer tubing that is used for monitoring arterial pressure and inserted into the compartment; pressure is measured on the monitor. In burn patients the threshold pressure for performing escharotomy or fasciotomy is 30 mmHg. While elevation and manipulation of the extremity may relieve minor deviations of pressure, escharotomy is necessary for 30 mmHg or higher.

Both escharotomies and fasciotomies may be done as bedside procedures with a sterile field and scalpel. Local anesthesia is unnecessary because third-degree eschar is insensate; small doses of intravenous narcotics may be utilized to control anxiety. The incision, which must avoid major nerves, vessels, and all tendons, should be placed along the mid-medial or mid-lateral aspect of the extremity and, to permit adequate separation of the cut edges for decompression, should extend through the eschar down to the subcutaneous fat. The incision should extend through the length of the constricting third-degree burn, and should be carried across involved joints (see Fig. 7-1).

When a single escharotomy incision in an extremity does not result in adequate distal perfusion, a second escharotomy incision on the contralateral aspect of the extremity should be performed. A finger escharotomy is seldom required, and should be performed only after consultation with the receiving burn center physician.

Escharotomy and/or fasciotomy is rarely required within the first 6 h postburn and should only be done under the supervision of a trained surgeon. Because burn patients are at risk for developing a compartment syndrome up to 72 h postinjury, any involved extremity should be reassessed continually for signs of the dangerous elevation in compartment pressures that can occur after initial decompression.

BURN SEVERITY

The severity of any burn injury is related to the size and depth of the burn and to the part of the body that has been burned. Burns are the only quantifiable form of trauma. The single most important factor in predicting burn-related mortality, need for specialized care, and the type and likelihood of complications is the overall size of the burn as a proportion of the patient's total body surface. Treatment plans, including initial resuscitation and subsequent nutritional requirements, are directly related to the size of burn.

Burn Size

A general idea of burn size can be made by using the *Rule of Nines*. Each upper extremity accounts for 9 percent of TBSA, each lower extremity accounts for 18 percent, the anterior and posterior trunk each account for 18 percent, the head and neck account for 9 percent, and the perineum accounts for 1 percent. Although the Rule of Nines is reasonably accurate for adults, a number of more precise charts have been developed. Most emergency rooms have a chart available comparable to the one shown in Fig. 7-2. A diagram of the burn can be drawn on the chart, and, theoretically, a precise calculation of burn size can be made from the accompanying TBSA estimates given.

Children under 4 years old have much larger heads and smaller thighs in proportion to body size than do adults. In infants the head accounts for nearly 20 percent of the TBSA; infant body proportions do not fully reach adult percentages until adolescence. Even when using precise diagrams, individual observer variation may differ by as much as ±20 percent. An observer's experience with burned patients rather than his or her educational level appears to be the best predictor of accuracy of estimation. To increase accuracy in burn size estimation, especially when burns are in scattered body areas, the observer should calculate the unburned areas on a separate diagram. If the calculations of the unburned areas and the burned areas do not add up to 100 percent, the observer should begin again with a new diagram.

For smaller burns an accurate assessment of burn size can be made by using the patient's hand, which amounts to 2.5 percent TBSA (see Fig. 7-2). The dorsal surface, including the fingers, accounts for 1 percent, the palmar surface, including the fingers, for 1 percent, and the vertical surface for 0.5 percent.

Burn Depth

Along with burn extent and patient age, depth of burn is a primary determinant of mortality. Burn depth is also the primary determinant of the patient's long-term appearance and function.

Burns not extending all the way through the dermis leave behind epithelium-lined skin appendages: sweat glands, and hair follicles with attached sebaceous glands. When dead dermal tissue is removed, epithelial cells swarm from the surface of each appendage to meet swarming cells from neighboring appendages, forming a new, fragile epidermis on top

of a thinned and scarred dermal bed. Skin appendages vary in depth, and the deeper the burn the fewer the appendages that contribute to healing and the longer the burn takes to heal. The longer the burn takes to heal, the less dermis remains, the greater the inflammatory response, and the more severe the scarring.

When nonoperative treatment is the routine, as it is in many developing countries, an accurate assessment of burn depth is of little importance except for predicting mortality. On the other hand, with aggressive surgical treatment, an accurate estimation of burn depth is crucial. Burns that heal within 3 weeks usually do so without hypertrophic scarring or functional impairment, although long-term pigmentary changes are common. Burns that take longer than 3 weeks to heal often produce unsightly hypertrophic scars; frequently lead to functional impairment; and provide only a thin, fragile epithelial cover for many weeks or months. State-of-the-art burn care, at least in patients with small and moderate burns, involves early excision and grafting of all burns that will not heal within 3 weeks. The challenge of course is to determine which burns *will* heal within 3 weeks and are thus best treated by daily local care. Other burns should be treated surgically.

An understanding of burn depth requires an understanding of skin thickness. The living epidermis is an intensely active layer of epithelial cells under layers of dead keratinized cells and is superficial to the active structural framework of the skin, the dermis. The thickness of skin varies with the age and sex of the individual and the area of the body. The thickness of the living epidermis is relatively constant, but keratinized (dead and cornified) epidermal cells may reach a height of 0.5 cm on the palms of hands and the soles of feet. The thickness of the dermis varies from less than 1 mm on eyelids and genitalia to more than 5 mm on the posterior trunk. The proportional thickness of skin in each body area in children is similar to that in adults, but infant skin thickness in each specific area may be less than half that of adult skin; the skin does not reach adult thickness until puberty. Similarly, in patients over 50 years of age dermal atrophy begins; all areas of skin become thin in elderly patients.

The depth of burn is dependent on the heat of the burn source, the thickness of the skin, the duration of contact, and the heat-dissipating capability of the skin (blood flow). A scald in an infant or elderly patient will be deeper than an identical scald in a young adult. A diabetic with impaired sensation, or an inebriated patient with an impaired sensorium, who lies on a heating pad (even of temperature less than 106°F (41°C) all night may sustain full-thickness burns because of the long duration of contact with the pad and the pressure of the body weight which occludes cutaneous blood flow and prevents heat dissipation.

Burns are classified according to increasing depth as first-degree, second- degree (superficial dermal and deep dermal), third-degree (full-thickness), and fourth-degree. Because most deep burns are removed surgically and grafted, such a precise characterization is not necessary for non-life- threatening burns. A more pertinent classification might be “shallow burns” and “deep burns.” Nevertheless, distinguishing between deep burns that are best treated by early excision and grafting and shallow burns that heal spontaneously is not always straightforward, and many burns have a mixture of clinical characteristics, making precise classification difficult.

Shallow Burns

First-Degree Burns

First-degree burns involve only the epidermis. First-degree burns do not blister, but become erythematous because of dermal vasodilation, and are quite painful. Over 2 to 3 days the erythema and the pain subside. By about day 4, the injured epithelium desquamates in the phenomenon of “peeling,” which is well known after sunburn.

Superficial Dermal Burns (Second-Degree)

Superficial dermal burns include the upper layers of dermis, and characteristically form blisters with fluid collection at the interface of the epidermis and dermis. Blistering may not occur for some hours after injury, and burns originally appearing to be first-degree may be diagnosed as superficial dermal burns after 12 to 24 h. When blisters are removed, the wound is pink and wet and currents of air passing over it cause pain. The wound is hypersensitive, and the burns blanch with pressure. If infection is prevented, superficial dermal burns heal spontaneously in less than 3 weeks, and do so with no functional impairment. They rarely cause hypertrophic scarring, but in pigmented individuals the healed burn may never completely match the color of the surrounding normal skin.

Deep Burns

Deep Dermal Burns (Second-Degree)

Deep dermal burns extend into the reticular layers of the dermis. Deep dermal burns also blister, but the wound surface is usually a mottled pink and white color immediately after the injury, because of the varying blood supply to the dermis (white areas have little to no blood flow; pink areas have some blood flow). The patient complains of discomfort rather than pain. When pressure is applied to the burn, capillary refill occurs slowly or may be absent. The wound is often less sensitive to pinprick than the surrounding normal skin. By the second day, the wound may be white and is usually fairly dry. If infection is prevented, these burns will heal in 3 to 9 weeks, but invariably do so with considerable scar formation. Unless active physical therapy is continued throughout the healing process, joint function can be impaired, and hypertrophic scarring, particularly in pigmented individuals and children, is common.

Full-Thickness Burns (Third-Degree)

Full-thickness burns involve all layers of the dermis and can heal only by wound contracture, by epithelialization from the wound margin, or by skin grafting. Full-thickness burns appear white, cherry red, or black, and may or may not have deep blisters. Full-thickness burns are described as being leathery, firm, and depressed when compared with adjoining normal skin, and are insensitive to light touch or pinprick. The difference in depth between a deep dermal burn and a full-thickness burn may be less than a millimeter. The clinical appearance of full-thickness burns can resemble that of deep dermal burns. Like deep dermal burns they may be mottled in appearance. They rarely blanch on pressure, and they may have a dry, white appearance. In some cases the burn is translucent, with clotted vessels visible in the depths. Some full-thickness burns, particularly immersion scalds, have a red appearance, and may be confused with superficial dermal burns. They can be distinguished, however, because they do not blanch with pressure. Full-thickness burns develop a classic burn eschar: the structurally intact but dead and denatured dermis that, over days and weeks, separates from the underlying viable tissue.

Fourth-Degree Burns

Fourth-degree burns involve not only all layers of the skin, but also subcutaneous fat and deeper structures. These burns almost always have a charred appearance, and frequently only the cause of the burn gives a clue to the amount of underlying tissue destruction. Electrical burns, contact burns, some immersion burns, and burns sustained by patients who are unconscious at the time of burning may all be fourth-degree.

The Assessment of Burn Depth

The standard technique for determining burn depth has been clinical observation of the wound. The difference in depth between a burn that heals in 3 weeks, a deep dermal burn that heals only after many weeks, and a full-thickness burn that will not heal at all may be only a matter of a few tenths of a millimeter. A burn is a dynamic process for the first few days; a burn appearing shallow on day 1 may appear considerably deeper by day 3. Further, the kind of topical wound care used can dramatically change the appearance of the burn. For these reasons, and because of the increasing importance of an accurate assessment of burn depth for planning definitive care of burn wounds, there is considerable interest in technology that will help determine burn depth more precisely than clinical observation.

Evaluation by an experienced surgeon as to whether an intermediate-depth dermal burn will heal in 3 weeks is about 50 percent accurate. In experienced hands, however, early excision and grafting provides better results than nonoperative care for such indeterminate burns.

Other techniques involve (1) the ability to detect dead cells or denatured collagen (through biopsy, ultrasound, vital dyes), (2) assessment of changes in blood flow (through fluorescein, laser Doppler, and thermographic assays), (3) analysis of the color of the wound (through light reflectance methods), and (4) evaluation of physical changes, such as edema (through *nuclear magnetic resonance (NMR)* techniques.

Biopsy

Biopsy and histologic examination would seem the most accurate technique for determining burn depth, but biopsies are expensive, leave permanent scars in wounds that would not be excised, and require an experienced pathologist to distinguish live from denatured collagen and cells. In addition, wound depth changes during the first 48 h, and Jackson reported that 7 days were necessary to get reproducible results from burn biopsies. Whatever the timing of biopsy, it requires another day or two to get permanent sections, and there is no guarantee that specimens from areas adjacent to the biopsy are the same depth as the biopsy specimens. For these reasons biopsies are rarely used in clinical practice, and to the authors' knowledge no studies have demonstrated a correlation between biopsy findings and healing within 3 weeks.

Vital Dyes

Theoretically, a vital dye directly applied to the burn wound would be useful in detecting dead tissue and also in determining the needed depth of surgical excision. Davies, in 1980, described important characteristics of such a dye. It should stain only dead tissue, not be removable with wound treatment, be nontoxic, provide a sharp demarcation between living and dead tissue, penetrate all dead tissue, and be compatible with topical treatments usually used in burn care. In a rat model methylene blue, toluidine blue, trypan blue, Evans blue, and sulpham blue were evaluated. Methylene blue, which is metabolized to a colorless compound by living cells, was selected for preliminary testing in patients. When methylene blue was mixed with silver sulfadiazine and applied topically within 48 h, a significant blue discoloration appeared that remained even after vigorous washing. Excision was carried down to dermis that was unstained. The authors reported encouraging results in this preliminary study. However, casual use of this technique in our burn centers did not produce a satisfactorily sharp demarcation to guide excision.

Fluorescein Fluorometry

Fluorescein, injected systemically, is delivered through a patent circulation and fluoresces under ultraviolet light. It has been widely used to determine viability of flaps, intestine, and even whole extremities. The use of fluorescein fluorescence to determine burn depth was first reported in 1943, but this technique was unused until more precise instrumentation was developed—a fiberoptic perfusion fluorometer—which could measure the magnitude of fluorescence. Gatti studied 63 burns with the fluorometer after intravenous administration of sodium fluorescein. The fluorescein kinetics were monitored for 1 h within the first 48 h, and again between the third and sixth days postburn, and compared to the kinetics in adjacent normal skin. Depth of burn was confirmed by biopsy and healing characteristics. Fluorometric analysis during both study periods consistently distinguished between partial-thickness and full-thickness burns. Partial-thickness burns uniformly exhibited fluorescence within 10 min; full-thickness burns showed no fluorescence. However, when this technique was reported in 1982, most burn surgeons only excised full- thickness burns, leaving partial-thickness burns to heal on their own, and there was therefore an advantage to distinguishing between partial- and full-thickness burns.

Gatti's results were confirmed in 1984. However, a 1986 report by Black could not confirm significant differences between partial- and full-thickness burns using a similar technique because standard deviations in both categories were too large to distinguish between groups, let alone be predictive in any given burn. Our own experience with fluorescein indicates that it confirms the clinical diagnosis in very deep and very shallow burns, areas where there is little confusion, but that it cannot distinguish between intermediate and deep dermal burns.

Laser Doppler Flowmetry

Laser Doppler flowmetry has been used since 1975 for monitoring cutaneous circulation. Light from a helium-neon laser is carried by a fiberoptic cable to the skin where it interacts with stationary structures and moving blood cells within a sample volume of approximately 1 mm. Back- scattered light from the moving cells is shifted in velocity using the Doppler principle, while back-scattered light from stationery objects remains at its original frequency. The mixing of these lightwaves is translated into an electrical signal, and mathematical estimations of blood flow can be made in normal versus study areas of skin. This technique is easy to use and noninvasive (although the probe must be held against the skin), and provides immediate results.

Sørensen's group in Denmark first reported the use of a laser Doppler flowmeter on a burn unit. Initial studies in our burn center showed excellent correlation with full-thickness burns (no flow) and shallow burns (normal or increased flow), but considerable variation from patient to patient with comparable burns, and, at different times, in the same area in the same patient with moderate and deep dermal burns. Readings varied particularly with: (1) temperature (immediately after bathing, a warm room, etc.), (2) the patient's state of anxiety (catecholamine response), and (3) elevation of an extremity (e.g., cutaneous blood flow essentially disappeared when the hands were elevated).

In further studies, the cutaneous circulation over time was followed in burned patients and rats to determine whether measuring changes in cutaneous blood flow would help predict the ultimate fate of indeterminate burns that were not obviously shallow or deep. A laser Doppler flowmeter was used to study cutaneous perfusion for at least 72 h in partial-thickness wounds on patients with burns of less than 15 percent TBSA, and in experimental wounds of similar size on rats. Clinical wounds that healed without grafting within 3 weeks consistently showed elevated perfusion levels that continued to increase over 72 h. Wounds eventually requiring grafting demonstrated lower perfusion levels with no obvious pattern of increase. The observed trends of increased flow for healing burns and flat flow for nonhealing burns were constant. Thus for patients to be followed for several days, this method has merit in deciding, after day 3, which patients will benefit from excision and grafting.

As instrumentation has improved, so have the results of serial measurements of burn blood flow. A differential analysis of multiple parameters during measurement has brought accuracy to the 80 to 90 percent range in predicting healing within 3 weeks.

Thermography

Diminished blood flow to deep dermal and full-thickness burns makes them cooler to touch, a finding confirmed by thermography in 1974 by Hackett. Initial studies of thermography as a tool for predicting the need for excision and grafting of deep dermal wounds in 30 patients presented by Mason in 1981 suggested that thermography might be more accurate than clinical judgment. Thermographic findings, like laser Doppler flowmetry, are highly dependent on room and patient temperature, the patient's anxiety and stress level, and the area of the body being considered, as well as the cooling effect of evaporative water loss. Despite these drawbacks, Cole, in 1990, compared thermography to clinical assessment of 32 burned hands. Superficial and deep partial-thickness burns were treated conservatively, with excision and grafting only of those that had not healed 2 to 3 weeks after injury. The group that had undergone the delayed surgical procedure and the healed group were analyzed retrospectively to determine the predictive value of the initial clinical evaluation and thermography as assessments of the depth of the burns. Obvious full-thickness burns were excised and grafted within 5 days and were not included in the study. Initial thermographic assessment correctly predicted the outcome (whether healed or excised and grafted) in 33 of 36 burns. This relationship was highly significant, while initial clinical assessment of depth had no significant relationship with the time taken to heal.

Ultrasound

Moserová, using an industrial ultrasound device in 1982, was able to detect differences between normal pig skin and pig skin that had been scalded for 5 and 15 s. His initial work was expanded as technology improved. Cantrell was able to detect denatured from normal collagen in pig skin. One problem with this technique is that collagen denatures at 149°F (65°C) while epidermal cells, from which the burn must heal, are killed at about 117°F (47°C), so ultrasonic apparent depth is likely to be underestimated. Further refinements in instrumentation enabled Brink to demonstrate a significant correlation between ultrasound burn depth and histology in pigs. Wachtel, in five burn patients, reported that ultrasound comparisons with clinical evaluation and histopathologic studies of burn wound biopsy specimens of the same burned areas failed to show any substantive improvement in predicting the depth of burn by the ultrasonic scanning techniques. Technology in this area has dramatically improved, so this may still be a technique of the future.

Nuclear Magnetic Resonance

Full-thickness burns result in slower resorption of wound edema than partial-thickness burns. Proton NMR parameters correlate with tissue water content, and Koruda tested whether proton NMR could distinguish between full-thickness and partial-thickness burns. Early after burning, NMR could distinguish higher water content in partial- and full-thickness rat burns than in adjacent normal skin. By 48 h, the partial-thickness burn had returned to control values, while the full-thickness burn remained edematous. However, the rat skin had to be excised in order to use NMR, and so there is no useful clinical application for the technique. In partial- and full-thickness scald wounds, reductions in PCr/Pi ratios correlated with burn depth and improved over time postinjury. Future advances in technology might enable more precise measurements in the clinical situation.

Light Reflectance

The skin is relatively transparent to short-wavelength infrared light, and reduced hemoglobin absorbs more of the light than oxygenated hemoglobin. Anselmo and Zawacki, in 1973, reasoned that thrombosed vessels in full-thickness burns would become visible in infrared light, and could be distinguished from the open vessels of partial-thickness burns. Computer analysis of photographs taken with red, green, and infrared filtered light generated ratios of the green/infrared, red/infrared, and red/green images point by point over the entire surface that accurately distinguished shallow, deep dermal, and full-thickness burns. The technique, however, was too expensive, time-consuming, and slow for clinical decision making. Heimbach and Afromowitz devised a portable, noninvasive (the wound is not touched) electronic device that could instantaneously measure the spectral characteristics of red, green, and infrared light reflected from the burn. The device was essentially 100 percent accurate in differentiating shallow and full-thickness wounds. For intermediate wounds, using the endpoint of wound healing in less than or more than 3 weeks, clinical assessment by two experienced surgeons was compared to readings from the device. In about one-third of cases, the surgeons were unwilling to commit to a prediction. When surgeons were willing to make a prediction, they were incorrect about 25 percent of the time. The reflectance device was significantly more accurate than the clinical assessment in those burn wounds predicted not to heal; an accuracy of 79 percent was achieved in the clinically indeterminate wounds. The dynamic qualities of the burn wound are emphasized in these studies because the light reflectance device clearly showed changes each day for the first 3 to 4 days, and it was most accurate on day 3.

PHYSIOLOGICAL RESPONSE TO BURN INJURY

Burn patients with or without inhalation injury commonly manifest an inflammatory process involving the entire organism; the term *systemic inflammatory response syndrome (SIRS)* was introduced to summarize that condition. The most common cause of SIRS is the burn sepsis. SIRS with infection or bacteremia is a major factor determining morbidity and mortality in thermally injured patients. Pathologic alterations of the metabolic, cardiovascular, gastrointestinal, and coagulation systems occur with hypermetabolism, an increase in cellular, endothelial, and epithelial permeability, typical hemodynamic alterations, and often extensive microthrombosis. The circulatory manifestations of the systemic inflammatory response largely disappear within 24 h, but the patient remains in a hypermetabolic state until wound coverage is achieved.

Burn Shock

Burn shock is a complex process of circulatory and microcirculatory dysfunction, not easily or fully repaired solely by fluid resuscitation. Hypovolemic shock and tissue trauma result in formation and release of local and systemic mediators, which produce an increase in vascular permeability or an increase in microvascular hydrostatic pressure. Most mediators act to increase permeability by altering venular membrane integrity. The early phase of burn edema, lasting from minutes to an hour, is attributed to mediators such as histamine, bradykinin, and vasoactive amines, products of platelet activation, and the complement cascade of hormones, prostaglandins, and leukotrienes. Vasoactive amines also may act directly by increasing microvascular blood flow or vascular pressures, accentuating the burn edema.

Histamine is probably responsible for the early phase of increased capillary permeability after burn injury, because it is released in large quantities from mast cells in burned skin immediately after injury. Histamine increases leakage of fluids and proteins from systemic microvessels; its major effect is on the venules, in which an increase in intravascular junction space is characteristic. Serum histamine peaks in the first several hours postinjury, suggesting that histamine is involved only in the very early increase in permeability.

Serotonin is released immediately upon postburn platelet aggregation and acts directly to increase pulmonary vascular resistance and indirectly to amplify the vasoconstrictive effects of norepinephrine, histamine, angiotensin II, and prostaglandin.

Prostaglandins, vasoactive products of arachidonic acid metabolism, are released in burn tissue and contribute to formation of burn edema. These substances do not directly alter vasopermeability, but increased levels of vasodilator prostaglandins, such as PGE₂, and prostacyclin, PGI₂, result in arterial dilatation in burn tissue, increasing blood flow and hydrostatic pressure in the injured microcirculation, accentuating the edema process. Increased concentrations of PGI₂ and the vasoconstrictor thromboxane A₂ have been demonstrated in burn tissue, burn blister fluid, lymph, and wound secretion.

The activation of the proteolytic cascades, including those of coagulation, fibrinolysis, the kinins, and the complement system, occurs immediately after burn injury. Kinins, specifically the bradykinins, increase vascular permeability, primarily in the venule. In addition to the loss of capillary integrity, thermal injury also causes changes at the cellular level. Baxter demonstrated a generalized decrease in cellular transmembrane potential involving nonthermally injured and thermally injured cells. Platelet activating factor is released after burn injury and increases capillary permeability. The reduction of cardiac output after burn injury is a result of hypovolemic and cellular shock, increased systemic vascular resistance due to sympathetic stimulation and hypovolemia, with release of catecholamines, vasopressin, angiotensin II, and neuropeptide Y. After successful resuscitation, cardiac output normalizes after 18 to 24 h and increases to supernormal levels during the wound-healing phase of burn management.

Metabolic Response to Burn Injury

Hypermetabolism

Resting energy expenditure (REE) after burn injury can be as much as 100 percent above predictions based on standard tables for size, age, sex, and weight. Some debate persists regarding the genesis of this phenomenon, but increased heat loss from the burn wound and increased b-adrenergic stimulation are probably primary factors. Radiant heat loss is increased from the burn wound secondary to high blood flow. Measurement of resting energy expenditure is helpful in assessing nutritional status. On average, resting energy metabolism equals approximately 1.3 times the predicted basal energy expenditure obtained from the Harrison-Benedict equation. Glucose metabolism is elevated in almost all critically ill patients, including those with burn injuries, but studies have focused particularly on burn patients because their relatively stable condition allows reproducible experimental conditions. Gluconeogenesis, particularly from alanine, and glycogenolysis are increased. Protein is excreted primarily in the urine as urea, contributing to the progressive depletion of body protein stores. Proteolysis in burn patients is increased as compared to normal individuals who are fed the same amount of protein and calories. This results in increased efflux of amino acids from the muscle, including glucogenic amino acids. Alanine, in particular, is released at an increased rate. Increased gluconeogenesis from amino acid renders these amino acids unavailable for reincorporation into the body protein. Plasma insulin levels that are usually normal are elevated in burn patients. The basal rate of glucose production is elevated despite a normal or elevated plasma insulin level, which can be defined as hepatic insulin resistance. Fatty acids are released at a rate in excess of requirements of fatty acids and energy substrates. In burn patients, over 70 percent of released fatty acids are not oxidized, but rather reesterified into triglyceride,

resulting in fat accumulation in the liver. This is unfortunate because utilization of fat for energy would decrease dependence on proteolysis.

A number of studies have been designed to assess the optimal form of carbohydrate and fat. Both xylitol and fructose have been posed as alternative carbohydrates, and a wide variety of fats have been advocated, including fish oil, medium-chain triglycerides, and structured lipids in which medium- and long-chain fatty acids are incorporated into the same triglyceride molecule. Xylitol and fructose require energy for transposition to glucose before utilization for energy. Xylitol in large quantities is hepatotoxic, and fructose may cause lactic acidosis.

Major trauma, burns, and sepsis have in common a rapid net catabolism of body protein, as well as a redistribution of the nitrogen pool within the body. Muscle protein breakdown is accelerated while “acute phase” proteins are produced at an increased rate in the liver. Wound repair requires amino acid protein synthesis and increased immunologic activity, and may require accelerated protein synthesis. Protein intake over 1 g/kg/day has been recommended for thermally injured patients; for thermally injured patients with normal renal function, the recommended protein intake is 2 g/kg/day. The importance of glutamine intake in critically ill patients has been investigated. Current oral and enteral formulations have largely omitted glutamine, but some beneficial effects have been found with enteral glutamine. Including glutamine in intravenous formulations results in improved nitrogen balance, which, while statistically significant, probably is not biologically significant because of its insufficient magnitude.

Neuroendocrine-Mediator Response

Catecholamines appear to be the major endocrine mediators of the hypermetabolic response in thermally injured patients. Pharmacologic blockade of beta receptors diminishes the intensity of postburn hypermetabolism. Thyroid hormonal serum concentrations are not elevated in patients with large burns. Total thyronine (T₃) and thyroxine (T₄) concentrations are reduced, and reverse T₃ concentrations are elevated while cellular concentrations are likely normal. Concentrations of free T₃ and T₄ fall markedly in the presence of sepsis in burned patients.

Burn injury abolishes the normal diurnal variation in glucocorticoid concentrations, but these hormones do not appear to influence metabolic activity directly and only have a permissive role in catecholamine stimulation. They are, however, primarily responsible for increased proteolysis. Glucagon concentrations are related directly to metabolic rate and cortisol concentrations and may modulate resting metabolism through anti-insulin effects.

Immune Response to Burn Injury

The immune status of the burn patient has a profound impact on outcome in terms of survival, death, and major morbidity. The greatest difficulty in attempting to decipher the body's response to injury is the complex interaction of the cytokine cascade, the arachidonic acid cascade, and the neuroendocrine axis.

Cytokine Cascade

Cytokines were considered originally to be regulatory chemicals secreted by cells of the immune system, and growth factors were seen as chemicals originating from inflammatory and reparative tissue. The distinction between growth factors and peptides, hormones, and cytokines is no longer distinct. Many of these cytokines and growth factors are released from damaged tissues at the wound site, where they exert local and systemic effects.

After injury, a number of cytokines are induced rapidly, including *tumor necrosis factor (TNF)*, interleukin-1 (IL-1), and interleukin-6 (IL-6). The timetable of induction is similar in burned and/or injured patients. Tumor necrosis factor alpha (TNF-α) is detectable early in the period of burn shock; the maximum level of TNF-α throughout the course is of prognostic significance. Because the physiological effects of TNF are almost indistinguishable from endotoxin, the induction of TNF has been held responsible for the clinical effects of endotoxemia. After initial induction of IL-1, synthesis is impaired significantly for several days after injury. By contrast, there is up-regulation of local production of IL-1 and IL-6 in inflammatory sites, inducing polymorphonuclear neutrophil chemoattraction.

Interleukin-2 (IL-2) is a key cytokine in the mediation of the cellular immune response, and patients with large burns have significantly suppressed production of IL-2, which correlates with the length of time from injury. Investigations of pulmonary production of IL-8 after respiratory distress syndrome are not inconclusive. Interleukin-6 (IL-6) is a ubiquitous cytokine that is produced by a variety of cells, and is detected in increased concentration in blood or tissues after disturbances of physiological homeostasis, including thermal injury. Its most important role is the induction of hepatic synthesis of acute phase response proteins that include antibacterial products, such as α₂-glycoprotein, C₃, and fibronectin.

Arachidonic Cascade

The major product of arachidonic acid cascade after thermal injury is *prostaglandin E₂ (PGE₂)*, produced by macrophages and partially mediated by endotoxin. PGE₂ exerts its immunosuppressive effect primarily by inhibition of lymphocyte IL-2 production and T-cell activation and down- regulation of IL-6. The induction of the arachidonic acid cascade is complex, and is apparently dependent at least on two pathways, one calcium-channel- dependent and one calcium-independent. There are massive increases of another arachidonic acid derivative, thromboxane B₂, in the plasma of burn patients, particularly immediately postburn and during septic episodes. Leukotriene B₄, another arachidonic acid product, is a potent neutrophil chemotactin that is produced after thermal injury.

Cell-Mediated Immunity

Cell-mediated immunity is impaired after burn injury, including documented delays in allograft rejection, impairment in mitogenic and anogenic responsiveness of lymphocytes, burn-size-related suppression of graft- versus-host activity, suppression of delayed cutaneous sensitivity tests, and diminution of peripheral lymphocytes and thoracic duct lymphocyte concentration. There is agreement that the functional capacity of thymodependent lymphocytes (T cells) to perform their normal physiological response is impaired. Whether this failure is the result of “overuse” or indirectly the result of down-regulation by cytokine cascades and other products of the inflammatory reaction is unclear.

Macrophages

Macrophage function is impaired after thermal injury. Macrophage products suppress mitogenic responsiveness in normal lymphocytes. Proinflammatory cytokines are produced by macrophages in short bursts, probably inhibited by a feedback loop with decreased receptor expression. Activation includes pulmonary macrophages and may provide the background for the development of the adult respiratory distress syndrome seen in burn patients.

B Cells

The function of bone marrow–derived thymocytes, or B cells, after thermal injury is less well documented than that of the macrophages or T cells. The B-cell population is subject to the same nonspecific activation as the rest of the lymphocyte population.

Neutrophils

Neutrophil dysfunction after thermal injury has been extensively studied; it is manifested by a decreased Fc receptor expression, depressed intracellular killing capacity, and leukocyte chemotaxis that is accompanied by a brief increase in neutrophil respiratory burst. In addition, expression of CD16 (FcR, Fc, IgG receptors) and CD11 (adhesion molecules) on neutrophils is impaired after thermal injury, and this reduction seems to be directly related to the appearance of bacteremia and pneumonia. Baseline granulocyte oxidative activity in burn neutrophils is increased. Induction of neutrophil activation probably requires several different stimulants, but it is known that TNF and endotoxin can both activate neutrophils; IL-6 is also a potent inducer of superoxide production by the neutrophil.

Humoral Immunity

After thermal injury there is a marked diminution of total serum IgG concentration and all subclasses. These levels return to normal between 10 and 14 days postburn. Extremely low levels of IgG on admission are predictive of a poor prognosis. These changes have been ascribed to a combination of leakage through the burn wound, protein catabolism, and a relative diminution in synthesis of IgG. IgM and IgA levels appear to be relatively unaffected.

The classical and the alternative complement pathways are depleted, but the alternative pathway is more profoundly altered. Complement inactivation by heat appears to ameliorate cell-mediated immunosuppression, suggesting that some of the impairment of the cell- mediated immunosuppression postburn may be due to a complement- associated mechanism. The production of granulocyte colony-stimulating factor (GCSF) and of granulocyte-macrophage colony-stimulating factor (GM-CSF) is also impaired.

Unidentified or partially identified immunosuppressive factors are present in burn serum and in burn subeschar tissue fluid. A low-molecular-weight immunosuppressive peptide has been found in blood that is capable of suppressing neutrophil chemotaxis, T-cell blastogenesis, and B-cell blastogenesis.

FLUID MANAGEMENT

Proper fluid management is critical to survival in major thermal injury. In the 1940s, hypovolemic shock or shock-induced renal failure was the leading cause of death after burn injury. Mortality related to burn-induced volume loss has decreased considerably with increased knowledge of the massive fluid shifts and hemodynamic changes that occur during burn shock. A vigorous approach to fluid therapy has led to reduced mortality rates in the first 48 h postburn, but 50 percent of the deaths occur within the first 10 days after burn injury from a multitude of causes. One of the most significant causes is inadequate fluid resuscitation therapy. Fluid management after burn shock resuscitation is also important.

Historical Perspective

The necessity for fluid resuscitation after burn injury was appreciated over a century ago, but the magnitude of the fluid loss was not apparent until the studies of Frank Underhill of the victims of the Rialto Theater fire in 1921. That burn shock was due to extravascular fluid loss was further elucidated by Cope and Moore, who conducted studies on patients from the Coconut Grove disaster in 1942. They developed the concept of burn edema and introduced the body weight–burn formula for fluid resuscitation. In 1952, Evans developed a burn surface area–weight formula that became the first simplified means of calculating fluid resuscitation needs for burn patients. Surgeons at the Brooke Army Medical Center modified the original Evans formula and this became the standard for the next 15 years.

Pathophysiology of Burn Shock

Burn shock is hypovolemic and cellular in nature, and is characterized by specific hemodynamic changes including decreased cardiac output, extracellular fluid, and plasma volume, and oliguria. As with other forms of shock, the primary goal is to restore and preserve tissue perfusion. In burn shock, resuscitation is complicated by obligatory burn edema, and the voluminous transvascular fluid shifts that result from a major burn are unique to thermal trauma.

One major component of burn shock is the increase in total body capillary permeability. Direct thermal injury results in marked changes in the microcirculation. Most of the changes occur locally at the burn site; maximal edema formation occurs between 8 and 12 h postinjury in smaller burns, and 12 and 24h postinjury in major thermal injuries. The rate of

progression of tissue edema is dependent upon the adequacy of resuscitation.

Multiple mediators have been proposed to explain the changes in vascular permeability. The proposed mediators produce an increase in vascular permeability or an increase in microvascular hydrostatic pressure. The end result of the changes in the microvasculature due to thermal injury is disruption of normal capillary barriers separating intravascular and interstitial compartments, and rapid equilibrium between these compartments. Plasma volume is severely depleted, clinically manifested as hypovolemia, with a marked increase in extracellular fluid.

Thermal injury also causes changes at the cellular level. Baxter has demonstrated that in burns greater than 30 percent TBSA, there is a systemic decrease in cell transmembrane potential, involving nonthermally injured cells. This decrease in cell-transmitting potential, defined by the Nernst equation, results from an increase in intracellular sodium concentration secondary to a decrease in sodium ATPase activity responsible for maintaining the intracellular-extracellular ionic gradient. Resuscitation only partially restores the membrane potential and intracellular sodium concentrations to normal levels, demonstrating that hypovolemia, with its attendant ischemia, is not totally responsible for the cellular swelling seen in burn shock. Membrane potential may not return to normal for many days postburn despite adequate resuscitation. If resuscitation is inadequate, cell membrane potential progressively decreases, resulting ultimately in cell death.

Moyer, Baxter, and Shires established the role of crystalloid solutions in burn resuscitation, and delineated the fluid volume changes in the early postburn period. Moyer's studies, in 1965, demonstrated that burn edema sequesters enormous amounts of fluid, resulting in the hypovolemia of burn shock. Baxter and Shires in 1968, using radioisotope dilution techniques, demonstrated that edema fluid in the burn wound is isotonic with respect to plasma, and contains protein in the same proportions as that found in blood. This was further evidence of the complete disruption of the normal capillary barrier in major burns, with free exchange between plasma and extravascular extracellular compartments. In a canine model, they also established the end points of crystalloid resuscitation as optimal cardiac output and restoration of ECF at the end of 24 h. Clinical studies confirmed the efficacy of restoring ECF to within 10 percent of controls within 24 h. This became the basis for the Baxter (Parkland) formula. The associated mortality rate was comparable to that obtained with a colloid-containing resuscitation formula.

Moncrief and Pruitt characterized the hemodynamic alterations in burn shock with and without fluid resuscitation. Their efforts culminated in the Brooke formula modification, which was based on 2 mL per kilogram of body weight per percentage of TBSA burned (2 mL/kg body weight/% burn) during the first 24 h. Fluid needs were estimated initially according to the modified Brooke formula, but the actual volume for resuscitation was based on clinical response. In their study, resuscitation permitted an average decrease of about 20 percent in both extracellular fluid and plasma volume, but no further loss accrued in the first 24 h. In the second 24 h postburn, plasma volume restoration occurred with the administration of colloid. Cardiac output, initially low, rose over the first 18 h postburn, despite plasma volume and blood volume deficits. Peripheral vascular resistance rose during the initial 24 h, but decreased as cardiac output improved. When plasma volume and blood volume loss ceased, cardiac output rose to supranormal levels where it remained until healing or grafting occurred.

Moylan and associates in 1973, using a canine model, defined the relationships between fluid volume, sodium concentration, and colloid in restoring cardiac output. No significant colloid effect on cardiac output was noted in the first 12 h postinjury. In addition, 1 meq of sodium was found to exert an effect on cardiac output equal to 13 times that of 1 mL of salt- free fluid volume. Thus, any combination of sodium and fluid volume within the broad limits of the study would effectively resuscitate a thermally injured patient.

Arturson's 1979 studies characterized the nature of the "leaky capillary" in the postburn period. In a canine model, increased capillary permeability was found locally and in remote nonburned tissue when the TBSA burned exceeded 25 percent. He proposed that the burn wound is characterized by rapid edema formation due to dilatation of the resistance vessels (precapillary arterioles), increased extravascular osmotic activity due to the products of thermal injury, and increased microvascular permeability to macromolecules. The increased permeability permits molecules with molecular weights of up to 350,000 to escape from the microvasculature, a size that allows essentially all elements of the vascular space, except red blood cells, to escape. Studies by Demling and co-workers have demonstrated that in 50 percent TBSA burns, one-half of the initial fluid resuscitation requirement may end up in nonthermally injured tissues.

Resuscitation from Burn Shock

The primary goal of fluid resuscitation is to replace fluid sequestered as a result of thermal injury. The critical concept in burn shock is that massive fluid shifts can occur even though total body water remains unchanged. What actually changes is the volume of each fluid compartment, with intracellular and interstitial volumes increasing at the expense of plasma volume and blood volume. The edema is accentuated by the resuscitation process. The National Institutes of Health consensus summary on fluid resuscitation in 1978 was not in agreement in regard to a specific formula, but there was consensus on two major issues: general guidelines to be used during the resuscitation process, and type of fluid. The volume infused should be the least amount of fluid necessary to maintain adequate organ perfusion and should be continually titrated to avoid under- or overresuscitation. Replacement of the extracellular salt lost into the burned tissue and into the cell is essential for successful resuscitation.

Crystalloid Resuscitation

Crystalloid, in particular lactated Ringer's solution with a sodium concentration of 130 meq/L, is the most popular resuscitation fluid. Proponents of the use of crystalloid solution argue that other solutions, specifically colloids, are no better, and certainly more expensive, than crystalloid for maintaining intravascular volume after thermal injury. Even large proteins leak from the capillary after thermal injury, negating any theoretical advantage from colloid. Capillaries in nonburned tissues may maintain relatively normal protein permeability characteristics.

The quantity of crystalloid needed is dependent upon the parameters used to monitor resuscitation. If a urinary output of 0.5 mL/kg of body weight/h indicates adequate perfusion, approximately 3 mL/kg/% burn will be needed in the first 24 h. If 1 mL/kg body weight/h is optimal, considerably more fluid will be needed, and more edema will result. The Parkland formula recommends 4 mL/kg/% burn in the first 24 h, with one-half of that amount administered in the first 8 h (Table 7-1). The modified Brooke formula recommends beginning burn shock resuscitation at 2 mL/kg/% burn in the first 24 h (Table 7-1). In major burns, severe hypoproteinemia usually develops with these resuscitation regimens. The hypoproteinemia and interstitial protein depletion may result in more edema formation.

Hypertonic Saline

The resuscitation of burn patients with salt solution of 240 to 300 meq/L rather than lactated Ringer's solution results in less edema because of the smaller total fluid requirements. Urine output is used as the indicator of adequate resuscitation. Demling and colleagues demonstrated in an animal model that the net fluid intake was less if burned animals were resuscitated with hypertonic saline to the same cardiac output as compared with lactated Ringer's. Urine output was much higher with hypertonic solution. Soft tissue interstitial edema in burned and nonburned tissue, as reflected by lymph flow, was increased with hypertonic saline to a similar extent as with lactated Ringer's. A shift of intracellular water into extracellular space occurs as the result of the hyperosmolar solution. Extracellular edema increases as intracellular fluid decreases, giving the external appearance of less edema. Several studies have reported that this intracellular water depletion does not appear to be deleterious, but the issue is controversial. Current recommendations are that the serum sodium levels should not be allowed to exceed 160 meq/dL. Gunn and associates in a prospective randomized study of patients with 20 percent TBSA burns evaluated hypertonic sodium lactate versus lactated Ringer's solution and were not able to demonstrate decreased fluid requirements, improved nutritional tolerance, or decreased body weight gain percentage.

We have used a modified hypertonic solution in major thermal injuries of greater than 40 percent TBSA. The resuscitation fluid contains 180 meq Na^+ (lactated Ringer's + 50 meq NaHCO_3), and is used until reversal of metabolic acidosis has occurred, usually by 8 h postburn. Resuscitation is begun at 4 mL/kg/% burn, but the administered volume is titrated to maintain urine output at 30 to 50 mL/h. After 8 h, lactated Ringer's is administered to maintain urine output at 30 to 50 mL/h. Hyponatremia is avoided in infants and in the elderly.

Colloid Resuscitation

Plasma proteins generate the inward oncotic force that counteracts the outward capillary hydrostatic force. Without protein, plasma volume could not be maintained. Protein replacement was an important component of early formulas for burn management. The Evans formula used 1 mL/kg body weight/% burn each for colloid and lactated Ringer's, over the first 24 h. In the original Brooke Army Hospital formula, 0.5 mL/kg/% burn was administered as colloid, and 1.5 mL/kg/% burn as lactated Ringer's. Moore's formula proposed a substantial amount of colloid. Considerable confusion exists concerning the role of protein (albumin) in a resuscitation formula. There are three approaches:

(1) Protein solutions are not given in the first 24 h because during this period they are no more effective than salt containing crystalloid water in maintaining intravascular volume. Protein may also promote accumulation of lung water when edema fluid is absorbed from the burn wound.

(2) Proteins, specifically albumin, should be given from the beginning of resuscitation with crystalloid.

(3) Protein should not be given between 8 h to 12 h postburn because of the massive fluid shifts during this period, after which they should be used.

Demling demonstrated that restoration and maintenance of plasma protein content are not effective until 8 h postburn, when adequate levels can be maintained with infusion. Because nonburned tissues appear to regain normal permeability shortly after injury and because hypoproteinemia may accentuate the edema, the first alternative is the least appropriate.

Heat-fixed plasma protein solutions, e.g., Plasmanate, contain some denatured and aggregated protein, which decreases the oncotic effect. Albumin solutions are clearly the most oncologically active solutions. Fresh frozen plasma contains all the protein fractions that exert the oncotic and the nononcotic functions. The optimal amount of protein remains undefined. Demling uses between 0.5 and 1 mL/kg/% burn of fresh frozen plasma during the first 24 h, beginning at 8 to 10 h postburn, and also argues that while all major burns require large amounts of fluid, the following groups of patients develop less edema and better maintain hemodynamic stability if fresh frozen plasma is used during resuscitation: older patients with burns, patients with burns and concomitant inhalation injury, and patients with burns in excess of 50 percent TBSA.

Slater and co-workers used fresh frozen plasma during burn shock, lactated Ringer's, 2 L/24 h, and fresh frozen plasma, 75 mL/kg/24 h (Table 7-1). The volume of fresh frozen plasma is calculated, but the volume infused is titrated to maintain an adequate urine output. These authors use colloid early in the burn shock period, but most burn patients have received lactated Ringer's in significant volumes during field management. In the young pediatric burn patient with major burn injury, colloid replacement is frequently required because serum protein concentration rapidly decreases.

Dextran

Dextran is a colloid consisting of glucose molecules that have been polymerized into chains to form high-molecular-weight polysaccharides. This compound is available commercially in a number of molecular sizes. Dextran, with an average molecular weight of 40,000, is referred to as low- molecular weight-dextran. British dextran has a mean molecular weight of 150,000, but the dextran used in Sweden has a molecular weight of 70,000. Dextran is excreted by the kidneys, with 40 percent removed within 24 h, and the

remainder is slowly metabolized. Demling and associates used dextran 70 in a 6% solution to prevent edema in nonburned tissues. Dextran 70 is associated with some risk of allergic reaction, and can interfere with blood typing. Dextran 40 improves the microcirculatory flow by decreasing red blood cell aggregation. The net requirements for maintaining vascular pressure at the baseline levels with dextran 40 are about half those noted with lactated Ringer's alone during the first 24 h postburn, with an infusion rate of dextran 40 and saline of 2 mL/kg/h with sufficient lactated Ringer's to maintain adequate perfusion. At 8 h, an infusion of fresh frozen plasma at 0.5 to 1.0 mL/kg/% burn over 18h is instituted with necessary additional crystalloid (see Table 7-1).

Special Considerations in Burn Shock Resuscitation

Fluid Resuscitation in the Thermally Injured Pediatric Patient

The burned child represents a special challenge, because resuscitation therapy must be more precise than that for an adult with a similar burn. Children have a limited physiological reserve. Children require proportionately more fluid for burn shock resuscitation than adults with similar thermal injury; fluid requirements for children average 5.8 mL/kg/% burn. Children commonly require intravenous resuscitation for relatively small burns of 10 to 20 percent TBSA, a finding confirmed by Baxter. Graves and associates give children 6.3 ± 2 mL/kg/% burn. The Cincinnati Shriners Burns Institute uses the Parkland formula, adding maintenance fluid to the resuscitation fluid volume, to begin burn shock resuscitation, 4 mL/kg/% burn, plus 1500 mL maintenance fluid per square meter of burn surface area (BSA), per 24 h (Table 7-2). Graves found that if maintenance fluids were subtracted from the resuscitation fluid requirements, the resulting resuscitation volume approached 4 mL/kg/% burn. At the Galveston Shriners Burns Institute, fluid requirements are estimated according to a formula based on TBSA, and burned BSA, in square meters. Total fluid requirements for the first day are estimated as follows: $5000 \text{ mL/m}^2 \text{ \% burn/24 h} + 2000 \text{ mL/m}^2 \text{ BSA/ 24 h}$.

Inhalation Injury

Inhalation injury increases the fluid requirements for resuscitation from burn shock after thermal injury. Patients with documented inhalation injury require 5.7 mL/kg/% burn, as compared to 3.98 mL/kg/% burn in patients without inhalation injury. Inhalation injury accompanying thermal trauma increases the magnitude of total body injury and requires increased volumes of fluid and sodium to achieve resuscitation.

Choice of Fluids and Rate of Administration

All the solutions reviewed are effective in restoring tissue perfusion. Most patients with burns under 40 percent TBSA with no pulmonary injury can be resuscitated with isotonic crystalloid fluid. In patients with burns of over 40 percent TBSA, and/or in patients with pulmonary injury, hypertonic saline can be used in the first 8 h postburn, after which lactated Ringer's is infused to complete resuscitation. In pediatric and elderly burn patients, using less concentrated but hypertonic concentrations of sodium (e.g., 180 meq/L) gives the benefits of hypertonic resuscitation without the potential complications of excessive sodium retention and hypernatremia.

In patients with massive burns, young pediatric patients, and burns complicated by severe inhalation injury, a combination of fluids can be used to achieve the desired goal of tissue perfusion while minimizing edema. In these patients, the regimen of modified hypertonic (lactated Ringer's + 50 meq NaHCO₃) saline fluid containing 180 meq Na/L is used for the first 8 h. After correction of the metabolic acidosis, which usually requires 8 h, the patients are given lactated Ringer's only for the second 8 h. In the last 8 h, 5% albumin in lactated Ringer's solution completes the resuscitation. The resuscitation solution used in Galveston for pediatric patients is an isotonic glucose-containing solution to which a moderate amount of colloid (human serum albumin) is added. The solution is prepared by mixing 50 mL of 25% human serum albumin (12.5 g) with 950 mL of 5% dextrose in a lactated Ringer's solution.

The volume of infused fluid should maintain a urine output of 30 to 50 mL/h in adults and 1 mL/kg/h in children. In children weighing more than 50 kg, the urine volume should not exceed 30 to 50 mL/h. Heart rate and blood pressure are not indicative of fluid volume status in the burn patient; therefore, fluid volume status and cardiac output should be measured directly via thermodilution pulmonary artery catheterization, but a low measured filling pressure with evidence of adequate perfusion is common. Placement of a Swan-Ganz catheter to monitor burn shock resuscitation should be reserved for burn patients with limited cardiac reserve, such as the elderly or patients with significant concomitant disease, or burn patients who require large volumes.

None of the resuscitation formulas can be more than general guidelines for burn shock resuscitation. The Parkland formula, for instance, decreases the volume administered by 50 percent at 8 h postburn. The relationship between the fluid volume required and time postburn depicted by the smooth curve in Fig. 7-3 represents the influence of temporal changes in microvascular permeability and edema volume on fluid needs. The gentle changes depicted by that curve are in sharp contrast with the abrupt changes in fluid infusion rate prescribed by the formula.

Resuscitation is considered successful when there is no further accumulation of edema fluid, usually between 18 and 30 h postburn, and the volume of infused fluid needed to maintain adequate urine output approximates the maintenance fluid volume, which is the patient's normal maintenance volume plus evaporative water loss.

Fluid Replacement Following Burn Shock Resuscitation

Heat-injured microvessels may manifest increased vascular permeability for several days, but the rate of fluid loss is considerably less than that seen in the first 24 h. Burn edema at 24 h postburn is near maximal, and the interstitial space may well be saturated with sodium. Additional fluid requirements depend on the type of fluid used during the initial resuscitation. If hypertonic salt resuscitation was used during the entire burn shock period, a hyperosmolar state is produced, and the addition of free water is required to restore the extracellular space to an iso-osmolar state.

If colloid was not been used during burn shock and the serum oncotic pressure is low because of intravascular protein depletion, protein repletion frequently is needed. Protein requirement varies with the resuscitation used. The Brooke formula proposes 0.3 to 0.5 mL/kg/TBSA burn of 5% albumin during the second 24 h. The Parkland formula replaces the plasma volume deficit, which varies from 20 to 60 percent of the circulating plasma volume, with colloid. We have used colloid replacement based on a 20 percent plasma volume deficit during the second 24 h (circulating plasma volume $\times$ 20 percent).

In addition to colloid, the patients should receive maintenance fluids. The total daily maintenance fluid requirement in the adult patient is calculated by the following formula, where m₂ is square meters of TBSA:

Total maintenance fluid = (1500 mL/m²) +

evaporative water loss [(25 + % burn) $\times$ m² $\times$ 24]

This fluid may be given intravenously or via enteral feeding. The solution infused intravenously should be 50% normal saline with potassium supplements. Because of the loss of intracellular potassium during burn shock, the potassium requirement in adults is about 120 meq/day.

After the initial 24 to 48 h postburn period of resuscitation, urinary output is an unreliable guide to sufficient hydration. Respiratory water losses; osmotic diuresis secondary to glucose intolerance; high-protein, high- calorie feedings; and derangements in antidiuretic hormone (ADH) mechanisms contribute to increased fluid losses, despite an adequate urine output. Adult patients with major thermal injuries require a urine output of 1500 to 2000 mL/24 h; children require 3 to 4 mL/kg/h.

Measurement of serum sodium concentration is not only a means of diagnosing dehydration, but the best guide for managing successful fluid replacement. Other useful laboratory indices of the state of hydration include body weight change, serum and urine nitrogen concentrations, serum and urine urea glucose concentrations, the intake and output record, and clinical examination.

For very large burns, and in the pediatric burn patient, continuous colloid replacement may be required to maintain colloid oncotic pressure Maintaining serum albumin levels above 2.0 g/dL is desirable. Electrolytes, calcium, magnesium, and phosphate should also be monitored and maintained within normal limits.

RESPIRATORY INJURY

Of the nearly 50,000 fire victims admitted to hospitals each year, smoke or thermal damage to the respiratory tree may occur in as many as 30 percent. Carbon monoxide poisoning, thermal injury, and smoke poisoning are three distinctly separate aspects of clinical inhalation injury, and though symptoms and treatment are distinct, they may coexist and require concomitant treatment.

Carbon Monoxide Poisoning

As many as 60 to 70 percent of deaths from house fires can be attributed to carbon monoxide poisoning. Carbon monoxide is a colorless, odorless, tasteless gas that has an affinity for hemoglobin 200 times greater than oxygen. When inhaled and absorbed, carbon monoxide binds to hemoglobin to form carboxyhemoglobin (COHb). COHb interferes with oxygen delivery to tissues by at least four mechanisms. First, it prevents reversible displacement of oxygen on the hemoglobin molecule. Second, COHb shifts the oxygen-hemoglobin dissociation curve to the left, thereby decreasing oxygen unloading from normal hemoglobin at the tissue level. Third, carbon monoxide inhibits the cytochrome oxidase a₃ complex, resulting in less effective intracellular respiration. Fourth, carbon monoxide may bind to cardiac and skeletal muscle, causing direct toxicity, and act in the central nervous system in a poorly understood fashion, causing demyelination and associated neurologic symptoms. The degree of enzymatic and/or muscle impairment may not be directly correlated with the levels of blood carboxyhemoglobin. Levels of carboxyhemoglobin are measured easily. COHb levels less than 10 percent do not cause symptoms, although patients with exercise-induced angina may show a decreased exercise tolerance. At levels of 20 percent, healthy persons complain of headache, nausea, vomiting, and loss of manual dexterity. At 30 percent, patients become weak, confused, and lethargic. In a fire, this level can be fatal because the victim loses the ambition and the ability to flee the smoke. At levels between 40 and 60 percent, the patient lapses into coma, and levels above 60 percent are usually fatal. In very smoky fires, carboxyhemoglobin levels of 40 to 50 percent can be reached after only 2 to 3 min of exposure.

Carbon monoxide is reversibly bound to the heme pigments and enzymes and, despite its intense affinity, readily dissociates according to the laws of mass action. The half-life of carboxyhemoglobin, when breathing room air, is between 4 and 5 h. On 100% oxygen, the half-life is reduced to 45 to 60 min. In a hyperbaric oxygen chamber at 2 atm, it is about 30 min, and at 3 atm it is about 15 to 20 min.

The importance of carbon monoxide poisoning in victims of isolated smoke inhalation injury during fires was dramatically demonstrated in the 1979 MGM Grand Hotel and 1981 Hilton Hotel fires in Las Vegas. Although only a small number of burn injuries occurred, 123 people died at the scene, primarily from carbon monoxide intoxication. At the same time, the efficacy of prompt assessment and treatment of smoke inhalation was demonstrated. Of more than 400 individuals who received hospital evaluation for smoke inhalation injury, mortality was less than 1 percent, and the rate of significant complications (myocardial infarction, respiratory failure, or pneumonia) was 1 percent each.

Patients burned in an enclosed space or having any suggestion of neurologic symptoms should be placed on 100% oxygen while awaiting measured carboxyhemoglobin levels. The use of *hyperbaric oxygen (HBO)* is controversial. Only two randomized studies have been conducted. In a group of patients with CO exposure but no unconsciousness, half received normobaric oxygen, and the other half received one treatment in a hyperbaric chamber. There was no difference in immediate or delayed neurologic sequelae. Group two included patients who lost consciousness and who received either one or two HBO treatments. Again there were no differences. Hyperbaric oxygen was not useful in patients with moderate CO exposure, whether or not they lost consciousness, regardless of their COHb levels at admission. Nor were two sessions of HBO in patients with a brief loss of consciousness better than a single session. It is not clear that hyperbaric oxygen is better than normobaric oxygen.

While hyperbaric oxygen treatment may be innocuous in isolated CO poisoning, in the presence of associated burns and smoke poisoning, the rate of potentially fatal complications during treatment in the chamber is extremely high. Patients who have not lost consciousness and who have a normal neurologic examination on admission will almost always recover completely without treatment beyond administration of 100% oxygen. Patients who remain comatose in the emergency room have a poor prognosis and rarely awaken.

Thermal Airway Injury

The term “pulmonary burn” is a misnomer. True thermal damage to the lower respiratory tract and lung parenchyma is extremely rare, unless live steam or exploding gases are inhaled. The air temperature near the ceiling of a burning room may reach 540°C (1000°F) or more, but air has such poor heat-carrying capacity that most of the heat is dissipated in the nasopharynx and upper airway. The heat dissipation in the upper airway, however, may cause significant thermal injury.

Thermal injury to the respiratory tract is usually immediate, and consists of mucosal and submucosal edema, erythema, hemorrhage, and ulceration. Thermal injury is usually limited to the upper airway (above the vocal cords) and trachea for two reasons: (1) the nasopharynx and oropharynx provide a very effective mechanism for heat exchange because of their relatively large surface area and associated air turbulence, as well as their mucosal water lining that acts as a heat reservoir, and (2) sudden exposure to hot air may trigger reflex closure of the vocal cords, reducing the potential for lower airway injury. Animal experiments have demonstrated that significant heat exchange also occurs in the airway segment between the vocal cords and the tracheal bifurcation, protecting the lower airway. Thus, the lower airway is rarely exposed to hot, ambient gas at a fire scene. An exception is superheated steam inhalation, where because of energy released in the respiratory tract as the steam condenses to water, severe injury has been reported in the lower airways with measurable injury in the alveoli. In these patients the lower airway is rapidly obstructed, and they usually die from untreatable asphyxiation.

Patients with greatest risk of upper airway obstruction are those injured in an explosion (gasoline vapor, propane, butane, or natural gas) with burns of the face and upper torso, and those who have been unconscious in a fire. Mucosal burns of the mouth, nasopharynx, and larynx result in edema formation and may lead to upper airway obstruction at any time during the first 24 h postburn. Any patient with burns of the face should have a careful visual inspection of the mouth and pharynx, and, if these are abnormal, the larynx should be visualized immediately. Red or dry mucosa or small mucosal blisters raise the possibility of airway obstruction; in the presence of a closed space fire significant smoke poisoning may be present. The presence of significant intraoral and pharyngeal burns is a clear indication for early endotracheal intubation, as progressive edema can make later intubation extremely hazardous, if not impossible. Mucosal burns are rarely full-thickness, and can be successfully managed with good oral hygiene. Once the patient is intubated, the tube should remain in place for 3 to 5 days, until the edema subsides.

Smoke Inhalation

A nightclub fire that claimed 48 lives in Dublin in 1981 added a great deal to our understanding of smoke inhalation injury because the disaster site was meticulously reconstructed and the event reenacted for scientific study. Within minutes, visibility was reduced to less than 1 m and ambient temperatures reached 1160°C. Near the fire, dramatic changes in inhaled gas concentrations were noted; oxygen was reduced to less than 2 percent, carbon monoxide increased to greater than 3 percent, hydrogen cyanide was measured at 250 ppm, and hydrogen chloride was measured at 8500 ppm.

Hydrogen cyanide, a common product of polyurethane combustion, is a more effective inhibitor of cellular respiration than carbon monoxide, and also interferes with normal oxygen utilization at the tissue level. By inhibiting the final step of oxidative phosphorylation at the cytochrome a_3 level, cyanide halts aerobic metabolism, inducing lactic acidosis and cellular asphyxia. The effects of cyanide are specifically injurious to tissues with little anaerobic reserve, i.e., the central nervous system. Combined exposure to cyanide and carbon monoxide results in a deadly synergistic decrease in tissue oxygen utilization.

A vast array of toxic products are released during combustion (flaming) or pyrolysis (smoldering), depending on the type of fuel that is burned, whether burning occurs in a high- or low-oxygen environment, and the actual heat of combustion. Some 280 toxic products have been identified in wood smoke. Petrochemical science has produced a wealth of plastic materials in homes and automobiles that, when burned, produce nearly all of these and many other products not yet characterized. Prominent by-products of incomplete combustion are oxides of sulfur, nitrogen, and many aldehydes. One aldehyde, acrolein, causes severe pulmonary edema in concentrations as low as 10 ppm.

After inhalation, the highly soluble organic aldehydes produced by combustion and pyrolysis (e.g., formaldehyde, acetaldehyde, acrolein) rapidly dissolve in water lining the mucosa of the upper and lower airways, causing direct epithelial injury. The result is epithelial necrosis, edema, and submucosal hemorrhage, primarily in the lower airways. Ammonia is also highly soluble, and reacts with respiratory tract water to form ammonium hydroxide, a strong alkali. Inhaled sulfur dioxide becomes similarly hydrated and then oxidizes to form sulfurous and sulfuric acid. These caustic acids (including hydrogen chloride) and bases cause significant mucosal coagulation and liquefaction necrosis, producing an injury pattern similar to that of the aldehydes.

Smoke inhalation can cause direct epithelial damage at all levels of the respiratory tract, from oropharynx to alveolus. The anatomic level at which the damage occurs is dependent on the ventilatory pattern, the smoke constituents (e.g., particulate concentration, particulate size, and chemical components), and the anatomic distribution of particulate deposition. Although the chemical mechanisms of injury may be different with different toxic products, the overall end-organ response is reasonably well defined. There is an immediate loss of bronchial epithelial cilia and decreased alveolar surfactant. Microatelectasis, and sometimes macroatelectasis, results and is compounded by mucosal edema in small airways, with immediate development of atelectasis that is only slowly reversible by normal ventilation. The regional hypoventilation results in significant alveolar atelectasis, intrapulmonary shunt, and subsequent hypoxemia. Chemical irritation of the respiratory tract, particularly the upper and lower airways, causes an acute inflammatory response.

The initial response is an approximately tenfold increase in bronchial blood flow. Concurrent with this is the stimulation of alveolar macrophages, the release of chemotactic factors, the activation of circulating neutrophils that localize to the site of injury, and the release of oxygen radicals and tissue proteases resulting in changes in vascular permeability. Development of airway edema, combined with sloughing of necrotic epithelial mucosa and impairment of mucociliary clearance of secretions, produces airway obstruction in small and large airways, and the result is ventilatory inhomogeneity. The mismatch between ventilation and perfusion leads to hypoxemia.

Wheezing and air hunger are common early symptoms of smoke inhalation. In a few hours, tracheal and bronchial epithelium begins to slough, and a hemorrhagic tracheobronchitis develops. The pulmonary parenchymal injury appears to be dose-dependent. Alveolar macrophages are activated and attract other white blood cells to the pulmonary endothelium where their release of inflammatory mediators and oxygen free radicals further disrupts the endothelial-epithelial barrier. Pulmonary lymph flow increases with an increased protein content after the double insult of smoke inhalation and cutaneous burns. The severe impairment of chemotaxis of pulmonary alveolar macrophages undoubtedly contributes to the high incidence of late pneumonia seen in patients with associated cutaneous burns.

In very severe cases, the hemorrhagic tracheobronchitis and small airway plugging result in severe ventilatory difficulty during the first 48 h and patients succumb to a severe respiratory acidosis because of their inability to clear CO₂. In moderately severe cases with associated extensive burns interstitial edema becomes prominent, resulting in *adult respiratory distress syndrome (ARDS)*, with difficulty in oxygenation.

Concomitant cutaneous burn injury results in the systemic release of inflammatory mediators, including prostaglandins and oxidants that can aggravate pulmonary injury independent of smoke inhalation. Thromboxane A₂ released from burned tissue causes a variety of changes in the lung, including pulmonary hypertension, reduced dynamic compliance, and increased lipid peroxidation. Oxidants generated as a consequence of neutrophil activation and increases in xanthine oxidase contribute to lung injury. Decreased plasma oncotic pressure from the loss of plasma protein through increasingly permeable vessels in both burned and unburned tissue creates an abnormal oncotic pressure gradient in the lung that, when combined with pulmonary hypertension, results in transient hydrostatic pulmonary edema. These changes help explain the degree of comorbidity in cases of combined inhalation and burn injuries.

Early in the course of smoke poisoning pulmonary function is variable. Typically, decreased lung volume (*functional residual capacity [FRC]*), decreased vital capacity, and evidence of obstructive disease with reduction in flow rates, an increase in dead space, and a rapid decrease in compliance occur. Much of the variability in pulmonary response appears to be related more to the severity of the associated cutaneous burn than to the degree of smoke inhalation. Without associated cutaneous burns, the mortality from smoke poisoning is very low, the disease rarely progresses to ARDS, and symptomatic treatment usually leads to complete resolution of symptoms in a few days. In the presence of burns, smoke poisoning approximately doubles the mortality from burns of any size. Pulmonary symptoms are usually present on admission, but they may be delayed for 12 to 24h. The earlier the onset, the more severe the disease.

Diagnosis

The incidence of smoke inhalation injury in victims of fire varies with diagnostic criteria. The incidence may be as low as 2 to 15 percent when single or restrictive criteria based on history and physical examination are used, but as high as 20 to 30 percent when based on tests such as fiberoptic bronchoscopy. The overall incidence of smoke inhalation in the United States has fallen in the past two decades, primarily because of the use of home smoke detectors.

Anyone with a flame burn and anyone burned in an enclosed space should be assumed to have smoke poisoning until proved otherwise. The acrid smell of smoke on the victim's clothes should raise suspicion. In obtaining a history, emphasis should be placed on data specific to the smoke exposure and to the type of therapy instituted prior to hospitalization. When exposure occurs in a closed space, such as a building or an automobile, the smoke is less diluted by ambient air, resulting in greater pulmonary exposure to carbon monoxide and smoke constituents than in an open-space exposure. The duration of exposure correlates with the severity of lung injury.

An examination should be performed, including evaluation of the face and oropharyngeal airway (edema, stridor, or soot impaction suggesting smoke inhalation), chest auscultation (wheezing or rhonchi suggesting injury to lower airways), level of consciousness (decreased with hypoxemia, carbon monoxide poisoning, or cyanide poisoning), and testing for the presence of specific neurologic defects that might be associated with carbon monoxide. A careful inspection of the mouth and pharynx should be done early. Hoarseness and expiratory wheezes are signs of potentially serious airway edema or smoke poisoning. Copious mucus production and carbonaceous sputum are signs of injury, but their absence does not indicate that injury is absent. Carboxyhemoglobin levels should be obtained; elevated carboxyhemoglobin levels or any symptoms of carbon monoxide poisoning are presumptive evidence of associated smoke poisoning.

Anyone suspected of smoke poisoning should have a set of arterial blood gases drawn. One of the earliest indicators is a falling P/F ratio, the ratio of arterial P_{O_2} to the percentage of inspired oxygen (FiO_2). A ratio of about 400 is normal; patients with impending pulmonary problems have a ratio of less than 350 (e.g., an arterial P_{O_2} of less than 140 with an FiO_2 of 0.40). A ratio of less than 250 is an indication for vigorous pulmonary therapy, not an indication for increasing the inspired oxygen concentration.

The early need for bronchoscopy remains controversial. Some recommend the routine use of fiberoptic bronchoscopy, noting that it is inexpensive, quickly performed in experienced hands, and useful in assessing edema of the upper airway. Aside from documenting the presence of tracheal erythema and carbon deposits, however, it does not materially influence the treatment for smoke poisoning. To determine the role of this examination in patients with smoke inhalation, fiberoptic bronchoscopy was performed in 100 consecutive patients admitted to a regional burn unit presenting with at least one warning sign of inhalation injury (closed-space smoke exposure, facial burn, singed nasal vibrissae, perioral burn, pharyngeal edema, hoarseness, carbonaceous sputum, bronchorrhea, or wheezing). A 96 percent correlation was found between positive bronchoscopic findings and the triad of closed-space fire, COHb levels >10 percent, and carbonaceous sputum. If two items of the triad were present, the correlation dropped to 70 percent, and if only one was present, the correlation was less than 30 percent. No other positive correlations were detected. Upper airway edema could best be correlated with an explosion (flash burn) that involved both the face and the upper torso. Nearly 50 percent of these patients had significant upper airway edema and underwent prophylactic airway intubation. Based on these observations and the limitations of fiberoptic bronchoscopy, it is recommended that a history, clinical examination, and laboratory studies be used to make the diagnosis of inhalation injury, and the use of fiberoptic bronchoscopy be reserved for exceptional cases (e.g., expansion of lobar atelectasis or removal of obstructing intrabronchial secretions).

Two clinical studies of burn patients with clinical signs of smoke inhalation found poor correlation of bronchoscopic findings with the need for ventilatory support or the subsequent development of ARDS, concluding that immediate bronchoscopy neither indicates the level of respiratory support that will be required nor predicts its duration. Flow volume loops may be useful, but are complex to perform and difficult to interpret. The simple admission chest x-ray is notoriously insensitive in detecting severely injured lung early after smoke exposure, with false-negative rates as high as 92 percent. Computed tomography (CT) may be useful in demonstrating early atelectasis and bronchial edema, but it is expensive and delays treatment, and, like bronchoscopy, has no practical implications for therapy.

Treatment

Upper Airway

No standard treatment has evolved to ensure survival after smoke poisoning. In the presence of increasing laryngeal edema, nasotracheal or orotracheal intubation is indicated. A tracheostomy is never an emergency procedure and should not be used as the initial step in airway management in patients with burns to the face and neck. Instead, a soft-cuffed endotracheal tube should be placed, and left in place for about 72 h or until the generalized oropharyngeal edema subsides. An adult patient's ability to breathe around the tube with the cuff deflated is an indication for removal of the tube. This assessment is difficult in children due to their smaller anatomy, the use of uncuffed endotracheal tubes, the increased incidence of postextubation stridor, and the frequent need for reintubation. The incidence of postextubation stridor in burn victims is as high as 47 percent, compared to 4 percent in elective surgical patients. The treatment of postextubation stridor includes the administration of racemic epinephrine and helium-oxygen (Heliox) mixtures.

Lower Airway and Alveolar Damage

Tracheobronchitis, commonly seen in smoke and toxic gas inhalation victims, produces wheezing, coughing, and retained secretions. The ventilation-perfusion mismatch present in these patients can result in mild to moderate hypoxemia, depending on the degree of underlying lung disease; therefore, supplemental oxygen should be administered routinely. Increased airway resistance is more often the result of decreased airway caliber (from mucosal and/or submucosal edema and retained secretions) than true bronchospasm. Although a trial of bronchodilators is indicated in those with preexisting bronchospastic disease, its efficacy is questionable. Nebulized or metered dose therapy with β_2 agonists or racemic epinephrine, subcutaneous terbutaline, or intravenous aminophylline is used most commonly.

The presenting sign of lower airway damage is hypoxemia, diagnosed by pulse oximetry or, preferably, arterial blood gas analysis. Because most inhalation victims receive supplemental oxygen, significant alveolar-arterial oxygen gradients can be missed by pulse oximetry; saturations less than 95 percent do not occur until arterial P_{O_2} is less than 80 mmHg. Arterial blood gas analysis is the monitor of choice in assessing oxygenation after inhalation injury. Initial therapy should always include the administration of high-flow oxygen, to supplement oxygenation and to reduce carboxyhemoglobin in cases of carbon monoxide inhalation. Upper airway patency must be assured, and airway resistance minimized with chest physiotherapy and/or bronchodilators. Central hypoventilation caused by carbon monoxide or cyanide poisoning should be treated immediately with endotracheal intubation and assisted ventilation, and efforts to reverse intoxication.

Treatment for smoke poisoning is supportive, with the goal of maintaining adequate ventilation and oxygenation until the lung heals itself. Mild cases of smoke poisoning are treated with highly humidified air, vigorous pulmonary toilet, and bronchodilators as needed.

The need for mechanical ventilation to supplement oxygenation is determined by repeated blood gas measurements. As a guideline, the Pa_{O_2}/FiO_2 (P/F) ratio may be calculated without mixed venous blood sampling and used as an approximation of the shunt fraction. A P/F ratio between 200 and 400 indicates mild to moderate injury, usually requiring only supplemental oxygen therapy. A P/F ratio below 200 is evidence of serious parenchymal lung injury, and usually indicates a need for intubation and ventilation with high inspired oxygen fractions or the use of *positive end-expiratory pressure (PEEP)*. Because of the frequent presence of atelectasis after alveolar exposure to smoke, PEEP can be useful, provided pressures are not excessive, subsequent to the initial use of large tidal volumes (10 to 15 mL/kg) initially in a standard volume-control ventilator setting. The tidal volume should be monitored by measuring total respiratory compliance over a range of tidal volumes, with avoidance of those volumes associated with a reduction in compliance (and increased risk of lung rupture).

High-frequency percussive ventilation has been attempted in patients with inhalation injury. This mode of ventilation provides adequate oxygenation at a lower FiO_2 , with lower peak and mean airway pressures. The benefit to inhalation injury is the apparently enhanced clearance of bronchial secretions achieved with this technique. Initial reports suggest potential superiority to standard ventilation techniques in patients with smoke inhalation. Mechanical causes for poor ventilation include restricted chest-wall motion from full-thickness burns, pneumothorax from high ventilator pressures, and mechanical difficulties with the endotracheal tube.

Establishing a tracheostomy in burn patients is controversial. If the upper airway is in danger of imminent obstruction and endotracheal intubation attempts are unsuccessful, emergent cricothyroidotomy is indicated. The indications for nonemergent tracheotomy have changed. After a period in the 1970s when tracheostomy was the standard method of securing the upper airway after severe burn injury, several reports associated the procedure with mortality rates ranging from 52 to 100 percent due to a greater incidence of overwhelming pulmonary infection. Improvement in endotracheal tube construction resulted in specific efforts to avoid tracheotomy in burn patients in the 1980s. Currently, mortality rates for burn patients with tracheostomy are not different from those for patients treated with endotracheal tubes, despite the fact that the former group is more likely to include patients who are burned so severely as to preclude survival. For patients requiring prolonged endotracheal intubation, tracheostomy should be performed between 3 and 30 days after intubation. Patients with anterior neck burns who require tracheostomy should undergo excision and grafting of the area 5 to 7 days prior to creation of the tracheostomy. This minimizes pulmonary and burn wound infectious complications associated with the tracheostomy.

Prophylactic antibiotics are not valuable in burn-related chemical pneumonitis, and subsequent burn management and treatment of eventual bacterial pneumonia can be made more difficult if the early use of antibiotics leads to the selection of resistant organisms. Steroids are commonly used in patients with severe asthma. There has been a tendency when dealing with smoke poisoning to use steroids for their spasmolytic and anti-inflammatory action. In a prospective blind study of patients with smoke poisoning and associated major burns, Moylan and Chan demonstrated that mortality and infectious complications were higher in the patients treated with steroids. Robinson found that steroids did not alter the hospital course of patients without associated burns admitted to hospital after the MGM Grand and Hilton hotel fires in 1981. A trial of genetically engineered surfactant in patients with smoke poisoning was unsuccessful.

The decision on whether to admit a patient to the hospital, as well as the need for specialized care, depends on the severity of symptoms from the smoke and the presence of associated burns. A patient who has symptoms associated with smoke inhalation and who has more than trivial burns should be admitted. If the burns are greater than 15 percent TBSA, the patient should be referred to a burn center intensive care unit. In the absence of burns, admission depends on the severity of symptoms, the presence of preexisting medical problems, and the social circumstances of the patient. Otherwise healthy patients with mild symptoms (only a few expiratory wheezes, minimal sputum production, CO level <10, and normal blood gases) who have a place to go and someone to stay with them can usually be watched for a few hours and then discharged. Patients with preexisting cardiovascular or pulmonary disease should be admitted for observation if they have symptoms related to the smoke. Patients with moderate symptoms (generalized wheezing, mild hoarseness, moderate sputum, CO levels of 5 to 10 percent) and normal blood gases can be admitted for close observation and treatment. Severe symptoms (air hunger, severe wheezing, copious, usually carbonaceous, sputum), require intubation, possible therapeutic bronchoscopy, ventilator support, and placement in an intensive care unit.

WOUND MANAGEMENT

Early Excision and Grafting

For many years, burns were treated by daily washing, removal of loose dead tissue, and topical application of saline-soaked dressings until they healed by themselves or granulation tissue appeared in the base of the wound. Superficial dermal burns healed within 2 weeks and deep dermal burns healed over many weeks if infection was prevented. Full-thickness burns lost their eschar in 2 to 6 weeks through bacterial collagenase production and daily mechanical debridement. When the granulating bed became free of debris and relatively uninfected, split-thickness skin grafts were applied, usually some 3 to 8 weeks after injury, and a 50 percent graft take was considered acceptable. Repeated graftings eventually closed the wound. The prolonged and intense inflammatory response made hypertrophic scar and contractures part of normal burn treatment. Vigorous physical therapy, nutritional support, psychological support, and pain management were required on a daily basis for many weeks to yield a satisfactory result.

This is no longer standard procedure. For deeper burns, rather than waiting for spontaneous separation, the eschar is surgically removed and the wound closed, with grafting techniques and procedures for immediate placement of flaps tailored to meet patients' individual needs. Several technical advances have made this possible. There is "safer" blood, better monitoring equipment and methods, and a better understanding of the altered physiology and increased metabolic demands of patients with major burns. The ability to stabilize the patient within a few days of the injury has enabled the surgeon to remove deep burn wounds before invasive infection occurs. An aggressive surgical approach to large and small burns has produced a number of advantages. Early wound closure shortens hospital stay and duration of illness. Early studies did not demonstrate dramatic differences in cosmetic and functional results, but as surgeons have become more experienced, both improved function and appearance have resulted. This is particularly true with burns of the face, hands, and feet.

Historical Perspective

The surgical principle that "clean wounds should be closed" has been applied since the days of Hippocrates. For technical reasons, burns have been the exception to this rule. Early in the twentieth century, primary burn wound closure was attempted in patients with major burns, but systemic instability, massive hemorrhage, graft loss, malnutrition, and infection resulted in such high mortality rates that major burn excisions were abandoned. Because of their relatively limited extent, electrical burns remained an exception. Cope was the first to report a series of 58 primary excision and graftings in 38 patients after a 1947 nightclub fire. From 1961 to 1974, Janzekovic treated 2615 of 4370 burned patients with early tangential (or sequential) excision and sheet autografting; most of the burns were small (under 20 percent TBSA). The hospital stay dramatically decreased, pain was less, need for

reconstructive procedures decreased, and “aesthetic disability” was greatly reduced. The early 1980s produced more clinical and experimental data suggesting that prompt wound closure produced better results and improved metabolic response. It is more difficult to prove that early excision improves mortality in patients with extensive burns (greater than 60 percent TBSA). Until a useful “artificial skin” is available, the goal of early complete wound closure in patients with massive burns cannot be achieved. In these patients, donor sites are limited and excised burns must be covered with temporary biologic dressings until the donor sites heal and can be recropped. Recent FDA approval of a permanent “off the shelf” dermal substitute made of collagen matrix combined with a glycosaminoglycan (chondroitin 6-sulfate) that acts as a template for endogenous cells to reproduce a new dermis is a major step in the development of a permanent skin substitute.

Elderly patients present unique problems. Continued stress from the burn injury results in a high incidence of cardiac and cerebrovascular catastrophes. The atrophic skin of elderly patients presents problems in burn wound and donor site healing. No substantial decrease in mortality for elderly patients has occurred. The mortality rate for patients over 65 years of age with burns less than or equal to 20 percent TBSA remains at approximately 10 percent. This increases logarithmically as the size of the burns increases, and there are few elderly survivors with burns over 50 percent TBSA.

More burn centers are practicing early excision and grafting. When experience has made these procedures routine, early excision and grafting will become the treatment of choice for all deep dermal and full-thickness burns. The procedure is still limited by difficulty in diagnosing burn depth, by limited donor sites, and the difficulties involved in excision of three- dimensional areas, such as the perineum, ears, and nose.

Current Status of Wound Care

Evidence supports the following conclusions:

- (1) Small (less than 20 percent) full-thickness burns, and burns of indeterminate depth (deep partial versus full thickness), if treated by an experienced surgeon, can be safely excised and grafted with a decrease in hospital stay, cost to the patient, and time away from work or school.
- (2) Early excision and grafting dramatically decreases the number of painful debridements required by all patients.
- (3) Patients with burns between 20 and 40 percent TBSA will have fewer infectious wound complications if treated with early excision and grafting.
- (4) In animals with experimental burns, the depressed immune response and hypermetabolism associated with burns can be ameliorated by early burn wound removal.

Clinical impressions without hard data supporting them include the following:

- (1) Scarring is less severe in wounds closed early, leading to better appearance and fewer reconstructive procedures. There is no good measure of acceptable “cosmetic appearance ” and comparative studies await an acceptable scale to measure results.
- (2) Mortality from wound infection is lower in patients with major burns after early excision. Because wounds exceeding the donor sites cannot permanently be closed completely until donor sites can be reharvested, proof will come only when a durable permanent cover can be applied in a timely fashion.
- (3) Mortality from other complications of major burns may be lower with early excision and grafting. Decreasing stress, hypermetabolism, and the overall bacterial load of the patients enables them to resist other complications. The only data to support this conclusion come from animal studies.

Technical Considerations

Excision of more than 10 percent of the total body surface should be done in a highly structured environment. Without tourniquets, blood loss can be massive. Graft loss can be catastrophic. Excellent monitoring, nursing, physical therapy, nutritional support, anesthesia, and 24-h physician coverage are mandatory. Smaller burns in important areas (hands, face, and feet) also require considerable experience.

Excisional procedures should be performed as early as possible after the patient is stabilized. This allows the wound to be closed before infection occurs and, in extensive burns, allows donor sites to be recropped as soon as possible. Cosmetic results are better if the wound can be excised and grafted before the intense inflammatory response associated with burns becomes well established. Any burn projected to take longer than 3 weeks to heal is a candidate for excision within the first postburn week. Wound excision is adaptable to all age groups, but infants, small children, and elderly patients require close perioperative monitoring.

Excision can be performed to include the burn and subcutaneous fat to the level of the investing fascia (fascial excision), or by sequentially removing thin slices of burned tissue until a viable bed remains (sequential excision). Fascial excision assures a viable bed for grafting, but takes longer, sacrifices potentially viable fat and lymphatics, and leaves a permanent cosmetic defect. Sequential excision can create massive blood loss and risks grafting on a bed of uncertain viability, but sacrifices minimal living tissue and leads to a far superior cosmetic result than fascial excision. Current practice reserves fascial excision for patients with fourth-degree burns and patients with such massive burns that they can afford no graft loss.

Tangential (Sequential) Excision

The principle of tangential excision is to shave very thin layers of burn eschar sequentially until viable tissue is reached. The burn can be removed with a variety of instruments, usually power- or hand-driven dermatomes. Relatively shallow burns and some burns of moderate depth will bleed briskly from thousands of capillaries after one slice. If the bed does not bleed briskly, another slice of the same depth is taken until a viable bed of dermis or subcutaneous fat is reached. If inspection of the dermal or fatty bed reveals a surface that appears gray or dull rather than white and shiny, or if there is evidence of clotted vessels, the excision should be carried deeper. Any fat that has a brownish discoloration, has blood staining, or contains clotted blood vessels will not support a skin graft and must be excised until the bed contains uniformly yellow fat with briskly bleeding vessels. Bleeding is controlled with sponges soaked in 1:10,000 epinephrine solution applied to the excision bed for 10 min. Continued bleeding is then controlled with an electrocautery. Major bleeding is rare; when bleeding has occurred, it has invariably been associated with inadequate cauterization of a vessel with pulsatile flow.

Areas on the extremities may be excised using a tourniquet. The cadaver- like appearance of the dermis and the lack of brisk bleeding can easily mislead the surgeon into sacrificing normal tissue by carrying the excision deeper than necessary.

Fascial Excision

Fascial excision is reserved for patients with very deep burns (charred flame burns, prolonged contact burns, molten metal burns, and electrical burns), or for patients with very large, life-threatening, full-thickness burns. The most common technique uses an electrocautery with cutting and coagulating capabilities.

The advantages of fascial excision include:

- (1) It results in a reliable bed of known viability.
- (2) Tourniquets can be routinely used for extremities.
- (3) Operative blood loss is less than with sequential excision.
- (4) Less experience is required to ensure an optimal bed.

The disadvantages include:

- (1) The operative time is longer.
- (2) There may be severe cosmetic deformity, especially in obese patients.
- (3) There is a higher incidence of distal edema when excision is circumferential.
- (4) There is greater danger of damage to superficial nerves and tendons.
- (5) Cutaneous denervation, which may or may not be permanent, may occur.
- (6) Skin graft loss from the relatively vascular fascia over joints (elbow, knee, ankle) can lead to an ungraftable bed and require eventual flap coverage.

Early Reconstruction

A potential advantage to excision and grafting is to provide a closed wound before the intense inflammatory response begins. If careful attention is given to sound principles of plastic surgery, the risk that there will be a need for subsequent reconstruction can be decreased. Skin graft junctures should be avoided over joints, and grafts should be placed transversely when possible. Thick skin grafts yield a better appearance than thin skin grafts. If the burn is well excised, and the skin can be spared, thick skin grafts should be used on the face, neck, and other cosmetically important areas. The resultant donor sites can be overgrafted with thin skin grafts to minimize hypertrophic scarring of the donor site. Whenever possible, cosmetically important areas should be grafted with sheet skin grafts. Although meshed skin grafts provide cover with excellent function, the meshed pattern persists as a permanent reminder of the burn.

Adjacent pieces of skin graft should be approximated carefully. While staples are adequate for areas in which cosmetics is not an issue, for critical areas, such as the face, suturing

the edges together is preferred. If the wound can be left open or dressed with a dry bandage after sheet skin grafting, steri-strips can be used effectively. They will not remain in place if the wound is covered with moist dressings.

Keeping these early reconstructive principles in mind during the first operations may avert the need for later procedures entirely, and will help convert what could be major reconstructive efforts into minor ones.

Donor Sites

In previous years, when only full-thickness burns were skin-grafted, and patients endured many weeks of daily debridement, donor sites were treated superficially. They were covered with either dry fine mesh gauze, or gauze impregnated with a dye or other antimicrobial agent. They were left to desiccate, and the gauze usually separated from the wound in 2 to 3 weeks, sometimes removing substantial areas of new epithelium. As aggressive programs of early excision and grafting developed, donor sites became a priority. With early excision, the patient was spared the painful daily debridement, and with burn pain diminished, patients concentrated on donor site pain.

There are hundreds of dressings available for donor site and after-grafting wound care. Reports indicate that there is no optimal donor dressing. All dressings seem to work, and differences in healing times are only 1 or 2 days. Comfort levels and ease of care are the most significant determinants.

Healed donor sites are still not free of complications. In addition to hypertrophic scarring and changed pigmentation, patients may be troubled by blistering for several weeks. Blisters are self-limiting and are usually treated with bandages or ointments until they reepithelialize. Infections occur in about 5 percent of patients. Infection is treated with systemic antibiotics and continuously moist dressings or silver sulfadiazine.

SKIN SUBSTITUTES

The next major step in burn care is likely to be an artificial skin that will be readily available, perform barrier function (epidermis), and provide the structural durability and flexibility of the dermis. It must be permanent, affordable, not susceptible to hypertrophic scarring, provide normal pigmentation, and grow with developing children. Progress toward this goal has been substantial over the past decade.

Cultured Epidermal Autograft

In the earliest grafting procedures, successful in vitro culturing of epidermal cells (keratinocytes) produced a permanent skin cover whereby small bits of unburned skin could provide seed keratinocytes that could be grown to form sheets of cells and grafted onto a burn wound bed, closing massive wounds when donor sites were limited. The first successful grafting was reported in children in 1986. In 3 weeks' time, an initial skin biopsy could be enlarged 1000 times, producing hundreds of 5- by 5-cm sheets of epidermis, three to eight cell layers thick. Placing these fragile sheets on an excised burn wound could provide a permanent wound cover. Considerable experience has been gained with *cultured epidermal autografts (CEAs)*. Areas of concern and controversy remain with respect to efficacy of take, durability, necessity, and cost-effectiveness.

Variability in take may be related to the bed on which the CEAs are applied, with native or allogenic dermis (from cadaver allografts) being the most successful. Bacterial contamination and colonization of the grafted bed results in rapid CEA disappearance from the site.

Engrafted CEAs are poorly adherent and extremely fragile for months after application. Care must be taken to avoid blistering and graft loss with movement, rubbing, scratching, and physical therapy because of the lack of a dermis in excisions that reach fat or fascia. The histologic events leading to CEA maturation also appear inconsistent. One study reported that within 6 days "flat epidermis with all normal strata had regenerated, and the process of de novo dermal-epidermal junction formation had begun" and "within three to four weeks, the dermal-epidermal junction was complete, but full maturation of anchoring fibrils required more than a year." Compton reported that "the subjacent connective tissue initially healed to form normal scar, but it remodeled dramatically, regenerated elastin, and resembled a true dermis within four to five years." Putland, however, indicated that "the CEA interface with underlying bed remained flat for up to three years in three of four patients. CEA epidermal rete ridges, if formed subsequently, were fewer, thinner, and shorter, whereas expanded split-thickness skin grafts had well-defined rete ridges after one year." It was concluded that the persistent fragility of CEAs is related to the delayed formation of rete ridges.

When the patient is admitted, a 1-cm² skin biopsy specimen is usually sent to a commercial laboratory for culturing. Three weeks later 5- by 5-cm² sheets of cultured cells are delivered. CEAs are expensive. Rue reported that the average cost of CEAs covering only 4.7 percent TBSA was \$43,000.

The following conclusions can be drawn:

- (1) Cultured keratinocytes can be grown within 3 weeks and can be grafted successfully on a viable, noninfected excised burn wound bed. For a massive burn with few or no available donor sites, this may be life-saving, especially in children.
- (2) Take varies from poor to fair, with an optimistic range of 30 to 40 percent.
- (3) Because epidermal cells lack a dermis, in early stages of wound healing, CEAs can provide only a barrier function to prevent fluid exudation and bacterial invasion.
- (4) The cover is fragile and must be protected from mechanical disruption for months, limiting daily activities and vigorous physical and occupational therapy.
- (5) The cost is approximately \$6000 to \$10,000 for each 1 percent TBSA covered.
- (6) CEAs are a temporary measure, permitting survival in the patients with massive burns. It is unlikely that they can ever be a permanent solution because they provide only one-half of the necessary bilaminar constituent of skin.

Dermal Substitutes

Many investigations have looked for an acceptable dermal matrix onto which CEA or thin epidermal grafts could be placed. The only FDA-approved synthetic dermal substitute, a material developed by Burke and Yannis, is a bovine collagen matrix with fiber size and distance similar to that of dermis, with a ground substance, chondroitin 6-sulfate, filling the pores. It provides a template on which native fibroblasts, endothelial cells, and macrophages can replace the collagen with a dermal matrix resembling dermis more than disorganized scar. In a multicenter trial to determine whether results with ultrathin epidermal grafts over this material could provide cover equal to conventional meshed grafts, the results were excellent. The material is now in use, offering better cosmetic and functional results using ultra-thin epidermal grafts so that donor sites can be recropped frequently in the treatment of large burns.

NUTRITIONAL SUPPORT

The nutritional effects of the hypermetabolic response to thermal injury are manifested as exaggerated energy expenditure and massive nitrogen loss. Nutritional support is directed primarily toward provision of calories to match energy expenditure and provision of nitrogen to replace or support body protein stores.

Changes in metabolism are triggered by drastic changes in the hormonal profile, including elevated levels of catecholamines, glucocorticosteroids, and glucagon. These hormones, together with other circulating peptides, such as IL-1, TNF, and probably IL-6, accelerate protein catabolism, gluconeogenesis, and lipolysis. Insulin levels are usually in the normal range or elevated, but they are low in relation to the increased glucagon concentrations in plasma. Catecholamines and glucocorticoids antagonize the action of insulin, the key anabolic hormone that promotes storage of the metabolic fuels within the cells. These metabolic and hormonal consequences have important effects on nutritional status.

Caloric Requirements

Malnutrition in patients who have undergone a surgical procedure was first characterized in terms of negative energy balance. Hypermetabolism and hypercatabolism are universal consequences of injury. The cause of hypermetabolism seems to be dictated by the neurohumoral and cytokine stress response. The magnitude of the increase in metabolic rate is directly proportional to the size of burn injury. The total energy expenditure may be elevated from 15 to 100 percent of basal needs, exceeding those of other injuries and directly proportional to burn size. Energy needs must be evaluated carefully in formulating a parenteral or enteral diet therapy program. If the regimen is deficient in calories, protein synthesis will not be optimal, and nitrogen balance will continue to be negative. Mathematical derivations exist for the calculation of daily caloric needs in burns. The formula most used is the Long's modification of the Harris-Benedict equation (Table [7-3](#)). The Harris-Benedict equation estimates *basal metabolic rate (BMR)* with reasonable accuracy. Long proposed that the BMR be multiplied by various stress factors depending upon type of injury. The current revision for burn patients uses a multiplication factor of 1.3. The more severely ill the patient, the less accurate standard formulas are for estimating calorie expenditure.

Routine determination of *resting energy expenditure (REE)* from the measurement of oxygen consumption and carbon dioxide production is conducted at least twice weekly on burn patients for proper adjustments of caloric needs. REE determinations should not be construed as equivalent to the 24-h calorie requirement. Compensations must be made for daily energy fluctuations that occur with physical therapy, stress, temperature spikes, dressing changes, and other influences on metabolic rate. The patient's calorie goal should be calculated at 120 to 130 percent of the measured REE. Urinary nitrogen excretion is relatively easy to measure, but nitrogen losses in dressings and skin make accurate measurements of nitrogen balance difficult to obtain.

Carbohydrates

Carbohydrates, primarily in the form of glucose, appear to be the best source of nonprotein calories in the thermally injured patient. Certain tissues, including the burn wound, neural tissues, and the formed elements of the blood, utilize glucose in an obligatory fashion. Provision of glucose to these tissues occurs at the expense of lean body mass if adequate nutrition is not provided. In the unaliminated state, the major sources of three carbon precursors for new glucose production by the liver are the wound and skeletal muscle. The wound uses glucose by anaerobic glycolytic pathways, producing large amounts of lactate as an end product. The wound meets its high glucose requirements by means of high glucose delivery rates, which are made possible by the enhanced circulation to the wound.

In the liver, lactate is extracted and utilized for new glucose production by the Cori cycle. Concomitantly, alanine, glutamine, and other glycogenic amino acids contribute to increased gluconeogenesis. Increased ureagenesis, with urea ultimately derived from body protein stores, parallels the rise in hepatic glucose output. Peripheral amino acids and wound lactate account for approximately one-half to two-thirds of new glucose produced by the liver. The mild hyperglycemia observed in hypermetabolic burn patients is a

consequence of accelerated glucose flow arising from increased hepatic glucose production, not from decreased peripheral utilization.

Because glucose that is obtained by gluconeogenic pathways is ultimately derived from protein stores, depletion of body protein during periods of starvation leads to energy deficits and malfunctioning of glucose- dependent energetic processes at the cellular level. Active transport mechanisms responsible for maintaining transmembrane ionic gradients in erythrocytes are deranged in catabolic, thermally injured patients. The abnormal sodium and potassium gradients in red blood cells can be reversed by providing these patients with high caloric levels of carbohydrate as glucose. Hepatic clearance of indocyanine green, an energy-dependent active transport process, is decreased in severely injured patients when energy normally supplied as glucose is replaced by an isocaloric glucose-free source. Glucose-insulin solutions correct the “sick cell syndrome” in burned patients who exhibit a prompt natriuresis and nonosmotic diuresis when metabolic requirements are met by glucose.

Protein

Combining glucose and nitrogen-containing nutrients improves nitrogen balance and allows more calories to be used for the restoration of nitrogen balance than would be the case if either nutrient group were used alone. Energy and protein cooperatively contribute to the improvement in protein conservation. After injury, the individual effects of glucose and amino acids on nitrogen equilibrium operate by at least two different mechanisms. Amino acid administration promotes synthesis of visceral and muscle protein without affecting the rate of protein breakdown. Glucose retards whole- body protein breakdown and decreases the total amino acid pool, but exerts little effect on protein synthesis. Both mechanisms improve nitrogen balance, and glucose and nitrogen should be components of the nutritional regimen for the severely burned catabolic patient.

The unique importance of glutamine as a fuel source has been recognized. The gastrointestinal tract uses glutamine as a respiratory energy source, and disposes of the majority of glutamine as ammonia, urea, and citrulline. The alanine generated from glutamine in the intestine and kidney is used for gluconeocentesis. During critical illness, circulating concentrations of glutamine fall, and supplemental glutamine is required to meet gastrointestinal tract energy requirements. While glutamine is easily supplied by the enteral route, and all agree on its efficacy, parenteral preparations are not routinely available. There is controversy as to whether parenterally administered glutamine is efficacious.

Administration of arginine after injury has become increasingly important. Increased dietary arginine may diminish protein catabolism, reducing urinary nitrogen secretion in trauma or stress and improving immune function. Another beneficial effect of arginine is its secretagogue activity on pituitary and pancreatic hormones. Dietary arginine supplementation was shown to increase plasma insulin levels after glucose administration in protein-depleted rats. Tube feedings designed to enhance immune function have demonstrated the beneficial effects of arginine on anabolic hormone secretion.

Fat

The role of fat as a source of nonprotein calories is dependent on the extent of injury and the associated hypermetabolic response. When hypercaloric diets that do not contain nitrogen are administered, carbohydrate alone is more effective in sparing body protein than is fat alone. Fat appears to be a poor calorie source for the maintenance of nitrogen equilibrium and lean body mass in hypermetabolic patients with large burns. Patients with only moderate elevations of metabolic rate can use lipid calories efficiently, but these patients rarely require parenteral nutrition; most table foods and defined diets contain all necessary fat nutrients.

Linoleic acid was established as “essential” in the 1930s. It cannot be synthesized and has a specific role in maintaining cellular integrity. Consumption of 1 to 3 percent of total calories as linoleic acid is sufficient to prevent deficiency in humans. Studies suggest that fatty acids of the omega-3 family (particularly a-linolenic and eicosapentaenoic acid) are also important in dietary constituents. Eicosapentaenoic acid is the primary source of the triene prostaglandins. Omega-3 fatty acids form a series of compounds similar to the omega-6 series, but have different biologic effects. These effects are less catabolic and less injurious than prostaglandins derived from the omega-6 fatty acids.

Not only the amount of total fat, but also the structure of the fatty acids used in nutritional support programs, can have divergent effects on metabolism, morbidity, and mortality. Enteral tube feeding products are largely devoid of omega-3 fatty acids; a-linolenic deficiency has been demonstrated in patients on long-term tube feedings.

Vitamins and Minerals

Vitamin requirements in critically ill hypermetabolic burn patients remain poorly defined. The fat-soluble vitamins (A, D, E, and K) are stored in fat depots and are slowly depleted during prolonged feeding of solutions that do not contain any vitamin formulations. The water-soluble vitamins (B- complex and C) are not stored in appreciable amounts, and are depleted rapidly. All vitamins should be supplemented. The dosage guidelines recommended by the *National Advisory Group/American Medical Association (NAG/AMA)* are reasonable for burn patients unless symptoms of deficiency occur. Ascorbic acid has an essential role in wound repair, and plasma levels are frequently depressed in burn patients. It is prudent to supplement the NAG/AMA formulation with 250 to 500 mg of vitamin C daily. Larger doses may cause diarrhea and formation of renal stones, and will interfere with laboratory studies. Excessive doses of vitamins A and D produce toxic symptoms, and monitoring of serum levels in critically ill patients is often misleading, since the concentrations of the vitamin carrier proteins are commonly decreased in these patients.

Mineral nutrients are important because of their role in metabolic processes. Frequent determinations of serum sodium, potassium, chloride, calcium, magnesium, and phosphorus are the best guides to electrolyte replacement. Less is known about trace metal requirements after thermal injury. Zinc is an important cofactor in enzymatic function and wound repair, and zinc deficiency has been documented in burn patients. After injury in animal models, zinc and other trace metals seem necessary for nitrogen retention, but the level of these metals may merely reflect nitrogen balance and have little direct implication. Periodic measurements of zinc, copper, manganese, and chromium are the best way to determine replacement-dosage guidelines. Trace elements are present in varying concentrations as contaminants in amino acid parenteral solutions, and contribute to satisfying daily requirements.

Route of Administration

The route of administration of nutrients is important because it seems to influence outcome. Total parenteral nutrition is used only when the patient's needs cannot be wholly met by the enteral route.

Patients with burns under 25 percent TBSA that are not complicated by facial injury, inhalation injury, or malnutrition, and are not associated with psychological difficulties, including possible abuse, can usually be maintained on high-calorie, high-protein diets ingested orally. The nutritional requirements of patients with large burns cannot be met by the oral route alone, and these patients should be fed gastrointestinally or nasointerally. A functionally intact alimentary tract always should be used.

In severely burned patients, gastric ileus may limit the stomach's role in nutritional support, at least in the early postburn phase, but the small bowel usually maintains normal mobility and absorption. The safest route for infusion of nutrients is distal to the ligament of Treitz. The placement of a small bowel feeding tube, during resuscitation or during surgical treatment, can be the first step in providing nutritional support. A protective nasogastric tube is used to measure gastric residual content. Enteral feeding has advantages over parenteral feedings. Enteral nutrients seem to maintain the integrity of the gastrointestinal tract, and increased hepatic protein synthesis may reduce the incidence of bacterial translocation from the gut. An oral diet preserves gut mucosal mass and maintains digestive enzyme content; parenteral feeding results in decreased mucosal cell turnover. Studies have verified that oral feeding stimulates the gut to elaborate trophic hormones, particularly gastrin. Enteral calories initiate greater insulin release than parenteral nutrition, and insulin appears to promote anabolism. Studies have shown that institution of enteral feeding immediately after admission of patients with burn trauma is beneficial. This feeding technique blunts the intensity of the hypercatabolic response and more effectively maintains preinjury weight. Associated findings are decreased circulating concentrations of the counterregulatory hormones epinephrine, glucagon, and corticosteroids.

Total parenteral nutrition should be instituted when enteral feedings alone cannot provide adequate nutritional support. Prolonged postresuscitation ileus, overuse of narcotics, and constipation are frequently causes of failure of successful enteral alimentation. Sepsis is associated with ileus and severe glucose intolerance, and these symptoms may be the only evidence of this complication. Previously tolerated feedings must often be discontinued while hyperglycemia is being controlled and the patient is resuscitated. Ileus commonly persists, and nutrition is reinstituted by the parenteral route, often requiring large doses of insulin. If total support cannot be supplied enterally, it is useful to continue enteral nutrition even if the majority of nutrition is supplied parenterally. The benefits of enteral nutrition are realized even when 20 percent of needs are given enterally.

Composition of Enteral Nutrition

Three decades ago, burn and trauma patients requiring nutritional support beyond that provided by a hospital diet received tube feedings consisting of food solutions prepared in a blender. These blended meals have been standardized, and are available in commercially prepared formulas. The goal is to provide nutritional support tailored to meet the needs of critically ill burn patients. Nutritional support should provide substrates in proportions based on the specific metabolic derangements in burns. Standard meal replacement products formulated for nonstressed or minimally stressed patients do not meet the unique nutritional requirements of moderately or severely metabolically stressed patients. Because these regimens can be grossly incompatible with needs, they are often counterproductive, exacerbating nutritional inadequacies and increasing the chance of hepatic, pulmonary, and gastrointestinal tract complications, as well as other metabolic dysfunction. Studies of patients with renal failure, pulmonary insufficiency, hepatic encephalopathy, and burns indicate that specialized feeding regimens improve disease-related metabolic derangements while enhancing nutritional status.

In burn patients, significant amounts of omega-3 fatty acids should be used. The modular tube feeding at the Shriners Burns Institute is a high- protein (20 percent of calories), low-fat (15 percent of nonprotein kilocalories [kcal]) nucleic acid–restricted formulation (only enough to supply essential fatty acid), which is enriched with omega-3 fatty acid (half of lipid calories), arginine (2 percent of kcal), cysteine (0.5 percent of kcal), histidine (0.5 percent of kcal), vitamin A (5000 IU/L), zinc sulfate (220 mg/day), and ascorbic acid (1 g/day). The composition is structured to improve immune function, optimize wound healing, and lower production of the proteolytic and immunosuppressive dienoic prostaglandins. Commercially available immune function–enhancing enteral feedings have been shown to improve critically ill patients. Monitoring enteral and tube feeding regimens to determine the tolerance and effectiveness of the dietary program is as important as selection and initiation of the formula. Careful nutrition and metabolic assessment can help ensure optimal support with minimal complications. Table [7-4](#) outlines suggested clinical and laboratory parameters that should be continuously monitored. The most effective nutritional support regimens are effected by adherence to sound principles of early implementation of immune function–enhancing enteral feeding, with individual balancing and continuous monitoring.

Ancillary Nutritional Support Measures

Metabolic expenditure can be minimized by blunting stressful stimuli. Thermally injured patients, particularly children, have difficulty maintaining body temperature in cold environments. Because of the apparent change in the hypothalamic set point of thermal neutrality, burn patients require higher ambient temperatures for comfort. The temperature of thermoneutrality is approximately 38.2°C (100.7°F), 4 degrees higher than that of normal subjects. Warming burn patients to this level decreases the metabolic rate and corresponding energy requirements. Thermal blankets, radiation reflectors, and heat lamps may be required to maintain the patient's temperature above 37°C (98.6°F).

Pain that accompanies wound manipulation and other patient care procedures accentuates metabolic expenditure, and administration of narcotics reduces the metabolic rate. Adequate analgesia and sedation should be provided so that patients have periods of uninterrupted rest. Hypovolemia, dehydration, and sepsis are potent stimuli of catecholamine secretion, and appropriate regimens for volume replacement and antibiotic administration should be followed. Systemic infection exacerbates erosion of body mass, and additional

calories must be supplied to maintain nitrogen balance at the same level obtained before infection.

Human growth hormone increases nitrogen retention when administered with adequate calories and nitrogen. Improved nitrogen balance is reflected by increased retention of potassium, phosphorus, and amino acids. The actions of exogenous growth hormone appear to be mediated by the effects of increased insulin secretion on carbohydrate metabolism and perhaps increased secretion of insulin-like growth factor. Lack of activity promotes muscle wasting and atrophy. Vigorous physical therapy promotes preservation of muscle bulk and must be provided on a daily basis to all patients requiring prolonged hospitalization. Patients in skeletal traction or air-fluidized beds are relatively immobile and lose lean body mass as a result; simple isometric exercises can usually be done by these patients. Wound care and expeditious wound closure are the most effective measures for limiting the injury and its metabolic sequelae.

INFECTION

Most morbidity and mortality in severely burned patients are related to infection. Thermal injury causes severe immunosuppression that is directly related to the size of the burn wound. A direct relationship between specific immune defects and infection has yet not been established, but it is likely that this global immunosuppression makes the burn patient susceptible to infection. Sepsis occurs when the balance of interaction between the host and opportunistic organisms is altered unfavorably. Important determinants of sepsis in burn patients are factors such as the creation of new portals of entry, altered host defenses, and exposure to potential pathogenic and opportunistic organisms.

Predictors of Infection

Reliable predictors of infection in patients with severe burns would allow more timely intervention with surgical excision and/or anti-infective agents. Many aspects of the hypermetabolic response of uninfected burn patients are similar to those of infected and septic patients without large inflammatory wound surfaces. The extent of burn injury is one of the major demographic predictors of outcome. The incidence of infection and sepsis rises as burn size increases. Children appear to be more susceptible to systemic infection for a given burn size. The presence of inhalation injury correlates highly with infection and mortality. Patients with severe inhalation injury and no burn can have a fatal outcome. Burns involving less than 10 to 20 percent TBSA in otherwise healthy burn patients are almost never associated with life-threatening infection.

The search for a laboratory study to facilitate the early diagnosis of infection has led to intense examination of postinjury alterations of hormones, acute-phase proteins, and fluorescent substances in the blood and plasma of burn patients. Most laboratory studies are nonspecific and cannot distinguish between inflammation and infection.

Clinical Manifestations

Many of the physiological criteria that have been claimed to reflect sepsis are noninfectious manifestations of postinjury hypermetabolism. Hyperthermia, tachycardia, increased ventilation, and high cardiac output are present routinely in otherwise healthy patients with large burns.

Body temperature in burn patients is dependent partially on environmental conditions. Hyperthermia (39°C [102.2°F] or greater) occasionally represents a febrile response to infection, particularly in children, but episodic elevations in temperature are common in uninfected burn patients. This diagnosis remains one of exclusion, and a definitive diagnosis cannot be made without a workup designed to detect infection. Hypothermia, however, commonly indicates sepsis, usually due to gram-negative organisms. Leukocytosis is also nonspecific. As long as large wounds remain open, moderate elevations in leukocyte counts are common. Thrombocytopenia is caused by several factors, including infection and sepsis. Normal to high platelet counts almost always occur in burn patients who are stable, and are not an indication of the imminent likelihood of sepsis. Thrombocytopenia is one of the major manifestations of infection.

Other systemic manifestations are even more nonspecific. Decreasing mental status can be caused by excessive sedation, histamine receptor blocking agents, and cerebrovascular disease. Hyperglycemia may be due to irregular administration of high-calorie nutrient solutions or hypokalemia. Increased food requirements, hypotension, and oliguria may be related to underreplacement of evaporative water loss or unrecognized diarrhea. The most important observations are related to the temporal association of these physiological events. A precipitant onset of hyperglycemia, fall in blood pressure, and decrease in urinary output should suggest the possibility that the patient is becoming unstable. If these findings are associated with development of hypothermia, leukopenia, and a falling platelet count, the patient is probably developing sepsis, and it is important to do an immediate infection evaluation and administer the appropriate antibiotics.

The most common location of lethal infection is the respiratory tract. Awareness of the variety of infections commonly encountered in burn patients allows an orderly evaluation of the potentially infected patient.

Wound Infection

A change in the pattern of burn wound infections over the past few decades is probably related to the proliferation of broad-spectrum antibiotics. Before the availability of penicillin, streptococci and staphylococci were the predominant infecting organisms. By the late 1950s, gram-negative bacteria (*Pseudomonas* species) had emerged as the dominant organism causing fatal wound infections in burn patients.

All burn wounds become contaminated soon after injury with the patient's endogenous flora or with resident organisms in the treatment facilities. Microbial species colonize the surface of the wound and may penetrate the avascular eschar. This event is without clinical significance. Bacterial proliferation may occur beneath the eschar at the viable tissue–nonviable tissue interface, leading to subeschar separation. In a few patients, microorganisms may breach this barrier and invade the underlying viable tissue, producing systemic sepsis.

The essential pathological feature of burn wound sepsis is invasion of the organisms into viable tissue. The organisms then spread to the perivascular structures and directly invade the vessel wall, causing capillaritis and vascular occlusion. Hemorrhagic necrosis follows; subsequently, organisms invade the bloodstream, producing metastatic lesions. Any organisms capable of invading tissue can produce burn wound sepsis. The predominant organisms causing burn wound infection vary depending on the treatment facility. Burn wound infection can be focal, multifocal, or generalized. The likelihood of septicemia increases in proportion to the size of the burn wound. Since the introduction of effective topical therapy, fungal burn wound infection, primarily involving highly invasive *Phycomycetes* and *Aspergillus* species, has increased.

Pneumonia

One result of the prolonged survival of severely burned patients in critical care units, made possible by modern patient support techniques, is that the respiratory tract has become the most common locus of infection. Bronchopneumonia has replaced hematogenous pneumonia as the most common form of pulmonary infection in burn patients. A diagnosis of pneumonia is confirmed by the presence of characteristic chest radiograph patterns, and the presence of offending organisms and inflammatory cells in the sputum. After inhalation injury, early infiltrates usually represent chemical pneumonitis and not infectious pneumonia, although this damaged lung tissue may become infected. Prophylaxis with antibiotics should not be used, as it selects resistant organisms and does not reduce the incidence of pneumonia. Colonization of the upper airway of patients requiring intubation and mechanical ventilation should not be confused with a respiratory tract infection. For the diagnosis of bronchopneumonia, analysis of sputum samples may be adequate. If there is concern about the identity of the organism, bronchoscopy should be used.

Suppurative Thrombophlebitis

Suppurative thrombophlebitis is a major cause of sepsis in burn patients, occurring in up to 5 percent of patients with major burns. It is associated with the use of intravenous catheters, especially if the catheters have been inserted by cut-down techniques; the incidence increases with the duration of vein cannulation. The nidus of infection is usually located in the vein at the site of the catheter tip, where there is endothelial damage, injury, and fibrin clot formation. The fibrin mesh is subsequently seeded during episodes of bacteremia, which may occur at any time during the hospital stay. This complication can be eliminated by the placement of catheters in high-flow veins, such as the femoral, subclavian, or internal jugular veins, and by changing insertion sites every 48 to 72 h, dislodging the fibrin clot.

Bacterial Endocarditis

Endocarditis is occasionally the cause of occult sepsis in burn patients, and its incidence continues to rise with the increasing use of intravenous catheters for hemodynamic monitoring. Endocarditis should be suspected in patients with positive blood cultures and no other identifiable source of bacteremia. These patients should be examined repeatedly by biplanar, transthoracic, and transesophageal echocardiography until the source of the septicemia is identified. Most lesions are found on the right side of the heart, and over 85 percent of patients have had central venous or pulmonary artery catheters placed in the right atrium or through the right ventricle. Systemic antibiotic therapy should be instituted and continued for at least 4 weeks.

Urinary Tract Infections

Most patients with burns greater than 20 percent TBSA require indwelling urinary catheters to guide fluid resuscitation. Aseptic techniques of insertion and catheter care, the use of a closed drainage system, and the removal of the catheter at the earliest clinically indicated time are effective measures for preventing urinary tract infections. In the absence of an inflammatory response (less than 10 white blood cells per high-power field), the majority of patients with positive urine cultures do not require antimicrobial treatment. Candiduria in the absence of signs of systemic infection can be treated with bladder irrigations with amphoterin B. Burns of the penis usually do not require bladder catheter drainage unless they are severe. Full-thickness burns of the penis should be treated with excision and grafting.

Chondritis of the Ear

The pinna of the ear is composed almost entirely of cartilage with minimal blood supply and is vulnerable to infection. It is a rare complication. When chondritis does occur, a conservative approach with drainage of the helix centrally, in an attempt to preserve the outer cartilages, is usually successful.

Treatment of Infection

The definitive treatment of the septic burn wound is the expeditious excision of the wound. Many of the other infections common to burn patients require surgical intervention. Most infections of burn patients acquired in the hospital involve the organisms that originally colonized the burn wound.

Topical Antimicrobial Therapy

Before the introduction of effective topical antimicrobial agents, up to 60 percent of the deaths in specialized burn treatment facilities were caused by burn wound sepsis. The three agents with proved wide-spectrum antimicrobial activity when applied to the burn wound are silver nitrate, mafenide acetate, and silver sulfadiazine (Table 7-5). Silver sulfadiazine is the most common agent used in burn centers. Only mafenide acetate is able to penetrate the eschar, and it is the only agent capable of suppressing dense bacterial proliferation beneath the eschar surface. The main disadvantage of mafenide acetate is the strong carbonic anhydrase inhibition, which interferes with renal buffering mechanisms. Bicarbonate is wasted, chloride is retained, and the resulting hyperchloremia is compensated for by an increase in ventilation and subsequent respiratory alkalosis. Silver nitrate must be used after injury before bacteria have penetrated the wound. Its disadvantages are the associated electrolyte imbalances, which are common, and methemoglobinemia formation, which

is unusual.

Subeschar Clysis and Surgical Treatment

When burn wound sepsis has developed, the probability of survival is less than 10 percent. Subeschar infusion of antibiotics has been utilized to prevent or treat burn wound invasion in burn patients that escaped topical chemotherapeutic control. Injection of semisynthetic penicillins beneath the infected eschar is associated with markedly improved survival. Subeschar clysis is best used as adjuvant therapy in preparation of patients for eschar excision or as primary treatment for patients who are too unstable hemodynamically to tolerate surgery. Generalized wound sepsis in stable patients should be treated by surgical excision.

Antibiotics

The number and types of antibiotics used in a burn center should be restricted, and the criteria for documenting infections should be well- defined. An infection caused by an identified organism is treated by a single antibiotic. Controlled trials in burn patients have not demonstrated any improvement in survival rates achieved by the routine use of antibiotic combinations to treat serious infection. The indiscriminate use of multiple agents promotes overgrowth of *Candida* species, enterococci, and multiple-antibiotic-resistant organisms in the patient and in the burn center. The current problem of increase in staphylococcal and enterococcal resistance to Vancomycin emphasizes the importance of using the least complex antibiotic shown to be effective against the organisms.

Numerous studies have demonstrated that altered pharmacokinetics of antibiotics in burn patients result in lowered serum drug levels when the usual recommended dose is used. In most cases, these doses are subtherapeutic in the burn patient, especially with antibiotics that are predominantly renally excreted. Serum levels should be monitored frequently and early in the course of therapy. Inappropriate peak levels should prompt alterations in the dosage, while inadequate trough levels should prompt shortening of the dosage interval.

ELECTRICAL AND CHEMICAL BURNS

Electrical Burns

Care at the Scene

Electrical burns are particularly dangerous. If the patient remains in contact with the source of electricity, the rescuer must avoid touching the patient until the current can be turned off or the wires cut with properly insulated wire cutters. Once away from the source of current, the ABCs (airway, breathing, circulation) must be checked. Ventricular fibrillation, or standstill, is common; cardiopulmonary resuscitation should be instituted if carotid or femoral pulses are not palpable. If pulses are present, but the patient is apneic, mouth-to-mouth resuscitation alone may be life-saving. CPR should continue until a cardiac monitor can indicate further treatment. Once an airway is established and pulses return, a careful search must be made for associated life-threatening injuries. Electrocuted patients frequently fall from heights and may have serious head or neck injuries. The intense tetanic muscle contractions associated with electrocution can fracture vertebra or cause major joint dislocations.

Acute and Definitive Care

Electrical burns are thermal burns from very high intensity heat and from electrical disruption of cell membranes. As electric current meets the resistance of body tissues, it is converted to heat in direct proportion to the amperage of the current and the electrical resistance of the body parts through which it passes. The smaller the size of the body part through which the electricity passes, the more intense the heat and the less the heat is dissipated. Fingers, hands, forearms, feet, and lower legs are frequently totally destroyed; areas of larger volume, like the trunk, usually dissipate enough current to prevent extensive damage to viscera unless the entrance or exit wound is on the abdomen or chest. Arc electrical burns are common in addition to the usual entrance and exit wounds. These deep and destructive wounds occur when current takes a direct path, often between joints in close apposition to one another at the time of injury. Burns of the volar aspect of the wrist, the antecubital fossa when the elbow is flexed, and the axilla are most common. While cutaneous manifestations of electrical burns may appear limited, the skin injury is only the tip of the iceberg, and massive underlying tissue destruction may be present. Resuscitation needs are usually far in excess of what would be expected on the basis of the cutaneous burn size, and associated flame and/or flash burns often compound the problem. Myoglobinuria frequently accompanies severe electrical burns. Disruption of muscle cells releases cell fragments and myoglobin into the circulation to be filtered by the kidney. If this condition is untreated, the consequence can be permanent kidney failure.

Cardiac damage, for example, myocardial contusion or infarction, may be present. The conduction system may be deranged, and in some cases, there can be actual rupture of the heart wall or rupture of a papillary muscle, leading to sudden valvular incompetence and refractory cardiac failure. Household current at 110 V either does no damage or induces ventricular fibrillation. If there are no cardiac abnormalities present in a patient in the emergency room after shocks of 110 to 440 V, the likelihood that they will appear later is small. Even with injuries resulting from high- voltage currents, normal cardiac function on admission generally means that subsequent cardiac dysrhythmia is unlikely. Studies confirm that commonly measured cardiac enzymes bear little correlation to cardiac dysfunction, and elevated enzymes may be from noncardiac muscle damage. Monitoring ECG and isoenzymes in an ICU setting for 48 h may be unnecessary in patients with electrical burns who have stable cardiac rhythms on admission.

The nervous system is particularly sensitive to electricity. The most severe brain damage occurs when current passes through the head, but spinal cord damage is possible whenever current has passed from one side of the body to the other. Myelin-producing cells are susceptible, and delayed transverse myelitis can occur days or weeks after injury. Conduction remains normal through existing myelin, but as the old myelin wears out, it is not replaced and conduction stops. Damage to peripheral nerves is common, and may cause permanent functional impairment. Every patient with an electrical injury must have a thorough neurological exam as part of the initial assessment. Persistent neurologic symptoms may lead to chronic pain syndromes, and so-called posttraumatic stress disorders are much more frequent after electrical burns than after thermal burns.

Cataracts are a well-recognized complication of electrical contact burns. They occur in 5 to 7 percent of patients followed, they are frequently bilateral, and they can occur even in the absence of contact points on the head. They often occur within a year or two of injury. Electrically burned patients should undergo a thorough ophthalmologic examination during the admissions phase of acute care. In addition, electrical burns are frequently job-related, and a thorough baseline examination will help workers get job-related insurance if they develop cataracts in the future.

Wound Management

There are two situations in which early surgical treatment is indicated for patients with electrical burns. Rarely, massive deep tissue necrosis will lead to acidosis or myoglobinuria, which will not clear up with standard resuscitation techniques, and major debridement and/or amputation may be necessary on an emergency basis. More commonly, the deep tissues undergo swelling, and the risk of compartment syndrome further compromising damaged tissue is real. Careful monitoring, including measurement of compartment pressures, is mandatory, and escharotomies and fasciotomies should be performed at the slightest suggestion of progression. Routine compartment pressure measurements may be helpful, but any of the signs of impending compartment syndrome (increased pain, pallor, absence of pulseless, decreased sensation, and tense swelling) mandate prompt compartment release in the operating theater. Any progression of median or ulnar nerve deficit in a hand that has been electrically burned is an indication for median and ulnar nerve release at the wrist.

If immediate decompression or debridement is not required, definitive surgical procedures can be done between days 3 and 5, before bacterial contamination occurs and after the tissue necrosis is delineated. Vascular grafts to replace clotted arteries are sometimes an option. However, they may actually increase morbidity and prolong recovery, and amputation and one of the newer prostheses might provide better function than a hand or foot with poor sensation and motor function.

Chemical Burns

Emergency Care

In cases involving chemical burns, whenever possible, involved clothing should immediately be removed and the burns should be thoroughly flushed with copious amounts of water at the scene of the accident. Chemicals will continue to burn until removed, and washing for at least 15 min under a running stream of water may limit the overall severity of the burn. No thought should be given to searching for a specific neutralizing agent. Delay deepens the burns, and neutralizing agents may cause burns themselves; they frequently generate heat while neutralizing the offending agent, adding a thermal burn to the already potentially serious chemical burn. Powdered chemicals should be brushed off skin and clothing.

Chemical burns, usually caused by strong acids or alkalis, are most often the result of industrial accidents, assaults, or the improper use of harsh solvents and drain cleaners. In contrast to a thermal burn, chemical burns cause progressive damage until the chemicals are inactivated by reaction with the tissue, or diluted by flushing with water. Individual circumstances vary, but acid burns may be more self-limiting than alkali burns. Acid tends to “tan” the skin, creating an impermeable barrier that limits further penetration of the acid. Alkalis combine with cutaneous lipids to create soap and thereby continue “dissolving” the skin until they are neutralized. A full-thickness chemical burn may appear deceptively superficial, causing only a mild brownish discoloration of the skin. The skin may appear to remain intact during the first few days postburn, and only then begin to slough spontaneously. Chemical burns should be considered deep dermal or full-thickness, until proved otherwise.

Some chemicals, such as phenol, cause severe systemic effects, and others, such as hydrofluoric acid, may cause death from hypocalcemia even after moderate exposure. Unless the characteristics of the chemical are well known, the treating physician is advised to call the local poison control bureau for specifics in treatment.

OUTPATIENT MANAGEMENT OF THERMAL INJURIES

Minor burns comprise approximately 95 percent of all burns treated in the United States. These burns are usually superficial, do not exceed 10 to 15 percent of the body surface area, and rarely require hospitalization. Many moderate and even major thermal injuries, as classified by the American Burn Association Injury Severity Grading System, are amenable to outpatient management after initial evaluation and stabilization. Although survival is usually not an issue and most minor burns will ultimately heal regardless of therapy, undertreatment and (more commonly) overtreatment can result in infection or delay in healing with discomfort and prolonged morbidity. The goals of outpatient burn management include wound healing, patient comfort, and rapid rehabilitation.

Management of Minor Burns

Treatment at the Scene of the Accident

After elimination of the heat source, areas with minor burns should be placed in tepid water rather than ice water. The potential benefits of cooling burn wounds are controversial (Table 7-6). It has been suggested that the beneficial effects, if they do exist, last only for the first 2 or 3 minutes after thermal injuries, and the application of ice water after this initial period may result in prolonged edema and impairment of healing, and may convert a partial-thickness to a full-thickness injury. The burn area should then be wrapped in a clean cloth and the victim taken to an emergency facility.

Chemical burns should be irrigated with copious amounts of water. Tar burns should be cooled with water, but the tar should not be removed at the scene of the accident.

Initial Medical Management

A protocol for immediate wound care in the emergency room or outpatient facility is mandatory for efficiency in treating thermal injury, which is too often characterized by panic, confusion, and a multiplicity of approaches. A thorough history taking should elicit when and where the accident occurred, and the burning agent (flame, hot liquid, electricity, etc.). The history should also determine whether there is any possibility of smoke inhalation injury. Depending upon the circumstances of the accident, evaluation for possible associated injuries is also important. Pertinent past medical history, including drug allergies, medication history, and history of systemic illnesses, should also be obtained.

Tetanus prophylaxis is the same for minor burns as for any other injury. A tetanus toxoid booster is given to any patient who has not received one for 5 years or who cannot recall the date of last immunization. Patients not previously immunized should receive 250 units of tetanus human immune globulin, and the first of a series of active immunizations with tetanus toxoid.

Burn wounds may be soaked in tepid water or covered with saline-soaked sponges that decrease the pain until the physician can evaluate the patient. Ice water should not be used. The wounds should be washed with mild soap and warm water, excessive debris trimmed, and hair shaved within margins of at least 1 in around the burn wound.

The removal of tar and asphalt is best accomplished with the use of Medisol, a citrus and petroleum distillate with hydrocarbon structure that consists of 70% petroleum distillate (base oil), 25 to 27% limonene (orange oil), 2 to 3% lanolin, and 1% surfactant (dioctyl sodium sulfosuccinate). This product has proved to be the most efficient in removing tar without damaging the underlying burn wound. Mineral oil and petroleum ointments, such as bacitracin or Neosporin, may also be used to remove tar. The tar should not be peeled off because of potential damage to the hair and skin incorporated in the tar.

Chemical burns should be irrigated with water for 20 min if this was not done at the scene of the accident. A neutralizing agent should not be applied, because the neutralizing reaction is always exothermic (heat-producing) and may result in a more severe injury.

Blisters may be managed in one of three ways:

- (1) The blister is left intact and the underlying wound allowed to heal in the blister fluid environment.
- (2) The blister fluid is evacuated and the overlying skin allowed to cover the underlying wound.
- (3) The blister is debrided.

Which technique is used depends not only on the location and size of the blister, but also on the compliance of the patient. If there are questions concerning a patient's reliability, or there is a potential for wound infection, it is more practical and safer to debride the blister.

After the wound is cleansed and debrided, the extent and depth of injury and areas involved are estimated. If the burn is minor, the patient can be treated as an outpatient. If there is any question regarding the feasibility of outpatient management, it is safer to admit the patient to the hospital for 24 to 48h, after which outpatient management is feasible if everything is favorable.

Follow-up Wound Care

The problems associated with major thermal injury—immunosuppression, hypermetabolism, and increased susceptibility to infection—are not associated with minor burn wounds, as it is frequently erroneously assumed. Basic principles include keeping the wound clean and in a moist environment while the wound heals. Powerful topical chemotherapeutic agents such as mafenide acetate (Sulfamylon), or povidone-iodine (Betadine) should not be applied to minor burn wounds, since they have been shown to delay wound healing. In addition, systemic antibiotics are rarely indicated for the treatment of small burns, and may predispose the wound to later opportunistic infection with bacteria, fungi, or viruses.

Follow-up care should include: (1) washing the wound with bland soap and water in a bathtub or shower, (2) patting the wound dry with a clean towel, (3) applying a bland ointment, such as bacitracin, and a nonstick porous gauze, such as Adaptic or Xeroform, then wrapping the wound lightly with gauze rolls (Kerlix). This regimen is performed twice daily (see Table 7-6).

Normally, follow-up is performed weekly in the burn clinic. If there is some question regarding the extent or depth of the wound, or the reliability of the patient or his/her family, initial follow-up may be performed on a daily basis.

The patient with a minor burn should be given instructions for a vigorous program of range-of-motion exercises. Prolonged edema, which retards wound healing, is minimized with adequate physical therapy. Rehabilitation time may also be decreased if an active exercise program is followed.

If the wounds are deep partial- or full-thickness burns, the patient can still be treated as a outpatient until primary excision and grafting can be performed. In children, the thickness of the epidermis and dermis is decreased, and thus the depth of injury is difficult to determine. If there is any question regarding depth of injury, the wounds are treated conservatively for 10 to 14 days before excision and grafting.

If the wound is healing properly, it will be totally epithelialized in 2 to 3 weeks. A prediction of wound healing can be made by 14 days postinjury. If the wounds are not healing within this time period, then primary excision and grafting should be performed. Waiting for eschar separation and formation of granulation tissue delays wound closure, prolongs wound healing, and results in increased scarring and prolonged rehabilitation time.

A superficial partial-thickness injury should be followed until epithelial coverage has occurred and then examined at 6 weeks for evidence of hypertrophic scarring. If hypertrophic scarring occurs, compression dressings should be fitted and worn until the wound becomes quiescent, which usually requires 12 to 18 months. A problem that occurs in a healed burn is the formation of very thin water blisters, produced as a result of minor trauma. These blisters, which rarely exceed 1 cm, occur 2 to 6 weeks after wound closure and leave small open areas that heal without incident in 3 to 5 days if they are kept clean with bland soap and water and covered with a bland ointment, such as bacitracin. Recently healed partial-thickness burn wounds become very dry. A mild lanolin cream or lotion should be used until the natural skin lubrication mechanisms return, usually within 6 to 8 weeks.

The patient should be instructed to avoid sun exposure until the wound is completely healed; exposure to the sun may cause hyperpigmentation of the wound, which is frequently permanent. The use of a sun block (sun protection factor 30 to 50) is recommended for healed areas that must be exposed to direct sunlight.

Pruritus is a common complaint in patients with healing burn wounds, and severe pruritis is extremely difficult to treat. Diphenhydramine hydrochloride or hydroxyzine antipruritics have proved to be beneficial. Using a moisturizing cream also helps alleviate itching.

Alternative Methods of Wound Management

There are multiple methods for managing outpatient burn wounds. Some advocate bulky dressing for as long as 10 to 14 days. Although a bulky dressing prevents pain, there is a potential hazard of bacterial overgrowth in the warm, moist dressing, and range-of-motion exercising cannot be performed, which prolongs edema and interferes with rehabilitation. Topical chemotherapeutic agents, such as silver sulfadiazine, are frequently used in the management of minor burn injury. If this form of management is used, it is important to remember that silver sulfadiazine is inactivated by tissue secretions and must be changed at least twice a day. A pseudomembrane forms over the partial-thickness injury, which is frequently painful and difficult to remove.

The use of prosthetic skin substitutes in the treatment of partial-thickness outpatient burns has recently become popular. Two substitutes that are useful on partial-thickness injury are Biobrane and OpSite. Biobrane can be used effectively in partial-thickness burns. It is well tolerated, is capable of compressing underlying fluid collection, and does not promote bacterial proliferation. It may be left on until epithelialization occurs. OpSite is a synthetic barrier. Its use requires some expertise, because fluid collections beneath the barrier frequently occur. The problem of accurate diagnosis of depth of injury is a drawback to the use of either of these prosthetic skin substitutes. If the wound is a medium to deep partial-thickness injury, an eschar does form, necessitating frequent dressing changes.

Biological dressings including allograft, xenograft, or amnion have been used to treat outpatient burns in the past. The cost of cadaveric allograft is prohibitive. Xenografts should not be used on superficial partial-thickness injury because of the incorporation of xenograft tissue into the healing donor sites, which occurs in as many as 35 percent of the patients so treated.

Management of Critical Areas

Face

Superficial burns of the face should be left exposed. The face is washed twice daily with a mild soap and water, and a thin layer of a bland ointment (bacitracin) is applied to the open wounds to prevent drying.

Ears

Superficial burns of the ear should be treated with a bland ointment. Deeper injuries must be treated with topical antibiotics; excessive pressure may cause chondritis, and should be avoided.

Eyes

Suspected corneal burns should be stained with fluorescein for confirmation of diagnoses. Superficial corneal burns should be treated similarly to corneal abrasions, with vigorous irrigation, the application of ophthalmologic antibiotic ointment, and eye patching. Superficial corneal burns not asymptomatic by 48 h and more serious injuries should be evaluated by an ophthalmologist.

Hands

Superficial burns of the hand should be elevated for 24 to 48 h to minimize swelling. Circumferential hand burns may require hospitalization for observation of adequate circulation. Range-of-motion exercises should begin as soon as possible after injury. Instructions for the exercise program should be part of the management protocol.

Feet

Although burns of the feet are painful, walking and range-of-motion exercises should be performed. Crutches should not be allowed. To prevent edema, burned feet should be elevated when the patient is not walking or exercising. An elastic bandage should be applied over the wound dressing when the patient is walking or sitting, but it should be removed at night when the feet are elevated.

Perineum

Perineal burns frequently require hospitalization for 24 to 48 h for observation of urinary obstruction secondary to edema. Minor perineal burns can be treated with a bland ointment. Extensive superficial perineal burns, e.g., pediatric bathtub scald injuries, are best treated with topical chemotherapy (silver sulfadiazine), utilizing a diaper as the wound dressing.

Complications

Most complications in small burn injuries result from overtreatment: too-vigorous dressing changes that pull off newly formed epithelium, or the use of a variety of topical and systemic antibiotics that can cause secondary infection or formation of a pseudomembrane that may require debridement, either of which may delay healing. Treatment that is appropriate for larger burns is overtreatment of small burns. In small burns, systemic antibiotics are rarely indicated and topical agents are usually not necessary.

Management of Moderate or Major Burns

Patients with superficial partial-thickness moderate and major burn injuries can also be successfully managed as outpatients. In these burns, as in minor burns, survival is not an issue. The cost of burn care in the United States is approaching \$2000 per day, and outpatient management of these types of burns can markedly decrease these costs. The presence of endemic, drug-resistant microorganisms within any hospital environment, particularly in burn centers, poses a potential threat to the moderately severe superficial partial-thickness burn patient, with frequent colonization of the burn wound by endemic staphylococcal and pseudomonas organisms.

Medical Criteria for Outpatient Management

The medical criteria for whether a patient is treated as an outpatient include: (1) no existing complications of thermal injury, such as inhalation injury, (2) fluid resuscitation completed, (3) stabilized hospital course, (4) adequate nutritional intake, (5) adequate pain tolerance, and (6) no anticipated septic complications. The patient's family must be willing to participate in the care of the patient and must be capable of doing so. Criteria for "capability" include personal cleanliness, no apparent aversion to burn care, an ability to perform the dressing changes and assist in range-of-motion exercises, and access to transportation to return the patient for burn care and physical therapy. Not all families initially meet these criteria, but with persistent education by the burn team, most families can learn how to conform to the guidelines.

Outpatient Treatment Program

Outpatient management of moderate and major thermal injuries involves two phases of treatment: a home-treatment program and physical therapy. At home, the patients are instructed to bathe or shower twice daily, wash the wound with mild soap and water, gently debride the wound with a washcloth, and apply prescribed topical ointment followed by a light dressing. Patients exercise every hour, following a program outlined by the physical therapist. Family members are instructed to encourage self-care and active range of motion at all times.

When the patient is discharged from the hospital, an appointment is made for outpatient physical therapy. The frequency of treatments decreases as the wound heals, but initially patients are seen daily. The treatments consist of hydrotherapy, debridement of burn wounds, and a supervised exercise regimen. The wounds are evaluated by the physical therapist and feedback given to the family members regarding wound status, dressing changes, and range of motion. All patients are seen weekly in the burn clinic, where the wounds are examined, treatment reviewed, and necessary changes made.

PAIN CONTROL

All burn injuries are painful, whether the injury is a simple sunburn or an extensive second- or third-degree burn covering a large portion of the body. Attempts to manage pain in a patient with a burn injury are frequently frustrating because of the often-changing physiological and psychological reactions to the injury. A superficial, partial-thickness injury (first-degree burn) damages the outer layers of skin, the epidermis, producing mild pain and discomfort. The pain associated with moderate to deep partial-thickness or second-degree burns varies depending on the extent of destruction to the dermis. Superficial dermal burns initially are the most painful, and even the slightest change in air current on the exposed superficial dermis causes the patient to experience excruciating pain. Without the protective covering of the epidermis, nerve endings are sensitized and exposed to stimulation. Areas of deep partial-thickness or full-thickness injury show little or no response to sharp stimuli, yet a patient may complain of a deep, aching pain, which is related to the inflammatory response. The physiological effects of pain include increase in heart rate, blood pressure, and respiration; a decrease in O₂ saturation; palmar sweating and facial flushing; and dilatation of the pupils. No single physiological change is an absolute indication of pain.

The burn patient may experience acute pain from dressing changes, operative procedures, and rehabilitation exercises. The patient may also have chronic background pain associated with the wound maturation process. Pain management involves pharmacologic and nonpharmacologic modalities. Pharmacological modalities include hypnotics and analgesics, such as morphine, methadone, codeine, acetaminophen, and nonsteroidal anti-inflammatory agents. Anesthetic agents, such as ketamine nitrous oxide and fentanyl, are useful for severely painful dressing changes, such as those after skin-grafting procedures. Psychotropic drugs, such as antianxiety drugs, major tranquilizers, and antidepressants, may be useful in the management of burn wounds. Nonpharmacologic methods include providing verbal and/or physical comfort, arranging activities that will distract the patient from concentrating on the pain, and relaxation therapy.

During burn shock resuscitation, pain medication, such as morphine sulfate, should be given sparingly; if administered, the preferred route is intravenous. Because of irregular absorption, pain medication should not be given intramuscularly. Morphine and/or methadone therapy is begun early on all patients with acute burns admitted to the hospital, unless the patient will be in the hospital only for a very short time. Total elimination of pain in burn patients is not possible, short of general anesthesia. The major neuroleptic modalities, including ketamine nitrous oxide and fentanyl, all compromise respiratory function and should be given only under direct supervision by personnel skilled in airway control and respiratory support. The concomitant use of benzodiazepam, hypnosis, and psychological support reduces narcotic requirements. During the convalescent phase of burn management, a regular dose of an oral analgesic such as methadone produces more effective pain relief than unscheduled "as-needed" doses.

REHABILITATION AND CHRONIC PROBLEMS

Rehabilitation

Inpatient Therapy

Maintaining function and preventing the complications of prolonged immobility are the specific goals of the rehabilitative treatment of burn patients. Daily assessment of the patient's range of motion, ambulation, and functional status is necessary to determine the effectiveness of ongoing treatment plans and to make modifications as needed for new problems. The location of the burn in relation to the joint axis determines what movement will be limited as the burn heals. In most burns of extremities, the position of maximal comfort promotes the formation of scar contractures. Because compliance is a major factor in a successful rehabilitation program, the burn therapist must work closely with the entire burn team in developing the patient's trust, understanding, and confidence. Burn teams should include physical and occupational therapists, and a play therapist who can engage children in physical activities in an environment in which they often are not aware of the therapeutic nature of the exercises they are performing. Such an approach commonly enables children to achieve full range of motion independently. Passive exercises must be carefully planned, since overzealous activity may lead to tendon disruption, muscle tears, heterotopic ossification, and traumatic release of scar contractures.

Physical therapy begins on the day of admission. Burned extremities are elevated and actively exercised to minimize edema and reduce the need for escharotomy. Stable patients are initially placed in chairs; ambulation begins when it can be tolerated. Excessive use of analgesics and antianxiety drugs impedes a successful mobilization program. When patients get out of bed, burned legs are wrapped with disposable compression bandages to prevent venous stasis and edema. Even when patients are in bed, nearly all burned extremities develop varying degrees of edema. Active exercises maintain muscle mass and strength. Passive exercises are most often used with debilitated patients and patients whose state of awareness is clouded. Continuous passive motion devices and dynamic splinting increase function in these patients and do not require the continual presence of rehabilitation therapists. Objective measurements of joint stiffness can be quantified by piston-drive displacement transducers, which provide useful documentation of patient progress.

Burn contractures are unlike other types of contractures. Burn scars commonly envelop the entire circumference of single joints, and the scar may involve multiple joints. Contraction may pull a joint in one direction and an adjacent joint in the opposite direction. A classic example is boutonnière deformity of the fifth finger. The entire burn scar must be uniformly stretched; complex splints or multiple joint pin fixation are often required. Positioning of body parts in the antideformity posture prevents wound contracture. Splints are also used for immobilizing freshly grafted extremities to prevent inadvertent shearing of the new autograft.

All second- and third-degree burns produce permanent scarring. Some scars in healed second-degree burns are barely noticeable, while deeper burns, even when grafted, may develop bulky hypertrophic scar tissue. Scar hypertrophy can be retarded by the use of custom-fitted pressure garments over healed scars. Specially fitted inserts can be used to apply pressure to concave areas of skin. Patients whose burns do not heal by the second postburn week should be treated with pressure devices, first with a generic tubular elastic stocking and later, after the surface of the burn scar stabilizes, with custom-made compression garments. Adults usually wear these garments for 3 to 6 months (Fig. 7-4), while small children require up to 4 years of compression therapy before scar maturation is complete.

Outpatient Therapy

Many functional deficits persist after burn patients have been discharged; therefore follow-up must be continuous for prolonged periods. For many patients, the burn center outpatient facility provides their only access to primary care. Pressure garments require regular refitting. Patients using complex physical training devices and special techniques for reducing contracture may need to visit the rehabilitation department daily. Outpatients are evaluated 1 week after discharge, and the interval between visits is gradually lengthened, depending on individual patient needs. As burn scars mature, permanent residual deficits or deformities may be amenable to reconstructive surgical correction. Usually, multiple small operations are used; corrective surgical procedures may take place over a period as long as 10 years.

Patients develop follicular infection in the burn wound several months after injury. These plugged follicles usually disappear once hair erupts through the overlying epithelium. Severe itching and vague, but intense, neuritic pain are long-lasting and are poorly responsive to antipruritic medications and analgesics. Providing detailed printed explanations of burn care and treatment procedures is an essential component of follow-up care.

Psychological Support

Burned patients display a variety of psychological responses to their injury, including anxiety, depression, denial, withdrawal, and regression. Withdrawal and regression are especially common in children, who may refuse to participate in treatment regimens. Play therapy provides a way for children who have similar cosmetic deformities or functional deficits to interact. Rapport between team members—play therapists, physical and occupational therapists, burn nurses, and physicians—promotes compliance among the patients and encourages the proper use of pressure garments and assistive devices.

Nearly half of older children and adults develop posttraumatic stress disorder after thermal injury, which is characterized by recurrent and intrusive recollections of the initial injury, avoidance of circumstances that invoke memories of the event, loss of interest in daily activities, feelings of isolation, hyperalertness, memory impairment, and sleep disturbances. Noncompliance with burn therapy is a serious outward manifestation of a patient's attempt to avoid recollections of the traumatic event. A patient's psychological state after the burn injury, and symptoms of posttraumatic stress disorder during acute-care hospitalization, are predictive of the likelihood of chronic posttraumatic stress disorder. The severity of injury does not correlate with the symptoms. Both short- and long-term psychotherapeutic support is frequently necessary in burn patients, and a full-time psychiatrist is an essential member of the burn team. Burn patients rarely seek treatment for psychological problems. The frequency of posttraumatic stress disorder increases with length of follow-up.

Family support groups convene on a weekly basis. The burn team presents an update on the patient's progress, and addresses specific short- and long-term goals to allay anxieties. Psychosocial support is critical for the burn patient for the duration of the course of treatment and follow-up.

Chronic Problems

Hypertrophic Scar and Keloid Formation

Burn scar hypertrophy typically develops in deeper partial-thickness injuries and third-degree burns that are allowed to heal by primary intention. Hypertrophy of grafted areas of excised burn wounds occurs less frequently, and is dependent, in part, on the time from injury to excision, the site of the wound, and the surgical technique used. With tangential excision, necrotic tissue of a partial-thickness burn is removed in successive layers until a base of partially viable dermis is reached; in most circumstances, the wound is then immediately grafted. Sequential excision extends to varying levels of the skin and subcutaneous tissue until all nonviable tissue is removed. Sequential excision goes beyond tangential excision to include the complete excision of necrotic full-thickness injuries. Delayed tangential excision is more likely to result in residual scar hypertrophy in grafted burn wounds.

Because only a few epithelial elements, sweat glands, and hair follicles remain viable in deep, partial-thickness burns, healing takes place from these remnants over a period of 3 to 6 weeks. The resulting scar epithelium is of poor quality, and is prone to hypertrophy. Hypertrophic scar should be distinguished from a keloid. Both exhibit excessive collagen formation, but a keloid overgrows the original dimensions of the initial injury and hypertrophic scar develops in the bed of the injured tissue and is confined to its original anatomic boundaries. Hypertrophic scars frequently flatten with time and pressure, whereas keloids do not. Long- term controlled trials have not clearly demonstrated permanent benefits from compression therapy, but compression garments quickly reduce the mass of hypertrophic immature scars and provide patients with tangible evidence of the benefits of conscientious follow-up. The mechanism by which constant compression reduces scar mass is not well defined. It may work by causing ischemia in the microvasculature of hypertrophic scars, with focal degeneration of cells because of hypoxia after microvascular occlusion. Another mechanism may involve the healing sequence; electron microscopy has demonstrated that fibroblasts in pressure-treated wounds are more linearly organized than fibroblasts in non-pressure-treated wounds, and collagen is manufactured in a more organized fashion.

Other forms of therapy for hypertrophic scarring include radiotherapy, cryotherapy, and reexcision and wound closure. Radiotherapy in doses of 1500 to 2000 Gy has been used with varying results. Radiation probably reduces fibroplasia and capillary budding. Cryotherapy is rarely used. It is associated with depigmentation and increased melanocyte sensitivity to subsequent cold exposure. The most successful approach to residual hypertrophic burn scars is initial pressure therapy until the wound matures, followed by subsequent excision and application of skin grafts. Tissue expansion techniques have been used to expand normal skin and replace the excised hypertrophic scar or keloid. Complication rates with tissue expansion are as high as 40 percent, and include infection, implant extrusion, and device rupture. These complications usually require removal of the original implant, treatment of any infection, and replacement.

Because of their marked propensity to recur, keloids are difficult to treat. Excision of the keloid and primary closure are effective for linearly oriented keloids with a narrow base, but excessive wound tension leads to recurrence. Broad-based keloids may be removed flush with the surrounding skin, and a split-thickness skin graft placed over the base of the keloid to prevent it from recurring. Excision alone has a recurrence rate of greater than 50 percent. Intralesional injection of corticosteroids may reduce the bulk of keloid and hypertrophic scar mass, and may be used in combination with excision or split-thickness skin grafting. It is believed that triamcinolone, the most commonly used steroid, acts by decreasing collagen synthesis and increasing collagen degradation through the collagen inhibitors α_2 -macroglobulin and α_1 -antitrypsin. When steroid injection is used in conjunction with surgery, keloids should be injected for at least 1 month prior to the operation. Some surgeons inject triamcinolone in the base of the wound and along its edges during the surgical procedure. Postoperatively, the patient receives injections monthly until the wound matures. The major side effects of intralesional injection of steroids are hypopigmentation and atrophy of the skin surrounding the keloid.

Burn scar hypopigmentation and surface irregularity can be significantly improved by dermabrasion and thin split-thickness grafting. Adequate pigmentation and flat surfaces are obtained in most patients. Tissue expanders are particularly effective for treating burn scar alopecia.

Approximately 20 percent of patients treated in burn facilities are readmitted for reconstructive procedures. The most common areas of reconstruction involve the hand and wrist (most common), arm and forearm, face, and neck. Improved inpatient burn treatment and scar management have reduced the need for subsequent reconstructive surgery.

Marjolin's Ulcer

Chronic ulceration of old burn scars was noted by Marjolin to lead frequently to malignant degeneration. Squamous cell carcinoma is most common, although basal cell carcinomas occasionally occur. Rare tumors, including malignant fibrous histiocytoma, sarcoma, and neurotropic malignant melanoma, have also been described. Chronic breakdown of a healed burn wound scar should lead to suspicion of malignant degeneration. These lesions typically appear decades after the original injury, but burn scar carcinoma can be encountered within the first year. In the absence of cancer, most unstable burn scars should be excised and resurfaced. Burn scar carcinomas may metastasize aggressively. Malignancy dictates wide excision, but prophylactic regional node dissection has not improved mortality. Approximately 30 percent of burn scar carcinomas occur in the head and neck. Adjuvant radiotherapy improves survival. Very deep dermal burns that have not healed by the third or fourth postburn week occasionally develop nodules in the burn wound bed. These lesions are sometimes erroneously interpreted as carcinoma or lymphoma, but excision and grafting of the nodules wounds usually reveals that they are pseudoepitheliomatous hyperplastic lesions or keratoacanthomas.

Heterotopic Ossification

Heterotopic ossification occurs in up to 13 percent of burn patients. This complication may develop in patients with partial-thickness burns and around extremities not involved with the injury, but it most commonly involves patients with full-thickness burns greater than 20 percent TBSA, and is found adjacent to the involved joint 1 to 3 months after injury. The elbow is the most commonly affected joint. The diagnosis is usually made by the physical or occupational therapist, who discovers increased pain and decreased range of motion of the involved joints. Limitation of physical activity usually precedes radiographic evidence of calcification, which is located in the muscle and surrounding soft tissue of the joint. Although the mechanism causing heterotopic ossification is not known, it has been suggested that bleeding into the soft tissue, due to aggressive physical therapy, is the culprit. Prolonged immobilization of a joint encompassed by a burn also appears to promote heterotopic ossification. Restricted activity promotes mobilization of body calcium stores and may lead to deposition of calcium in the soft tissues. Some suggest surgical removal of all ossified soft tissue, but others recommend modification of rehabilitation therapy regimens and allowing the reabsorption of ossified tissue.

Fractures

Up to 10 percent of burned patients have associated fractures. Fractures in patients with large burns are treated with splints or traction until resuscitation is complete. Operative repair is preferably performed within 48 to 72 h of burn injury. Burn wounds adjacent to fracture sites are usually excised and autografted at the time of internal fixation. If internal fixation is not possible, external fixation is used, which permits access to the burn wound and provides stability.

CHAPTER 8 - Wound Care and Wound Healing

I. Kelman Cohen

INTRODUCTION

Wound healing has been described throughout recorded history. Empirically, the ancients recognized that foreign bodies and dead tissue must be removed from wounds. They knew that cleanliness prevented infection and that loculated pus required drainage. Wound elixirs such as honey decreased wound suppuration (hypertonic glucose is bactericidal), and acute open wounds could be sutured primarily with hairs, cloth, or insect jaws. In the sixteenth century, Paré discovered that surgical destruction of tissue, such as was effected by pouring boiling oil into acute open wounds, impeded healing and led to sepsis. His observations led to the maxim of all surgeons today—"Do not put anything in a wound you would not put in your own eye." The clinician's treatment of tissue must be as atraumatic as possible. Lister, Semmelweis, Ehrlich, Fleming, and Florey realized, with increasing sophistication, that bacteria were pathogens that prevented healing and led to sepsis and death. Control of bacteria by asepsis, antiseptics, and antimicrobials heralded a new era in wound management.

Control of pain, understanding fluid and blood replacement, and antibiotics, were the major contributions to wound management during the first half of the twentieth century. Objective assessment of abnormal tissue repair received little attention. During the past two decades, however, wound care has made more advances than it had over the past two thousand years. Four major factors account for the logarithmic advances in wound healing knowledge: (1) the biologic mechanisms of tissue repair are now being defined on a biochemical and a molecular level; (2) financial support for wound healing research has increased markedly because the social and financial devastation of wounds has come to be appreciated by health care providers and federal health care funding agencies; (3) the medical-industrial complex can envision profit in the discovery of more efficacious modalities for wound care and, hence, is supporting wound healing research; and (4) reconstructive surgical techniques have changed drastically in the past two decades with the advent of muscular and musculocutaneous flaps as well as microvascular free-tissue transfers. The recent advances are only a prelude to the changes in wound care and management that will occur in the near future.

Mammalian healing is primitive in comparison with that of the "lower" forms of life. It is paradoxical that in creatures considered low on the phylogenetic scale tissue heals by a process of *regeneration* that is much more sophisticated than the primitive *repair* process in human beings—"wound healing"—which involves mechanisms of inflammation, matrix deposition, and scarring. The ultimate goal of wound healing research is to enable human wound healing to proceed by a process of regeneration.

GENERAL CONSIDERATIONS

Wound healing is a vague term that often diverts the clinician from focusing on the specific mechanism involved in a particular healing process. Only after defining the specific biologic processes of a particular wound can the clinician formulate a rational approach to therapy. Therefore, the reader must first have a very clear definition of the *mechanisms* of wound healing and how they contribute to various *types of wound closure*.

Classification of Wounds

Wounds can be classified into two general categories: *acute* and *chronic*. Acute wounds "normally proceed through an orderly and timely reparative process that results in sustained restoration of anatomic and functional integrity." In contrast, "chronic wounds have failed to proceed through an orderly and timely process to produce anatomic and functional integrity, or proceeded through the repair process without establishing a sustained anatomic and functional result."

Types of Wound Closure

Primary closure approximates the acutely disrupted tissue with sutures, staples, or tape. With time, the synthesis, deposition, and cross-linking of collagen and other matrix proteins, which are of primary importance in this type of repair, provide the tissue with strength and integrity (Fig. 8-1).

In *delayed primary closure*, approximation of the wound margins is delayed for several days after the wound has been created (Fig. 8-2). Delay in closure is indicated to prevent infection in wounds in which there is significant bacterial contamination, foreign bodies, or extensive tissue trauma. During the period that the wound remains open, moist, sterile saline dressings should be changed at least twice a day to optimize the wound for closure. The use of peroxide and iodophors in these open wounds should be avoided because these solutions destroy the host's tissues as well as bacteria. The rationale for delayed primary closure is based on the normal biological event of healing. If the wound is open, there is less chance that bacterial colonization will occur. During the time the wound is open, events occur that will significantly decrease the chances of wound infection after closure. For example, leukocytes are attracted to the wound site, and angiogenesis proceeds to provide enhanced blood supply and needed oxygen. All of these phenomena lead to destruction and removal of bacteria. Simultaneously, the normal phases of healing progress even though the wound remains open. In fact, wound tensile strength after delayed primary closure eventually becomes the same as that of the primarily closed wound.

Spontaneous closure, or "*secondary*" *wound closure*, occurs when the margins of the open wound move together by the biologic process of contraction (Fig. 8-3). A striking example is the lower extremity amputation stump, which, if left open, will heal as the margins contract toward one another. Failure of spontaneous open wound closure is one of the phenomena that result in a chronic wound. *Partial-thickness wounds* heal by the process of epithelialization. This occurs first by migration and then mitosis of epithelial cells (Fig. 8-4).

Mechanisms Involved in Wound Healing

Three distinct biologic mechanisms are involved in all healing processes; however, there are significant differences in the contribution of each mechanism, depending on the type of wound. It is imperative that the clinical surgeon recognize each of these separate mechanisms and the contribution of each in the wound being treated.

Epithelialization is the process whereby keratinocytes migrate and then divide to resurface partial-thickness loss of skin or mucosa. Examples include partial-thickness skin graft donor sites, abrasions, blisters, and first- and second-degree burns.

Contraction is the mechanism whereby there is spontaneous closure of full-thickness skin wounds or constriction of tubular organs such as the common bile duct or esophagus after injury.

Connective tissue matrix deposition is the process whereby fibroblasts are recruited to the site of injury and produce a new connective tissue matrix. This process is of major importance in primary wound closure, be it of skin, tendon, or intestine at an anastomosis. The cross-linked collagen and its organization in the connective tissue formed in the process provide the strength and integrity to all tissues.

Phases of Healing

The healing of an acute, primarily closed wound or a wound created by any mechanism—be it surgical intervention, trauma, chemical, friction, heat, or cold—usually follows a predictable pattern under *normal circumstances*. Chronic dermal wounds (such as pressure, diabetic, and venous stasis ulcers) or chronic parenchymal injury (such as subacute chronic hepatic fibrosis) are discussed elsewhere in this text. Under normal conditions, the phases of healing are divided into four specific events. Although they are described in a sequential fashion, they actually comprise an overlapping symphony of complex interactions. There is not a "lag phase" in the healing process. This is a misnomer propagated by several generations of authors. From the moment of injury, healing is an active, dynamic process.

Coagulation

Injury causes hemorrhage from damaged vessels and lymphatics (Fig. 8- 5). Vasoconstriction occurs almost immediately as a result of release of catecholamines. Various other vasoactive compounds, such as bradykinin, serotonin, and histamine, are released from tissue mast cells. They initiate the process of diapedesis, a passage of intravascular cells through vessel walls and into the extravascular space of the wound. Platelets derived from the hemorrhage form a hemostatic clot.

The platelets release clotting factors to produce fibrin, which is hemostatic and which forms a mesh for the further migration of inflammatory cells and fibroblasts. Fibrin is produced from fibrinogen, which is formed by the action of thrombin in the presence of thromboplastin. If the fibrin mesh is eliminated, the wound's ultimate strength is diminished.

Platelets are also extremely important because they are the first cells to produce several essential cytokines, which modulate most of the subsequent wound healing events. The subject of cytokines is discussed in detail later in this chapter.

Inflammation

The inflammatory phase is characterized by the sequential migration of leukocytes into the wound (Fig. 8-6). Within 24 h the wound is predominated by polymorphonuclear leukocytes, and then by macrophages. Although it is well known that inflammatory cells regulate connective tissue matrix repair, the specific messengers of regulation are now defined. These are the various cytokines that in the past were termed "growth factors."

Fibroplasia

It is during the phase of fibroplasia that the healing events most important to the surgeon occur. In particular, the fibrous protein collagen is synthesized. It is not only the synthesis but also the cross-linking and deposition of collagen and other matrix proteins that provide the healed wound with strength and integrity (Fig. 8-7). Within 10 h after injury, there is evidence of increased wound collagen synthesis. After 5 to 7days, collagen synthesis peaks and then declines gradually. Collagen is unique because it is only after it has been secreted into the extracellular milieu that the tissue strength characteristics are achieved following cleavage of procollagen peptides and cross-linking steps. In addition, there is significant production of ground substance within the matrix and proliferation of blood vessels.

Remodeling

The wound is an "up-regulated" process until "remodeling." At that point, acute and chronic inflammatory cells diminish gradually, angiogenesis ceases, and fibroplasia ends. The

equilibrium between collagen synthesis and collagen degradation is gradually restored (Fig. 8-8). Normally a fibrous repair is imperfect, but functional and not excessive. The complex interactions and associations of the various processes that take place during normal dermal wound healing are summarized in Fig. 8-9.

Cytokines in Wound Healing

Cytokines provide all the communications for cell-to-cell interactions and are the most exciting recent wound healing breakthrough (Table 8-1). Their potential clinical use is just beginning to unfold. Cytokines may have important pharmacologic roles in the many areas of clinical management of wound healing. For example, cytokines appear to play a role in the regulation of fibrosis, in the healing of chronic wounds and skin grafts, in vascularization, in the enhancement of bone and tendon strength after repair, and perhaps even in the control of malignancy.

Cytokines are really “wound hormones” (Fig. 8-10). They may be *endocrine*, like somatomedin or insulin-like growth factor (IGF-1), when they are secreted by one cell and then circulate in the bloodstream to reach a distant target cell. Others are *paracrine*, produced by one cell and affecting an adjacent target cell; examples include *transforming growth factor beta (TGF- β)* and *platelet-derived growth factor (PDGF)*. *Autocrine* factors are secreted by a cell and then act on receptors on the same cell. Finally, *intracrine* factors are produced by a cell and remain active in the same cell.

Cytokines regulate cell proliferation as either *competence factors*—i.e., they get the cell into G₁ phase, such as PDGF—or *progression factors*, acting to promote the cell through the proliferation cycle, such as IGF-1. Cytokines are also chemotactic, stimulating cells to migrate to the wound site. In addition, cytokines direct the cell to produce specific components needed for matrix repair, including proteins, enzymes, proteoglycans, and attachment glycoproteins.

The cytokine nomenclature is complex and somewhat confusing. Some factors are named for their cell of origin—e.g., PDGF (platelet-derived growth factor); others are named for their action—e.g., EGF (epithelial growth factor); and others are named for their first reported action—e.g., TGF- β (transforming growth factor). Several of these cytokines are of major importance in wound healing processes (see Table 8-1).

PDGF, for example, which is one actually of several growth factors derived from platelets, initiates many wound healing events and stimulates production of several other wound cytokines. PDGF's functions include chemotaxis for fibroblasts, neutrophils, and macrophages as well as smooth muscle cells. PDGF also stimulates the production of fibronectin and hyaluronic acid and may stimulate wound contraction. During the remodeling phase of repair, PDGF is thought to stimulate the production and secretion of collagenase in fibroblasts. *TGF- β is produced by a host of cells, including platelets, fibroblasts, smooth muscle cells, endothelial cells, keratinocytes, lymphocytes, and macrophages. This important cytokine increases collagen synthesis by specifically enhancing matrix gene expression and by inhibiting collagenase production and activity (Fig. 8-11). As a result, there is a significant stimulation of collagen deposition mediated by TGF- β . This cytokine thus appears to be essential for normal healing, and an excessive amount of TGF- β or its receptor may be extremely important in the pathophysiology of fibrotic states such as keloid and hepatic fibrosis.*

There is a family of TGF- β 's, and the specific isoforms may have diverse activities during wound healing. Three isoforms of TGF- β are found in mammals, and they are designated TGF- β 1, β 2, and β 3. TGF- β 1 is the most abundant of the three isoforms. TGF- β 2 is found in amniotic fluid, saliva, breast milk, and aqueous and vitreous humor of the eye. TGF- β 3 has been isolated from human umbilical cord and is the least studied of the three isoforms. TGF- β 1 and β 2 are thought to be interchangeable, whereas TGF- β 3 appears to result in reduced scarring of incisional wounds.

The *fibroblast growth factor (FGF)* family is another group of cytokines. They bind to heparin and heparin-like glycosaminoglycans. *Basic FGF (bFGF)* is a potent angiogenic factor, causes increased epithelial cell migration, and hastens wound contraction.

Epithelial growth factor (EGF) stimulates epithelial migration and mitosis. Although it has been reported to hasten reepithelialization of burn wound donor sites, these data remain questionable; in another study, split-thickness donor sites in healthy, nonsmoking, volunteers treated with EGF did not heal any faster than control sites. There is still hope that EGF will provide acceleration of partial-thickness wound healing because EGF activity may be inhibited by wound proteases. Therefore, inhibition of these proteases should accelerate epithelialization in the presence of EGF. EGF and the closely related compound *transforming growth factor alpha (TGF- α)* continue to hold clinical promise as wound healing agents.

As summarized in Table 8-1, there are several other cytokines from a variety of cell and tissue sources that probably have key roles in the complex process of wound healing. Much of the basic information about these factors has been obtained by animal and cell culture studies in which single compounds were analyzed. In vivo, of course, they interact in complex associations.

Of equal importance are the mechanisms that regulate the expression of specific growth factor and cytokine receptors on the cell surface. This area of research is being explored in a number of laboratories and should provide additional insights into the critical role of these signals during tissue repair.

Extracellular Matrix Metabolism

The extracellular matrix is a complex structure in which a number of cell types and components interact (Fig. 8-12). Collagen is the major component of the extracellular matrix of all soft tissues, tendons, ligaments, and bone. At least 19 distinct forms of collagen have been characterized, the first five major forms of which are described in Table 8-2. In addition to collagen, the extracellular matrix contains glycosaminoglycans, proteoglycans, fibronectin, laminin, and elastin. The role of these components in normal connective tissue and during wound repair is summarized in Table 8-3.

Synthesis

There are several major steps in the biosynthesis of collagen (Fig. 8-13). First, at the transcription level, the amount of messenger RNA (mRNA) for the specific collagen is tightly controlled. Once synthesized, the mRNA undergoes extensive modifications before it is ready to be translated. The next point of regulation is at the translational step, where the actual synthesis occurs on ribosomes on the rough endoplasmic reticulum.

Collagen is composed of three polypeptide chains, and each chain is formed in a very orderly sequence with a high frequency of glycine-proline-x (Fig. 8-14). Collagen is unique because it contains the amino acid hydroxyproline. Hydroxyproline, however, is not incorporated as such into the collagen chain; hydroxylation occurs to specific prolines as synthesis occurs. This step is extremely important because failure to hydroxylate proline produces an unstable collagen molecule that is degraded rapidly in the intracellular or extracellular environment. This key hydroxylation step requires several hydroxyproline and cosubstrates. A lack of ascorbic acid or oxygen will compromise collagen production and result in insufficient wound strength.

As the collagen molecules are assembled, they are glycosylated by the addition of galactose and glucose to specific hydroxylysine residues, and then the three chains are stabilized to one another by hydrogen bonds. At the amino and carboxyl terminal ends of the molecule are extra pieces termed “extension peptides”; when they are present the molecule is termed “procollagen” (see Fig. 8-14). The carboxyl extension peptides “register” and hold the molecule in position as it is moved to the cell membrane for secretion into the extracellular space. Procollagen is approximately 1000 times more soluble than the final collagen product. The extension peptides are then removed by specific procollagen peptides as the molecule is secreted. Evidence suggests that the breakdown products of the procollagen extension peptides are taken up by the cell and down-regulate collagen expression.

Collagen is different from all other proteins because it undergoes several modifications once it has reached the extracellular environment. Here, collagen cross-linking occurs to form fibrils and fibers of collagen. The enzyme responsible for this step, lysyl oxidase, requires copper and can be inhibited by collagen cross-link inhibitors such as β -aminopropionitrile (BAPN) and α -aminocaproic acid. These collagen cross-link inhibitors have been used in animal studies and to a limited degree in human beings in an attempt to prevent excessive collagen deposition and subsequent adhesions and fibrosis. The results have been modest.

Degradation

For normal wound healing, collagen must be degraded as well as produced. The breakdown of extracellular components is initiated by very specific enzymes termed matrix metalloproteinases (MMPs), synthesized by a variety of cells including inflammatory cells, fibroblasts, and epithelial cells. MMP-1, 8, and 13 initiate degradation of the collagen molecule by splitting it into specific three-quarter and one-quarter fragments termed the TC_A and TC_B fragments. After this initial split, other nonspecific proteases can further degrade the pieces into peptides and eventually amino acids. The MMPs exist in an inactive or zymogen form that must be activated by other proteases such as plasmin. Once the MMPs are activated, they can be inhibited by complexing with the plasma and tissue protein α -2 macroglobulin. The MMPs can also be inhibited by forming a complex with tissue inhibitors of metalloproteinases (TIMPs). The pathway responsible for extracellular matrix degradation is thus complex and rigorously controlled.

Ground Substance

The precise role of ground substance, or proteoglycans and glycosaminoglycans, in wound healing remains unclear. Recent evidence suggests that ground substance has more importance in the healing process than recognized previously. Proteoglycans are composed of glycosaminoglycan subunits attached by covalent bonds via a serine residue to a protein core. They form a “bottle brush” structure and, as macromolecules, occupy a significant amount of space in the extracellular matrix. They function as molecular “shock absorbers” in combination with cartilage, provide for moisture storage, and also sequester cytokines. Some evidence suggests that after tissue injury, when ground substances are degraded, the bound cytokines are released to provide initial signals to facilitate the repair process. One specific glycosaminoglycan, hyaluronic acid, is most unusual because it is not sulfated and not bound to protein. It has a very high molecular weight and provides a fluid environment, thus facilitating rapid cell movement, cell differentiation, and extracellular matrix organization. Hyaluronic acid has an early and transient appearance soon after injury in the adult and has a much longer persistence in fetal skin and fetal wounds. Perhaps the application of hyaluronic acid to adult wounds could transform healing into the regeneration-like response seen in the fetus.

Wound Contraction

Contraction is one of the most powerful mechanical forces in the body. The precise biologic mechanisms of the process remain a controversial subject. Surgeons have always found the process of wound contraction both an ally and a foe. Even the ancients knew that open skin wounds healed if kept clean and protected with a dressing. During the healing process, the skin margins move in until they meet one another to provide a healed wound.

In the Civil War, more extremity amputations were performed than at any other time in human history. The wounds were left open because of the recognition that closure would usually lead to sepsis and death. Although healing often took months, very large, dinner-plate-sized, above-the-knee amputation sites would heal with a sturdy stump for a weight-bearing prosthesis. Similarly, today hidradenitis suppurativa in the groin region, which can be very difficult to heal, is often managed best by total excision of all involved skin in the groin and perianal area and then allowing the wound margins to come together spontaneously until the wound is healed (Fig. 8-15). In both instances, contraction is the ally of the surgeon, allowing closure without added morbidity.

However, in many instances, *contraction* (the normal, active biologic process) results in a *contracture*, a fixed deformity that is an aesthetic and functional disability to the patient. Most dramatic are contractures of skin and hollow organs. Loss of skin secondary to burn injury or trauma may result in a contracture as the skin edges are drawn together to heal a defect. In addition, whenever redundant skin is absent, a contracture will result. This is especially true over flexor joint surfaces such as the neck (Fig. 8-16) or the volar surfaces of digits. But the process is not limited to the skin. Any type of injury to hollow organs such as the esophagus or common bile duct may trigger the contractile process, resulting in a contracture that mechanically blocks the function of the hollow organ.

Mechanism

Alexis Carrel noted that open animal skin wounds healed by a process wherein the wound margins would remain open for a few days—a lag or plateau phase—after which followed a rapid rate of closure. The kinetics of the process of wound closure can be seen in the data shown in Fig. 8-17. There were and still remain questions as to whether the cells responsible for these powerful forces of tissue movement are located within the central granulation tissue of the wound or at the wound margins (picture-frame theory). Experimental studies by Gross have demonstrated that removal of the central granulation tissue did not alter the completeness of wound closure or the final pattern of the scar. The precise mechanisms responsible for wound contraction are not fully understood.

In the early 1970s researchers noted the presence of fibroblast-like cells in contracting open skin wounds that had smooth muscle components in the cytoplasm as well as fibroblast characteristics. They termed these cells *myofibroblasts*. They also found that when strips of open wound granulation tissue were placed in a water bath, they contracted in the presence of smooth-muscle agonists and relaxed in the presence of smooth-muscle antagonists. Furthermore, myofibroblasts have been identified in a number of contracted human tissues such as Dupuytren's contracture, burn contractures, and contractures of capsules around silicone breast implants. These cells are at their peak during and after the process of wound contraction (Fig. 8-18).

Some researchers postulate that the extracellular matrix may be as important as the cell type within the contracting tissue. The work that supports this hypothesis is based mainly on experiments done in vitro in a tissue culture system using a collagen gel lattice. Perhaps the varying evidence points to a contribution of both elements, i.e., contracting cells acting on a matrix susceptible to contraction.

All attempts to use pharmacologic agents to control contraction of wounds have failed. For example, some investigators attempted to inhibit open wound contraction with smooth-muscle inhibitors such as thiphenamil hydrochloride (Trocinate), which was successful only as long as the agent was present on the wound surface. Splinting a wound open will not prevent contracture. As soon as the splint is removed, the powerful biologic forces of the process place the wound margins in just the position they would have been had the splint not been placed.

Clinical Approaches

There are several helpful clinical principles for the surgical correction of contractures. If there are signs of inflammation remaining, the surgeon must be aware that various maneuvers, such as skin graft or Z-plasty, can result in recurrent contractures because of the various cytokines made by these cells and the myofibroblasts still present in the wounds. Before operation the surgeon should make a judgment as to the inflammatory status of the tissue. Mature scar is soft and pliable, whereas immature scar may be stiff, indurated, hypertrophic, and even tender. Remember that immature scar still has inflammatory cell components and residual myofibroblasts, which facilitate contracture of the bed under any skin graft that may be used in an attempt to correct the deformity. Often it is preferable to correct the defect by placing a flap that contains both skin and subcutaneous tissue and in some cases muscle. Because a flap is made of composite tissue and supplies the defect with all of the components of soft tissue, contraction is rare.

In correcting a mature contracture, a skin graft may be used to fill the defect. For reasons unknown, the open wound contracts less after the placement of a full-thickness graft than after the placement of a partial-thickness graft (Fig. 8-19). It is not a matter of graft thickness but of whether the graft is *full* or *partial*. In both instances, it is advisable to splint the repaired wound in a fully open position. It appears that splinting is required until all myofibroblasts and inflammation are gone from the wound, which may take as long as several months. Splinting time is highly variable, however, and must be determined by clinical judgment rather than science.

Epithelialization

All surfaces exposed to the external environment are covered by epithelial cells. Skin is an example of epithelialization, but mechanisms of epithelial repair are similar throughout the body. The outer layer of skin, the epidermis, is composed of a stratified squamous epithelium that protects the body from fluid loss, bacterial invasion, electromagnetic radiation, and general trauma. Normally the epidermal thickness is maintained at a constant level. Cells in the basal layer of the epidermis divide and migrate superficially and mature in the process. They become anuclear and die as they reach the surface and slough or desquamate, by which time they are really acellular masses of keratin. Although the term *keratinocyte* is used often interchangeably with the term *epithelial cell*, the epithelium is composed of several types of cells. The majority are keratinocytes, but the epithelium also contains other types, such as Langerhans' cells, which are involved in immunologic responses.

The collagen-rich dermis, and not the epidermis, provides all the strength attributed to skin. The epidermis, however, provides the barrier that protects the internal milieu of the host from the external environment. The basement membrane of the basal lamina provides structural support for the epidermis and attaches epidermis to dermis (see Fig. 8-12). It is a thin, glycoprotein-rich layer with complex layering and structures. A true adult-type wound healing response with classic inflammatory changes only occurs when the basal layer has been violated.

Mechanisms

Partial-thickness wounds heal by the process of epithelialization (see Fig. 8-4). There are two major phenomena in the process of epithelialization: *migration* and *mitosis*. After epithelial destruction, a blood clot is formed; it dries and forms a scab on the exposed dermis, thus protecting the dermis. Epithelial cell migration then begins the reparative process and is independent of epithelial mitosis. Migration of cells is the dominant process in epithelialization. Under experimental conditions, blocking cell mitosis has no significant effect on cell migration or closure of the wound. These migrating cells are derived from the margins of the wound and from hair follicles and sebaceous glands within the dermal base of the wound (see Fig. 8-4). The more superficial the wound, the more rapid the process of reepithelialization. Very superficial wounds such as minor burns and abrasions that do not penetrate the basement membrane heal by regeneration. Deeper dermal burn wounds or partial-thickness skin graft donor sites that penetrate the basement membrane also may heal by epithelialization, but the process requires a longer time. In addition, the result may be unsatisfactory because the inflammatory or healing response is initiated once the basement membrane is violated (Fig. 8-20).

Regardless of the type of injury, the basal layer of epithelium and the epithelium in the deeper hair follicles and sweat glands is where migration is initiated (see Fig. 8-4). One can observe these cells as they change morphologically. They flatten out and send out cytoplasmic projections into the surrounding tissue (Fig. 8-21). These cells also lose their attachments to their neighboring basal cells and begin to migrate, with the leading cells phagocytizing debris and blazing a path for the keratinocytes migrating behind them. The epithelial cells, which secrete proteases such as collagenase and plasminogen activator, do not migrate as single cells but in a sheet of cells. Some researchers have proposed that the keratinocyte sheets pile up at the leading edge and that cells tumble over the top in leapfrog fashion by a process called *epiboly*. When there are not enough cells for further migration, then mitosis begins.

Some of the biochemical mechanisms that control these processes have been defined. The blood and tissue fluids contain fibronectin and vitronectin—both of which support epithelial cell migration. Moreover, several growth factors stimulate keratinocyte migration and mitosis. These include bFGF, PDGF, TGF- α and EGF. By contrast, TGF- β inhibits epidermal cell proliferation but stimulates motility. Although the mechanical aspects of epidermal cell motility are not defined clearly, it is known that these cells contain a cytoskeleton and move by an actin-myosin contractile system. Once the surface is covered, the epithelial cells revert to their normal phenotypic behavior, with intercellular and basement membrane attachments. This reversion to a normal state may be a key to understanding epithelial cancer (Fig. 8-22).

The movement of epithelial sheets is most important in the healing of partial-thickness wounds. Clinically this process is enhanced by keeping the surface moist rather than dry. Nature's scab may be satisfactory, but appropriate nonadherent dressings that will keep the wound moist are of vital importance and can enhance significantly the process of epithelialization (see the section Wound Dressings later in this chapter). Growth factors also will be used in the near future to accelerate these processes. In addition, agents that enhance the detachment of cells and enhance the epibolic mechanisms will be added to the therapeutic regimen.

Nutrition

Inadequate nutrition is devastating to the healing process. If caloric protein intake stops for a mere 24 h, collagen synthesis ceases. Inadequate nutrition inhibits the immune response, and opsonization of bacteria is ineffective. Several dietary insufficiencies have been described.

Ascorbic acid is essential for human beings, and its lack is the most common cause of wound healing deficiency. The diseased state associated with a lack of vitamin C (ascorbic acid) is known as *scurvy*. Historians have reported that old scars in sailors would spontaneously open years after healing when the sailors were at sea for many months and without fresh fruits that contain large quantities of ascorbate. Long before biochemical analysis for ascorbate was available, the British admiralty recognized that scurvy could be avoided if all ships carried adequate supplies of ascorbate-containing fruits such as limes—hence the term “Limey” became affixed to British throughout the world.

The biochemical function of vitamin C is well known, and secondary functions relating to collagen gene expression have also been described. As mentioned in the discussion of collagen metabolism, ascorbate is a cofactor in the hydroxylation of proline to form the amino acid hydroxyproline during the synthesis of collagen. Ascorbate is essential for the addition of molecular oxygen to form the hydroxyl group of hydroxyproline. In human beings, thermally unstable collagen is produced if dietary ascorbate is insufficient. Old healed wounds thus tend to disrupt preferentially compared with the normal surrounding skin for two reasons. First, the scar is never as strong as surrounding skin. Second, there is more collagenase activity in normal scar tissue than in normal skin. Hence, in the scorbutic patient, scar tissue breaks down before there is breakdown of the normal skin. The problem is of more than mere historic and biochemical interest. Ascorbate deficiency is found commonly after major trauma and is more common than generally realized in malnourished people in the United States, particularly among the lower socioeconomic classes. Approximately 20 percent of patients seen in an inner-city emergency department may be ascorbate deficient. The mechanisms responsible for acute ascorbate deficiency after major trauma are not clear. There may be rapid sequestration of ascorbate in organs, or there may be renal loss, degradation, or lower absorption of this vitamin. Aggressive replacement of vitamin C should be undertaken immediately after major trauma to prevent wound healing complications. Although 60 mg/day is the current recommended daily allowance, up to 1 g of vitamin C per day has been recommended in trauma patients.

Iron in trace amounts is needed for prolyl hydroxylation. Calcium and magnesium are required for collagenase activity and protein synthesis in general. All the essential amino acids required for protein synthesis are needed for wound healing. Supplementation of the diet with increased levels of arginine appears to enhance the wound healing response, but the precise mechanism is not fully understood. An adequate supply of oxygen is essential for wound healing, not only for the hydroxylation of proline and lysine but also for all of the energy required for bacterial killing and cell viability. Some speculate that many chronic wound healing problems and perhaps impaired wound healing after trauma can be treated

effectively by increasing tissue oxygenation. There is evidence that if blood volume is low, then tissue oxygen will be low despite normal arterial blood gases. Some claim that hyperbaric oxygen enhances healing of chronic wounds and burn wounds, but there are few objective studies to support the concept that delivery of oxygen to the pathologic tissues enhances healing in a sustained fashion.

Immunosuppression

Only a small number of immunosuppressed patients actually manifest clinical wound healing problems. Acquired immunodeficiency syndrome (AIDS) is manifested by myriad signs and symptoms. A direct relationship between the leukocyte defect and healing, however, has not been reported. The wound complications found in AIDS patients are secondary to other manifestations of the disease—for example, various skin lesions such as Kaposi's sarcoma or infected traumatic wounds occur. Chronic wounds in these patients should undergo the same therapy as any other chronic wound (see the section Chronic Wounds later in this chapter).

Chemotherapeutic anticancer drugs inhibit healing. It is often unclear whether the wound healing problems are caused by the drugs or by the malignant tumor. Malignancies deplete nutrients and also inhibit wound healing directly. In animal models, chemotherapeutic agents have been demonstrated to be very harmful to healing. Various growth factors such as PDGF and TGF- β are able to prevent the harmful effects of these drugs on collagen metabolism.

Genetic Disorders of Connective Tissue Metabolism

Research in molecular biology is constantly providing new data on wound healing. Most exciting in recent years is information on a host of genetically controlled defects of collagen and glycosaminoglycan metabolism that result in both subtle and lethal diseases of connective tissue. There are probably hundreds of variants awaiting characterization and chromosomal identification. All of these genetic defects in connective tissue metabolism result in a poor wound healing response.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a congenital form of osteopenia due mainly to mutations in the genes for Type I collagen. There are four types of OI, ranging from mild to lethal manifestations (Table 8-4). Patients with OI present a particular problem to the surgeon because of (1) the increased propensity of the bones to break under minimal stress, (2) dermal thinning, and (3) increased bruisability. Scarring is usually normal in these patients, and the skin has normal extensibility.

Patients affected severely with OI may have difficulty with diaphoresis, which is not only unpleasant but also, coupled with fasting before surgery, may lead to dehydration and fever. The administration of parenteral fluids preoperatively may circumvent these problems. Children with OI also have a higher incidence of hernias, especially umbilical and inguinal. These can be corrected successfully with surgery.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is a genetically, biochemically, and clinically distinct group of collagen disorders characterized mainly by joint laxity, skin hyperextensibility and fragility, poor wound healing, and vascular rupture. At least ten types of this disorder have been distinguished. The enzyme or biochemical defects are known only for a few of the types. Each type presents a distinct challenge to the surgeon. These challenges encompass vascular complications such as arteriovenous fistulas, true and false aneurysms, varicose veins, bleeding ulcers, arterial rupture, and defective platelet adhesion. Invasive procedures such as angiography and surgery carry a very high morbidity and mortality in these patients. Rupture or dissection of a major artery may occur spontaneously in Ehlers-Danlos patients after minor trauma or with angiographic manipulation. Due to connective tissue weakness, adolescent males are at an increased risk during their normal growth and development as a consequence of the increased stresses of physical activities common in this age group. Due to connective tissue weakness, adolescent females are at a higher risk with the hormonal changes of menstruation. There are probably other forms of the syndrome that will be identifiable with modern molecular biological techniques. The types of Ehlers-Danlos syndrome are summarized in Table 8-5.

Marfan's Syndrome

Marfan patients are characterized by tall stature, arachnodactyly, lax ligaments, myopia, scoliosis, pectus excavatum, and often dissecting aneurysms of the root and ascending portions of the aorta. Some of these patients have defects in collagen structure, and some have abnormal fibrillin in their elastin. Spontaneous rupture of the aorta can cause sudden death. All these diseases may make surgery more difficult and wound healing more complicated.

Epidermolysis Bullosa

Epidermolysis bullosa is characterized by blistering and ulcerations. Some forms of this defect are thought to be caused by excessive production of matrix metalloproteinases by fibroblasts. Other forms are caused by abnormal matrix adhesion to the epidermis and associated basement membranes, resulting in tissue separation and blistering of skin after minimal trauma. The majority of these ulcers heal spontaneously, but in the more severe forms the epithelium cannot regenerate adequately, and chronic inflammation and scarring ensue. This genetic disease creates a challenge for the surgeon in several realms. Alimentary tract surgery exhibits poor healing that is impaired by stenosis and strictures in many cases. Dermal incisions and tissue injury must have meticulous skin care to limit the amount and severity of blistering in the traumatized tissue. Phenytoin decreases collagenase activity in human skin fibroblasts and has been used to treat patients with recessive dystrophic epidermolysis bullosa.

Clinical Importance

Patients with these genetic disorders provide a challenge for the surgeon. Because of the relatively rare occurrences of these genetic defects, any one surgeon may see no more than one or two cases in a lifetime. Despite this low exposure rate, it behooves the surgeon to be aware of the physical and clinical signs of these diseases so that disaster during surgery can be avoided. A thorough history and physical examination, with emphasis on the family history, may alert the surgeon to a potential problem, which can then be successfully overcome. At times, preoperative diagnosis is impossible.

Systems and General Factors that Affect Wound Healing

Inadequate or poor-quality matrix production may be secondary to a variety of causes, such as malnourishment or various drugs that inhibit cell proliferation and protein synthesis. Table 8-6 is a list of some of the many factors that may alter wound healing. Infection is the number one cause of impaired wound healing, and many factors can contribute to infection (Table 8-7).

SPECIFIC WOUND HEALING PROBLEMS

Gastrointestinal Tract

There has been progress in our understanding of healing and repair in the gastrointestinal tract over the past 10 years. This is a result of efforts to determine the cellular and connective-tissue elements involved in normal intestinal architecture and in the fibrotic responses that characterize many chronic inflammatory processes in the intestine.

Anatomy

The gastrointestinal tract is divided into several distinct layers (Fig. 8-23). The inner mucosal layer is for absorption, and the outer muscularis mucosae layer functions for motility. They are wrapped in a strong serosal layer, which is an extension of the peritoneum.

Unlike the skin, the mucosal epithelium is only one cell thick and renews itself about every 8 days. Beneath the epithelium is a basement membrane composed of Type IV collagen similar to the basement membrane of skin. Beneath this is the lamina propria, which is made up of collagen Types I, III, and V and elastin with an array of specialized cell types, including various inflammatory cells. The outermost layer of the mucosa is a very thin layer of smooth muscle, the muscularis mucosae, which contributes to gut motility. The submucosa separates the mucosa from the muscularis propria and appears to attach these two important layers to one another. It is composed of several collagen types in a ratio similar to that found in human aorta.

The muscularis propria is densely packed smooth muscle with a predominance of Types I and III collagen and a small amount of Type V. This collagen serves as an intramuscular tendon, or the source of strength through which a force can be transmitted through the smooth muscle cells. This is supported by the fact that hypertrophy of the muscularis propria also increases the collagen content of the muscle.

Injury and Repair

The quality of the intestinal repair process and its end result are determined by two important factors: the depth of the injury and the chronicity of the injury. Inflammation in the mucosa without epithelial injury, as seen in gastritis, is not associated with a repair or healing process. Once the inflammation subsides, the erythematous appearance of the mucosa seen at endoscopy returns to its pale salmon-pink appearance with easily identified ramifying blood vessels. If the epithelium is injured, a rapid restitution process activates, and the epithelial lining is restored within hours (Fig. 8-24). These lesions, termed erosions, are often induced by acid/peptic digestion or aspirin or chemotherapeutic agents in the stomach. There is no mesenchymal cell response if the injury is confined to the mucosal layer and does not penetrate the muscularis mucosae, even if the injury is chronic.

When the injury does penetrate into the submucosa, a mesenchymal cell repair response is evoked. Smooth muscle cells from either the mucosal or deeper muscle layers are significant in this response, migrating into the area of injury and laying down reparative collagen. This lesion is called an ulcer and would characteristically have a plug of smooth muscle cells and collagen at its base.

If the injury in the submucosal layer is acute, the reparative process abates, the collagen laid down is resorbed, and the normal architecture of the intestine is preserved. If the submucosal injury is chronic, however, scar tissue accumulates, the mucosa loses its compliant movement over the muscle, the bowel wall thickens, and stricture and obstruction can ensue (Fig. 8-25). In this way, any chronic lesion involving the intestinal submucosa can lead to stricture.

Crohn's disease is a chronic idiopathic inflammatory bowel disease that affects the terminal ileum and cecum most frequently but can involve any part of the gastrointestinal tract. It is characterized by inflammation in the submucosa rather than the mucosa and often extends from mucosa to serosa (transmural). Inflammation leads to collagen deposition and contraction, which cause stricture and symptoms of intestinal obstruction. Biochemically, there is increased collagen Type I and Type V content in the involved bowel compared with normal. This is in contrast to ulcerative colitis, in which the bowel tends to have thinning of its matrix and to perforate rather than get thicker and develop strictures. The healing process of ulcerative colitis is very different from that of Crohn's disease. In ulcerative colitis the inflammation is confined to the mucosa and does not extend into the submucosa.

Human intestinal smooth muscle cells isolated from normal human jejunum have been used to clarify further the pathogenesis of bowel healing. Demonstrating their differences when compared with normal skin, the bowel cells in vitro produce twice the collagen as skin fibroblasts. Moreover, *TGF- β enhances collagen synthesis by intestinal smooth muscle cells. Although corticosteroids inhibit collagen production by dermal fibroblasts, they are not effective in down-regulating collagen synthesis by human intestinal smooth muscle cells. Radiation injury* is commonly seen in the alimentary tract and terminates in extensive and progressive submucosal, muscularis, and serosal fibrosis with striking hyalinization of the

accumulated collagen. Resection is required in some patients but is hazardous because bowel anastomosis in irradiated tissue is associated with anastomotic leak and fistula formation.

Lye ingestion is a common cause of esophageal tissue injury. The mucosa is penetrated, and hence fibrosis and stricture occur. Although parenteral corticosteroids have proved efficacious in animals, there has never been a well-controlled study in human beings. Repeated dilatation of the esophagus may abate symptoms of obstruction, but repeated contractions often make serial dilatations a lifelong necessity.

Healing in the Gastrointestinal Tract

The same basic process of repair occurs with anastomotic healing in the gastrointestinal tract as occurs in skin. The same factors that inhibit development of tensile strength in skin do the same in the gastrointestinal tract. But the gastrointestinal tract is a unique tubular structure. It is closed with sutures or staple devices and must then rely on the anastomosis to provide bowel integrity until the anastomosis has developed sufficient tensile strength to prevent disruption. The major complications of intestinal anastomoses are anastomotic leakage and actual bowel wall disruption, which are associated with a significant morbidity and mortality. Although clinical complications of anastomotic leak occur in 2 to 18 percent of patients, up to 50 percent of anastomotic sites leak early, as demonstrated by contrast radiographic studies. Early bowel leak cannot be associated with insufficient collagen metabolism but must relate to mechanical anastomotic failure, bowel ischemia, or failure to obtain a mucosal seal. However, most studies have focused on collagen metabolism. During the first few days after anastomosis, there is significant turnover of collagen not only at the anastomotic site but in the adjacent bowel wall. Reduction in collagen content extends a significant distance from the actual anastomotic site. The significance of these data versus mucosa barrier defects remains to be clarified.

Skin

More wound healing data come from skin than from any other organ system. Most of the information gained from the study of skin in animal models and in human beings can be applied to the process of tissue repair in all other organ systems.

Keloids and Hypertrophic Scars

Keloids and hypertrophic scars are both abnormal healing processes that occur after injury from trauma or surgery, but they differ clinically and biochemically. Hypertrophic scars remain within the boundaries of the original wound and almost always regress over a period of time (Fig. 8-26). By contrast, keloids extend beyond the boundaries of the original wound and usually do not regress (Fig. 8-27); they usually recur after excision unless additional therapy is provided.

Normally there is an equilibrium between collagen synthesis and collagen degradation in skin and normal scar tissue. By contrast, both keloids and hypertrophic scars are characterized histologically by an overabundant deposition of collagen. However, the rate of collagen synthesis in keloid tissue or keloid fibroblasts in culture is significantly greater than in normal skin and normal scar tissue. The keloid tissue contains more soluble collagen and has a greater water content. Fibroblasts isolated from keloids continue to produce more collagen, through up to 40 passages in cell culture, than hypertrophic scars or normal skin. The equilibrium may be disrupted further by the collagenase inhibitor α_2 -macroglobulin, which is abundant in keloid and hypertrophic scar tissue. Both increased collagen synthesis and decreased degradation seem responsible for the increased collagen deposition in keloid and even hypertrophic scar tissue. Molecular biologic studies applied to these earlier findings seem to confirm the routine biochemistry. There is increased messenger RNA for Type I collagen, which suggests that these lesions result from abnormal regulation of collagen production at the level of transcription.

Growth factors may be important in the regulation of these lesions. Some studies suggest that cultured keloid fibroblasts produce increased amounts of cytokines compared with normal skin fibroblasts and that keloids may contain increased concentrations of TGF- β . In addition, the keloid fibroblast produces significantly more collagen when exposed to TGF- β in cell culture. Neutralizing antibodies to TGF- β placed in primary guinea pig wounds at the time of closure resulted in scarless healing. These observations suggest that inhibition of TGF- β may make a significant contribution in the clinical control of keloids and hypertrophic scars. Such animal studies require further validation before this basic science information can be applied in the clinical setting.

At present the clinical treatment of keloids and hypertrophic scars is not consistently effective. Surgical excision should be done only after careful consideration. Hypertrophic scar tissue will regress usually without operation. Keloid tends to recur after excision. There may, however, be clear indications for surgery in both groups of patients. In some patients, keloid is very disfiguring, and this alone may be reason enough to excise the lesion. Excision may be used for debulking so that pharmacologic agents can be used to control the abnormal scar. In other patients excision is indicated to improve function. All patients must be made aware of the high risk of recurrence and the importance of careful follow-up.

As in any disease process that is not understood clearly, many treatments have been advocated for keloids and hypertrophic scars. Perhaps the most popular and effective is the intralesional injection of triamcinolone, which is a long-lasting synthetic glucocorticoid. This treatment makes the lesion softer and often smaller, and it may be the only treatment required for small lesions. It also often relieves the burning, itching, and pain associated with keloids and hypertrophic scars. If these somatic symptoms are the patient's complaints, then corticosteroids may be all that is required regardless of the size or appearance of the lesion. The authors recommend triamcinolone 40 mg/mL, never using more than 2 mL every 6 to 8 weeks in adults to avoid any systemic effects. Complications include local atrophy of skin and subcutaneous tissue, which may be severe. Telangiectasia may appear locally, and there may be depigmentation in dark-skinned patients. Pregnant women should never be given triamcinolone because of the remote possibility that a birth deformity may be related to the use of corticosteroids. We do not recommend the use of a "Dermajet" to deliver triamcinolone through the epidermis to the keloid in the underlying dermis. Triamcinolone may be used in conjunction with surgery. Some inject triamcinolone into the wound margins at the time of closure after excision, and others begin treatment at various times after operation. The newer "supersteroids" such as clobetasol propionate (Temovate) may be effective topically and can be used with intralesional therapy.

Keloids are known to contain a significant number of mast cells and have increased histamine content as compared with normal skin or scar. As a result, these patients often suffer severe itching. An oral antihistamine is often helpful to control this symptom. Several other topical devices have been used to treat keloids and hypertrophic scars, including a pressure dressing, steroid-impregnated tape, and silicone sheets. There are no valid data indicating that any of these methods are efficacious. Recent data suggest that pressure garments and silicone sheeting may increase skin temperature enough to increase collagenase activity, which may reduce the bulk of the scar. Silicone sheeting is expensive and until its efficacy is validated, clinicians should avoid the expense. Simple pressure or tape over the scar is adequate. Radiation therapy is mentioned only to be condemned. There have been no long-term follow-up studies reported, and the late development of skin cancer after radiation constitutes a potential hazard.

Factitious Wounds

Factitious lesions are much more common than one might expect. The surgeon should always be on the alert for factitious diseases of a surgical nature. Beware of any patient who has had multiple surgical procedures, especially patients with some relationship to the health care field. When examining patients, note the pattern of scars, accessibility to self-mutilation, "la belle indifférence." Confrontation will often lead to the patient's leaving—never to return. Both diagnosis and treatment are extremely difficult.

Marjolin's Ulcer

Any nonhealing wound in an area of previous trauma may represent squamous cell carcinoma, termed Marjolin's ulcer. These virulent malignancies arise from old areas of trauma. Although the causation may be multifactorial, they appear to arise because the dense scar of the lesion does not allow normal immunologic surveillance of the area by the host, and the host cannot destroy the malignant transformation within the scar.

Tendon

Tendons link muscle to bone and thereby allow muscular force to exert motion. They are composed mainly of Type I collagen, with a significant amount of proteoglycan, which arranges and regulates the size of the collagen fibrils. If fetal muscle development is prevented, tendons do not develop. When tendons cross the concavity of a joint such as finger or wrist and do not insert immediately distal to the joint, they pass under fibrous structures called pulleys. Specialized cells located in the pulleys and elsewhere lubricate the tendons. In the areas where tendons are compressed, they receive blood supply from segmental vessels in mesotendon structures called vincula (Fig. 8-28).

There are some unique factors in flexor tendon healing that are important clinically. The flexor tendons within fibrous flexor sheaths of the digits present the surgeon with a healing problem so challenging that some termed the area "no-man's-land." Surgical results in the past in this area were generally poor. This is because healing must occur in the sutured ends of the tendon as well as in the sheath itself. Both are collagenous structures. When they heal together as a unit rather than separately, tendon function is lost because gliding is impeded by the scar between tendon and sheath. Surgeons have learned to use meticulous technique and early mobilization in "no-man's-land" to obtain good functional results. A major contribution to the functional healing of tendon within a fibrous flexor sheath has been the revelation that the segmental blood supply to the tendons through the vincula is extremely important in promoting healing with less restricting scar. Destruction of the vincula leads to ischemia and scarring, just as would occur in any ischemic tissue. Tendon nutrition is also supplied by synovial diffusion. Experiments have shown that, deprived of a normal blood supply, tendons still heal, obtaining nutrition from extrinsic diffusion.

There is excellent experimental and clinical work to show that early motion provides the stress forces to lengthen and remodel scar. Motion cannot prevent collagen deposition, but it can lengthen the scar and allow enough motion for functional gliding of tendon. Motion may also enhance lubrication from synovial fluid. Developments in flexor tendon surgery have focused on designing stronger, multistranded tendon repair techniques to withstand more aggressive early motion. While early passive motion has been used for a decade or more, early active motion requires stronger surgical repairs and has shown significantly improved results in motivated patients.

Experiments to enhance tendon healing include electrical stimulation, nonsteroidal anti-inflammatory agents, and growth factors, but there is no evidence that these treatments are effective. Various pharmacologic agents have been used experimentally in an attempt to reduce tendon adhesions. Hyaluronic acid holds some promise. The use of proline analogues has not been successful. β -Aminopropionitrile was used successfully in human beings undergoing flexor tendon grafting, but side effects led to termination of the study.

Bone

Fracture repair involves physical, biomechanical, and biochemical factors that interact in a process that often leads to a healed bone that is normal in form and function and indistinguishable from its preinjured state. Grossly, a fracture consists of a gap or break in a bone with or without displacement. This leads to a loss of structural support with subsequent instability and deformity based on the amount of displacement. Inflammation occurs with hematoma formation, edema, and pain. This early inflammatory phase is associated with a relative tissue hypoxia at the site of the fracture, which contributes to a transformation of surrounding osteoprogenitor cells and migration of hematogenous cells into the fracture site. These events provide the fracture with the platelets, monocytes, neutrophils, fibroblasts, osteoblasts, and osteoclasts needed to accomplish fracture repair. At the same time, new vascularization occurs, with extensive blood vessel ingrowth into the fracture.

Over the course of several weeks these changes lead to the formation of the soft callus, a local fibrocartilaginous splint of granulation tissue and cartilage that gives the fracture some stability. In a process that takes a total of 6 to 8 weeks from the time of injury in an uncomplicated fracture, the soft callus is transformed into bone by endochondral ossification. In this process the cartilage of the soft callus is ossified as osteoblasts originating in the periosteum and the medullary canal move from the periphery of the fracture inward creating new bone. As this process is completed, pain diminishes and union occurs. Over several years remodeling of the bone occurs as its structure is altered until its

appearance approaches a normal uninjured bone (Fig. 8-29).

The process of fracture repair is different when rigid internal fixation with plates and screws are used to immobilize the injury. When the bone ends are in exact opposition and there is no motion at the fracture site, no soft callus forms. Instead, there is direct bone-to-bone healing across the injury without endochondral ossification.

Delayed union or nonunion are failures of fracture repair. Many local and systemic factors are associated with these complications, which occur in approximately 5 percent of long-bone fractures. The local factors that seem to be the most important are the site of the fracture, presence and degree of soft-tissue injury, bone loss, inadequate reduction, inadequate immobilization, infection, previous radiation, malignant growth at the fracture site, and poor blood supply to the fracture. When the diagnosis of delayed union or nonunion is made or when a patient has a fracture known to be associated with these complications, treatment can be altered to enhance bone repair. This involves treatment of one or more of the local factors listed above, e.g., performing a muscle flap procedure to cover an open tibial fracture with extensive tissue loss, or bone grafting a fracture with bone loss.

Bone grafts can be used to treat established nonunion or to replace missing pieces of the skeleton. The healing of bone grafts involves many of the mechanisms present in fracture repair, with important differences. Osteogenesis and osteoconduction are the primary mechanisms by which bone grafts heal. Osteogenesis is the formation of new bone by cells that survive in the graft. This mechanism occurs primarily in vascularized bone grafts, such as fibula flaps, in which the blood supply to the graft is maintained or reconstituted with a microvascular anastomosis. Osteoconduction is the process by which blood vessels and cells from the surrounding tissues grow into the bone graft, which acts as a scaffold for the laying down of new bone as the dead bone of the graft is resorbed. Also termed "creeping substitution," this is the primary mechanism by which corticocancellous bone grafts, such as those from the iliac crest, heal.

Osteoinduction is the transformation of local, undifferentiated cells into bone-forming cells. Although this mechanism may participate in bone graft healing, it is a topic of active research in fracture repair and dentistry. This area of research has grown out of the increased understanding of the biochemical basis of the many cellular processes discussed earlier and the desire to control these processes to improve healing in fractures prone to delayed union and nonunion and to improve alveolar ridge contour in patients who need dentures.

Many proteins have been found to influence bone healing in experimental models. Bone morphogenetic protein (BMP), first described by Urist, was the first to be studied extensively and has been found to induce perivascular connective tissue cells to become osteoprogenitor cells. BMP's smallest active subunit is a protein that has been termed osteogenic protein-1 (OP-1). OP-1, a member of the TGF- β family of cytokines, accelerates the healing process in bone in both fracture and skull-defect models. Other cytokines, from the PDGF and FGF families of growth factors, also have effects on bone healing. As in other areas of wound healing research, pharmacologic manipulation of the process of bone healing should become a reality in the near future.

Cartilage

Cartilage of joints, unlike the bone that surrounds it, has little propensity to heal. Superficial injuries to articular cartilage cause minimal inflammatory response and are totally dependent on the chondrocytes of the cartilage to heal. Because the chondrocytes usually do not respond with enough proliferation and synthesis of the necessary proteoglycans and collagen for repair to occur, a persistent structural defect in the joint surface usually remains. Whether or not traumatic arthritis develops depends on the ability of the remaining joint cartilage to survive under increased stress.

Deep injury to articular cartilage that goes into the subchondral bone produces an exuberant inflammatory and healing response. The bone of the subchondral area is a source of reparative cells. A fibrocartilage intermediate is formed that creates hyaline cartilage over time. These properties are the basis for abrasion of severely injured joint cartilage and passive motion while healing is under way.

Cartilage grafts are used extensively in reconstructive and cosmetic surgery of the nose and ear. These grafts maintain their structure with minimal resorption over time. Carving cartilage can alter the balance of forces that maintain its shape and can lead to bending. This is important in carved rib cartilage grafts to the nasal dorsum, which can warp late after operation, and it is probably the mechanism by which an injured nasal septum becomes progressively more deviated after a broken nose.

Chronic Wounds

Chronic wounds remain one of the most costly unsolved problems in health care today. It is estimated that some 15 percent of the approximately 14 million diabetics in the United States develop skin ulcers, which result in about 60,000 amputations per year. The range of medical costs for diabetic foot ulcers and amputations has been estimated to be \$10,000 to \$27,000 per patient. Thus the overall cost of diabetic foot problems, including loss of productivity, could be as high as \$20 billion per year. In addition, there are 175,000 to 250,000 spinal cord injury patients in the United States, with approximately 7,000 to 10,000 new patients per year. Approximately 60 percent of these patients develop pressure ulcers, and cost estimates range from \$14,000 to \$25,000 per patient for medical, surgical, and nursing care. If the elderly nursing home population with pressure ulcers is added to the spinal cord injury population, then the figure for the care of all pressure ulcers is enormous. The care of venous stasis ulcers is also very costly.

Acute Versus Chronic Wounds

There are significant differences between acute and chronic wounds. An *acute wound* usually occurs in a normal, healthy person and is either closed primarily or allowed to close by "secondary intention." Most injuries to whole organs or tissues can be considered acute wounds.

A *chronic wound* is one that fails to heal because of some underlying pathologic condition. For example, pressure ulcers, diabetic ulcers, and venous stasis ulcers are chronic wounds. These complex wounds will not heal until the underlying cause is corrected. Curiously, many of these chronic wounds heal to a point, and then the healing process arrests. The precise factors that cause this phenomenon are unknown. With proper clinical management, most chronic wound healing problems are resolved and healing occurs, but recurrence is common.

Pathophysiology

The pathophysiologies of chronic wounds, such as diabetic foot ulcers, pressure ulcers, venous stasis ulcers, and ischemic ulcers, are complex and diverse, but they appear to share one common feature. Unlike acute wounds, which typically result from transient, externally induced damage to tissue, chronic wounds arise from physical and biochemical insults of extended duration. This prolongs the inflammatory stage of wound repair, resulting in extensive tissue damage and impaired healing. Impaired wound healing in the guise of chronic dermal ulcers represents a major health problem that affects millions of Americans yearly.

During normal wound repair, *polymorphonuclear leukocytes (PMNs)* quickly respond to chemoattractants, including fragments of fibrinogen, fibrin, the complement degradation fragment C5a, formyl methionyl peptides released from bacteria proteins, and soluble mediators such as platelet-activating factor (PAF) and PDGF. In response to these chemoattractants, PMNs become activated and transmigrate through the endothelium into the wound site. Wound PMNs destroy and phagocytize contaminating bacteria as well as damaged or necrotic tissue. To accomplish this task, PMNs release a large number of enzymes and cationic proteins and express plasma membrane enzymes that generate reactive oxygen metabolites.

In normal repair, PMN infiltration lasts only a few days. However, the perseverance of severely damaged or necrotic tissues, intermittent or continuous ischemia, or microbial infection leads to a persistent and excessive response by activated PMNs. The products released by PMNs continue to degrade the extracellular matrix (generating additional fragments, which are PMN chemoattractants) and prevent or impair the migration of other reparative cells into the wound. The high levels of active proteases in many chronic wounds may partly explain the disappointing results obtained when these wounds have been treated with peptide growth factors.

Venous Stasis Ulcers

Venous stasis ulcers are the eventual result of deep venous obstruction or valvular incompetence. The resulting increase in venous pressure dilates veins and increases capillary permeability, which promotes extravasation of fluid and high-molecular-weight proteins. Ulceration can result after several previous manifestations (swelling, leg pain, dilated superficial veins, and erythema) of chronic venous insufficiency. Ulcers typically occur superior to or near the medial malleolus and tend to be large and irregularly shaped (Fig. 8-30). The extent of ulceration can range from just below the epidermis to as deep as the fascia. The ulcers commonly are rimmed by an area of hyperproliferative keratinocytes.

The appearance of perivascular "fibrin cuffs" is a particular characteristic of this disease. The abundant presence of extracellular matrix components, such as laminin, collagen, and fibronectin, suggests that an attempt to seal the gaps between the endothelial cells may be occurring. Fibrin cuffs were once believed to act as barriers to transportation of oxygen, nutrients, and growth factors. However, cuff formation around the capillaries is discontinuous, and there is little correlation between the extent of cuff formation and the clinical presence of lipodermatosclerosis, ulcer size or transcutaneous oxygen measurements taken at sites adjacent to the ulcer.

An alternative hypothesis suggests that venous hypertension leads to endothelial cell damage, and this injury leads to an aggravated and persistent inflammatory response that involves PMNs. This concept is supported by the findings of fibronectin degradation products and elevated levels of PMN-specific proteolytic enzymes in fluid exudates of stasis ulcers.

Pressure Ulcers

Pressure and shear forces over bony prominences have a key role in the formation of pressure ulcers (Fig. 8-31). Immobilized persons are at risk because pressure causes cell death in the least vascularized tissues. In porcine models, damage initially occurs in the fat and deep muscles and progresses outward toward the skin. Necrosis spreads outwardly, beginning with the subcutaneous fat and eventually affecting the epidermis. Histologic analysis of the course of ulcer formation in human beings reveals a sequence of capillary and venule dilation accompanied by a perivascular infiltrate. As with venous insufficiency, capillary permeability allows intravascular cells to enter the connective tissue with the release of degradative enzymes and reactive oxygen metabolites. In cases in which ulceration extends to the bone, osteomyelitis can be a complicating factor. Marjolin's ulcers rarely occur in these chronic ulcers.

Patients with spinal cord injury are more susceptible to the ravages of pressure than the average healthy person. Although some factors remain unclear, it is well documented that spinal cord injury patients do not have a normal leukocyte response to injury below the level of denervation. These patients often have low ascorbate levels despite supplementation, which can be deleterious to proper collagen formation. In animal studies, collagenase activity is greater in denervated tissues. In patients with spasticity, shear forces may be even more harmful than pressure.

Elderly bedridden patients have additional promoting factors besides pressure. Fecal and urinary incontinence leads to maceration and skin breakdown. Poor nutrition also is a major problem.

In both groups, good wound care is critical. Antibiotics should not be used to treat these wounds unless they are causing systemic toxicity. When these patients develop fever, the cause rarely is the wound except if there is loculated purulence. Pulmonary, renal, or intraabdominal problems are more common. If the wound colony count is 100,000/g of tissue or higher and the patient is not septic, topical antibiotics should be used to reduce the bacterial load before closure or in order to facilitate spontaneous healing. Bacterial counts sometimes can be lowered with good wound care alone, without the use of antibiotics. The best evidence to date is that systemic antibiotics will not penetrate the ulcer and therefore will not decrease the bacterial colony count within the wound granulation tissue. The use of systemic antibiotics is often abused in patients with chronic wounds, often simply altering the bacterial flora and making the host more susceptible to resistant organisms.

The National Pressure Ulcer Advisory Panel has developed a staging system (derived from other systems) for classifying pressure ulcers:

Stage I. Nonblanchable erythema of intact skin, the heralding lesion of skin ulceration.

Stage II. Partial-thickness skin loss involving epidermis and/or dermis. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.

Stage III. Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

Stage IV. Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule, etc.).

One must use this classification with caution because it can be misleading.

Diabetic Ulcers

Chronic ulcers in diabetics typically present as foot ulcers (Fig. 8-32). Pressure and tissue trauma can be considered the major promoting factors, but the neuropathy from the primary disease is the most important causative element. Lack of sensation results in increased mechanical stress under the metatarsal heads, heel, and callosities. This in turn leads to intermittent or continuous ischemia, resulting in pressure ulceration. In addition, severe neuropathy prevents the timely detection of skin punctures, or improper shoes, or the detection of foreign bodies in shoes.

There are other factors that may be involved in the formation of diabetic ulcers. In addition to neuropathy, diabetics are also prone to angiopathy; the capillaries of diabetics are thicker and more permeable, and the absolute number of capillaries is smaller. Granulocyte chemotaxis and phagocytic function is impaired in diabetics. Diabetic wounds are characterized by decreased levels of extracellular matrix components. The collagen of diabetics is subject to nonenzymatic glycosylation, which alters the filtration function of basement membranes, thus leading to many of the pathologies characteristic of diabetes. These include reduced vessel permeability, altered lens-capsule function, and renal problems secondary to abnormal glomerulus filtration. The breaking strength of wounds in diabetics is also reduced.

Mechanisms Involved in the Healing of Chronic Ulcers

Sometimes the basic biologic mechanism of healing chronic ulcers is contraction, which reduces the area of the wound. Usually minimal epithelialization is required to heal chronic ulcers, and the result is often cosmetically and functionally acceptable. Pressure ulcers and diabetic ulcers heal mainly by contraction, but there are exceptions. For example, venous stasis ulcers do not heal by contraction, but mainly by epithelialization. If the margins of these ulcers are tattooed and then the wound heals, the tattoo marks remain in their peripheral location. It would appear that epithelial cells cover the wound and that these cells lead to the induction of a neodermis. This is supported by the evidence that cultured epithelial cells applied to a granulating wound bed will induce new dermis formation.

Chronic Wound Care

Most chronic wounds, regardless of the cause, will heal by secondary intention only if the underlying biochemical and mechanical causative factors are corrected. For example, compression stockings or dressings must be used to relieve venous hypertension in order for venous stasis ulcers to heal. Conversely, pressure must be eliminated over the pressure sore. Special pressure-relieving beds and other devices have been designed for this purpose. Diabetes must be controlled to ensure healing of diabetic ulcers. Bacterial counts above 100,000/g of tissue must be reduced and nutritional deficiencies corrected.

Successful treatment of a chronic ulcer depends on an accurate assessment of the factors contributing to the ulcer pathology (Table 8-8). For example, immunocompromised patients may require systemic or topical antibiotics to prevent or control infection and sepsis. Nutrition deficiencies must be corrected. Adequate amounts of protein, fats, carbohydrates, and vitamins are necessary to provide the energy and biosynthetic requirements for repair. Albumin level is an important indicator of malnutrition; it is sacrificed to provide essential amino acids in the event of inadequate protein intake. Because the half-life of albumin is 20 days, a low albumin level is indicative of chronic malnourishment; sporadic deficiencies in intake do not result in perceptible changes in serum albumin level.

Tissue perfusion and subsequent cellular oxygenation are important factors for chronic wound repair. Oxygen is required for the production of bactericidal reactive oxygen metabolites and for the synthesis of collagen. Destruction of bacteria by neutrophil-mediated oxidative killing is significantly reduced in hypoxic tissues. Poor perfusion can result in an increase in infection and an increase in the impairment of healing. There is no evidence that hyperbaric oxygen can improve the healing of most chronic wounds with the exception of osteoradionecrosis. This mode of therapy is very expensive. Although used for decades, its efficacy has never been validated. It is a prime example of a therapy lucrative for the manufacturers and therapists that has been promulgated by marketing without substantiation. It is to be hoped that third party payors will refuse such bogus therapy unless users can prove efficacy.

Other factors that influence repair include age, metabolic disorders (uremia, jaundice, diabetes), pharmacologic agents that interfere with repair (glucocorticoid steroids), distant malignancies, and infection. The location and severity of the ulcer also have a role in determining treatment. Small pressure and diabetic ulcers are best managed by local wound care and removal of the pressure source. Larger defects may require flaps for closure. Management of venous stasis ulcers involves removal of venous pressure by the use of elastic stocking support and elevation of the limb. Skin grafts and sometimes flaps are required for severe larger ulcers.

Wound cleansing has a limited role in the treatment of chronic wounds. The objective of wound cleansing is not wound sterilization but rather reduction of the microbial load, to remove necrotic tissue and foreign bodies, and to diminish levels of autolytic enzymes in the wound. Debridement to remove damaged and necrotic tissue often helps to accelerate healing. Sharp surgical debridement is the least expensive, quickest, and most effective method. Recent studies have demonstrated that total excision of diabetic ulcers accelerates the healing process. Use of disinfectants or high-power sprays should be avoided. Disinfectants such as povidone-iodine, acetic acid, hydrogen peroxide, or Dakin's solution (sodium hypochlorite) are as likely to injure normal tissue as they are to destroy microorganisms. In some cases irrigation of the wound with normal sterile saline is helpful.

Power sprays pose the danger of forcing microorganisms deeper into healing tissues, and they should be eliminated from chronic wound care regimens. Irrigation pressures should not exceed 15 pounds per square inch (psi). Whirlpool treatment has been recommended for debridement of large areas of foreign debris or nonviable tissue. Care must be taken to prevent infection between patients by strict hygienic control of whirlpools. Given the debate about the efficacy of whirlpool treatment, the concerns about spreading wound contamination, and the expense of using whirlpools, this therapy may become obsolete in the future.

WOUND DRESSINGS

During the past decade, dressings for acute and chronic wounds have changed dramatically. As new material technologies have evolved, new products have inundated the market. Dressing products should be selected on the basis of the type and characteristics of the wound.

The acute wound that is closed primarily requires coverage with a dry sterile dressing for a few days. This helps to protect the wound from bacterial invasion and absorbs any wound fluid. The dressing also may provide some psychological benefit to the patient in keeping the surgical wound out of sight. When epithelialization is complete, the dressing can be removed.

Partial-thickness wounds—e.g., donor sites, abrasions, first- and second- degree burns—require semioclusive dressings. These products provide a moist environment that enhances the reepithelialization of partial-thickness wounds. If a semioclusive dressing is applied early to a partial-thickness wound, dry scab formation can be avoided. Scab formation can damage the underlying dermis, and removal of the scab may be painful, cause bleeding, damage new epithelium, and increase the deformity in the final scar. Semioclusive dressings may not have enough absorption capacity to handle the amount of wound exudate produced in the early phase of healing. Wound fluid can become trapped and cause the area around the wound to macerate or leak, necessitating frequent dressing changes. Combining an absorbent dressing material, such as an alginate, with the polyurethane film or hydrocolloid alleviates this problem.

The classification, composition, indications, and functions of dressings are summarized in Table 8-9. Occlusive/semioclusive dressings may exacerbate infection when covering areas in which the bacterial count is higher than 100,000/g of tissue. This risk may be reduced by first controlling the wound bacterial count with topical antimicrobial or systemic antibiotics. In addition, several of the hydrogels can be used effectively with antibiotic creams. Hydrogels are thought to accelerate the rate of penetration of the antibiotic into the granulation tissue.

Dressings are used to debride. If the wound is dry, it is important that a slower and more gentle process be used, especially when tendons are exposed. This can be accomplished with hydrogels that have little permeability and therefore tend to keep the wound moist. When eschar is present, a hydrocolloid may be more appropriate than a hydrogel dressing. This type of debridement occurs through autolysis. The hydrocolloid traps the wound exudate and creates a moist environment that softens and lifts or causes proteolytic digestion of the eschar. However, in most cases, sharp surgical debridement of eschar is the most efficacious treatment.

Wounds with a large volume of exudate require dressing with a greater capacity to absorb. When dressings do not adequately absorb, the healthy tissue around the wound may become macerated. The use of a skin protectant around the wound may alleviate this problem. There has been concern that hydrocolloids leave pectin base in wounds, which forms granulomas. There are, however, several non-pectin-based hydrocolloids that address this problem and also absorb wound secretions. There are no data to support the contention that one dressing promotes healing better than another. However, selection of dressings may be made on the basis of overall costs, efficacy, and ease of use. It is likely that over the next decade dressings will be designed to have “selective absorption” properties to remove only factors that impede the healing of chronic wounds or prevent scar hypertrophy in primarily closed wounds. Most of the “new” concepts in dressings are marketing gimmicks rather than improvements based on solid and objective scientific data.

MECHANICAL WOUND CLOSURE

The materials used for wound closure are much less important than the techniques of closure. Sutures may be generally classified as *absorbable* or *nonabsorbable*. The absorbable sutures may be synthetic, such as polyglycolic acid sutures, or biologic, such as “catgut” sutures, which may be plain or chromium-treated. Traditional teaching is that absorbable sutures are buried and, as they absorb, will not be a nidus for late infection. Nonabsorbable sutures are used on the skin because they are less reactive and allegedly provide a better-appearing scar. These dogma make little sense in the schema of healing. Although it is true that gut sutures are more reactive than polyglycolic acid, which is more reactive than nylon, the argument that tissue reactivity to particular sutures is of significance in the healing process has never been validated. Nonabsorbable sutures may be used in subcutaneous tissue as well as in fascia or for organ repair. By contrast, absorbable sutures often are used on the skin in infants and children; 6-0 plain gut sutures placed in the skin do not require removal in a child, thus avoiding the additional trauma of suture removal. Similarly, absorbable sutures are used commonly for closure of hand wounds—even in adults.

The notion that nonabsorbable sutures in fascia are better than long- lasting absorbable sutures is partially myth, because tension will gradually cause remodeling of the connective tissue around the suture. If fascia wound strength has not developed adequately in the repair process, the suture material will not have an influence on outcome.

The most important fact about sutures is that any woven suture is more likely to facilitate infection than a smooth suture because bacteria can become entrapped in the interstices of a woven suture and not be destroyed by the normal host responses, thus leading to bacterial propagation and infection. Therefore, woven suture material should not be used in the closure of contaminated wounds.

A few suture materials deserve special comment. The nonabsorbable polypropylene suture is extremely smooth and is therefore the best material to use when creating a subcuticular pullout suture. The absorbable polyglycolic dermal suture (PDS) is best for areas in which long-term tensile strength is required. Although stainless steel sutures are still used, they should be banned in the operating room because they often cut through gloves and create an environment where the surgical team may be more susceptible to pathogens such as hepatitis or HIV.

Staples

Although surgical staples have revolutionized the repair of organ parenchyma and the anastomosis of various hollow organs, they must be used with discretion on the skin. Well-designed staples, applied properly, are excellent for everting the skin margins appropriately. Staples must be removed within a few days if permanent skin marks are to be avoided.

Adhesive Tape Strips

In certain types of wounds, adhesive tape strips can be used. For example, once dermal sutures are in place, tape strips may be substituted for surface skin sutures as long as the wound edges are well approximated. Tape strips also can be helpful in supporting the wound margins after early removal of skin sutures. The tape strips are simple and clean, and they may be used to close many small lacerations painlessly without the need for local anesthetics.

FETAL WOUND HEALING

During the past decade, there has been a logarithmic increase in interest in fetal surgery and fetal wound healing. Basic research focused on animal fetal surgery has led to the repair of life-threatening conditions in human fetuses without maternal mortality, though the long-term fetal survival is still disappointing. Fetal surgery likely will become routine in future decades and can be expected to have better survival. It is imperative that the mechanisms of fetal tissue repair be understood if human fetal surgery is to be performed optimally. An even more important reason to study fetal healing is to discover the mechanisms that make it so dramatically different from adult healing. Understanding fetal healing should prompt major advances in our treatment of the adult healing problems of scarring, contraction, and wound disruption.

Fetal wound repair is characterized by a significantly reduced inflammatory response. Studies have shown that fetal platelets have different aggregative characteristics and reduced cytokine release compared to adult platelets. However, an inflammatory response can be induced by the addition of living or dead bacteria, removal of hyaluronic acid from the connective tissue matrix, or a variety of cytokines, including TGF-b and PDGF. Rather than collagen, the major component of the wound matrix is the glycosaminoglycan hyaluronic acid.

Primarily closed skin wounds in a third-trimester rabbit cannot be detected on routine histologic examination or by electron microscopy. There are no architectural abnormalities in the matrix that is formed in the wound site. Collagen synthesis measured daily after wounding is significantly greater in fetal wounds than in normal fetal skin. In addition, there is an astonishing gain in the tensile strength of the closed fetal skin wound by 5 days, in marked contrast to wounds in the adult, which gain little strength in this time period. These data indicate that there must be a very rapid turnover, remodeling, and reorganization of collagen during fetal repair.

Third-trimester open fetal rabbit wounds do not contract, in contrast to second-trimester fetal sheep wounds, which do contract. There is no evidence of myofibroblasts in the noncontracting fetal rabbit wounds. However, if TGF-b is placed in the open fetal wound, the wound does not expand as does the untreated open wound. If the open wound is sealed from the amniotic fluid environment by a silicone patch, it closes by epithelial cell migration. There is reasonable evidence that amniotic fluid may inhibit fetal wound contraction, but the mechanisms and component(s) remain unclear. The content of the matrix of the open fetal wound is mainly hyaluronic acid, and this may be an important factor in the contractile process in both adult and fetus wounds. There is promise that the many clinical pathologic wound healing responses seen the adult will some day be treated with new strategies based on the optimal responses observed in the fetus.

Acknowledgments

The authors wish to thank Cary Klett, M.D., for her helpful contribution to the section on genetic defects in connective tissue metabolism, to Benedict C. Nyomeh, M.D., for compiling information in Table 8-1, “Cytokines that Affect Wound Healing,” and to Stephen J. Leibovic, M.D., for his helpful comments on the section on tendon repair. Portions of the information presented in this chapter were the result of studies funded by National Institutes of Health grants GM-20298 and GM-47566.

CHAPTER 9 - Oncology

John M. Daly
Monica Bertagnolli
Jerome J. DeCosse
Donald L. Morton

INTRODUCTION

Approximately 90 percent of patients with malignancy undergo surgical therapy for diagnosis, primary treatment, or management of complications. Resection is the initial curative treatment for about 75 percent of patients, because cancer is assumed to be a localized disease for an interval, allowing cure after adequate surgical removal. Long-term survival statistics of patients with cancer treated surgically support this assumption. The lack of further improvement of survival rates with larger or more radical operations suggests that other forms of treatment should be implemented to maximize cure rates. Inclusion of radiation therapy or chemotherapy, or both, may improve the overall survival rate while permitting less extensive operative resection and enhancing cosmesis and function.

The surgeon is responsible for the initial diagnosis and management of many types of cancer. Knowledge of tumor staging and the natural history of neoplastic disease is essential to a multimodal approach for treatment of the patient in collaboration with the medical oncologist and radiotherapist. The surgeon's guiding principles should be the accurate diagnosis and staging with adequate operative removal of localized disease (Table 9-1) and palliation of symptoms when possible.

If the cancer has spread beyond local cure, the goal is to control the patient's symptoms and to maintain maximum activity as long as possible. The success of palliative therapy is measured in terms of useful life. The most common criterion of incurability is distant metastasis. However, patients with solitary pulmonary metastases may be curable by resection, and those with widespread metastases from choriocarcinoma may be curable with chemotherapy. Local extension also may be a criterion of incurability. If extensive studies fail to demonstrate metastatic disease or incurable local extension, the patient's treatment should be directed toward a cure.

Management of the cancer patient is a multidisciplinary effort requiring collaboration among surgical oncologists, radiation oncologists, medical oncologists, reconstructive surgeons, and other oncologist specialists. Evidence suggests that combinations of surgery, radiation therapy, chemotherapy, hormone therapy, and immunotherapy significantly improve cure rates above those achieved with any single therapeutic modality. Multimodal therapy, for example, is standard for most breast and colon cancer patients (Fig. 9-1). As the primary coordinator in cancer management, the surgeon must fully understand the indications, risks, and benefits of surgery, adjuvant chemotherapy, hormonal therapy, radiation therapy, and the importance of reconstructive surgery.

The optimal combination and sequence of treatments is determined by the patient's physical, emotional, psychological, and rehabilitative needs. The patient's general condition and the presence of any coexisting disease must be considered. Surgery may be contraindicated in a patient who has recently experienced a myocardial infarction. A patient with preexisting diabetes will be more susceptible to the toxic effects of hormonal therapy with corticosteroids. Renal disease can increase the toxicity of some of the chemotherapeutic agents, such as methotrexate. Any evidence of infection or bleeding may require vigorous treatment before definitive therapy is initiated. The patient's psychologic makeup and family, friend, and job support structure must be considered. A patient who is unable to accept the realities of a given treatment should be offered an alternative approach if possible. This is particularly true of surgical procedures that significantly alter appearance or involve change of organ function requiring the patient's daily care, such as colostomy. Experimental forms of therapy, such as intraarterial infusion of drugs, should also be avoided in some patients; a patient who is unwilling to tolerate the inconvenience of an intraarterial catheter might remove it without medical approval.

Determining a treatment plan requires the integration of information from four areas: (1) natural history of the disease by histologic type, (2) clinical staging, (3) goals of specific treatments, and (4) indications and risks for each treatment (or combination of treatments) based on results of experience and clinical trials.

EPIDEMIOLOGY

Cancer is overtaking heart disease as the most frequent cause of death in the United States, accounting for 24 percent (approximately 520,000) of deaths each year. The five leading causes of cancer death among males in the United States are: lung, 32 percent; prostate, 14 percent; colon and rectum, 9 percent; leukemia and lymphoma, 9 percent; and pancreas, 5 percent (Fig. 9-2). Among females the leading causes of cancer deaths are: lung, 25 percent; breast, 17 percent; colon and rectum, 10 percent; leukemia and lymphoma, 8 percent; and ovary, 6 percent (Fig. 9-3). Prostate cancer is the most frequent life-threatening cancer in men, and breast cancer the most frequent in women. The impact of cancer is no less on a worldwide basis; hepatocellular cancer is the cause of approximately 1 million deaths a year.

Although neoplasia is a disease of the genome with many common molecular pathways, human cancer may be envisioned as more than 100 distinct entities, each defined by the cell or tissue of origin and the appearance under the microscope. For some, the initial inductive event is inherited, but, as demonstrated by Knudson, general belief is that more than one genetic or epigenetic event is necessary for promotion of human carcinogenesis. Each site has a host-tumor interface and a subclinical growth phase, which might be measured in decades before emerging at a clinical threshold. At a threshold level, almost all common sites of life- threatening cancer have a definable benign precursor (Table 9-2) that shares the epidemiology of the life-threatening tumor and that may be reversible.

Screening policies for the prevention and early detection of cancer emerge from understanding the natural history of cancer at specific sites. The hallmark of an effective screening policy is demonstration of a reduced mortality rate. This goal has been achieved by the Pap smear for cervical cancer, mammography for breast cancer, and the fecal occult blood test and sigmoidoscopy for colorectal cancer.

To a large extent our present knowledge about the etiology and control of cancer has emerged from epidemiology. Observational ecological studies, international correlations among populations and migrants, and cross- sectional surveys, reinforced by case-control and cohort studies, have been the basis for conclusions about etiology. Nevertheless, when all known causes are accounted for, the odds of a person's acquiring cancer still depend substantially on chance.

The primary determinants of risk have been incidence rates and mortality rates, the former defined by the number of new events or cases that develop in a population of individuals at risk during a specific interval. These rates should be distinguished from prevalence (the number of affected persons within a population). Rates can be crude, category-specific (e.g., age, gender, or race), or adjusted (e.g., accounting for mortality from other causes). Herein resides the value of population-based registries and of high-risk registries in which persons at risk can be concentrated for study and treatment.

Long-term changes in cancer incidence and mortality in the United States (see Figs. 9-2 and 9-3) defy a satisfactory explanation, but an aging population and some interventions are partial explanations. In the United States, a notable decrease in the incidence and mortality of gastric cancer has occurred over the past half century, presumably as a result of general public health measures and, possibly, refrigeration, but without a specific understanding or intervention. For many decades breast cancer incidence has been increasing while mortality has remained stable, but now there is a decline in mortality, a result of widespread acceptance of mammography and detection of breast cancer in an earlier, curable stage. In recent years the mortality rate of lung cancer has stabilized in men, an effect attributable to reduction in cigarette smoking.

From global studies by Doll and Peto, vastly different incidence rates of site-specific cancer have been found (Table 9-3). Cancer of the stomach remains a leading cause of death in Asia and eastern Europe. When natives of Japan, where gastric cancer is frequent and colorectal cancer uncommon, emigrated to Hawaii, over one generation the frequency of these cancers was reversed, a change attributed to adoption of the Western diet. Given that diet and nutrition may be characterized as an environmental factor, these differences incriminate environment-induced molecular events in human carcinogenesis. The more frequent occurrence of cancer in older persons may reflect accumulation of environmentally based genetic events as well as molecular events associated with senescence. Acquired genetic or epigenetic events originating in physical, chemical, and viral etiologies are described in more detail below; initial insights were derived from observational studies.

The increased incidence of colorectal cancer in the United States can be attributed to the high fat and meat content of the Western diet. Metabolic epidemiology encompasses other effects of the internal environment on carcinogenesis as well. For example, breast cancer in women can be related to the lifetime duration of unprotected exposure to biologically active estrogens. Early menarche, late menopause, and delayed or absent child- bearing increase risk, whereas oophorectomy and estrogen antagonists reduce risk.

Recognition of internal and external environmental interactions in human carcinogenesis provides the means for risk reduction and the development of prevention strategies. Elimination of exposure to asbestos or radiation, avoidance of occupational carcinogens, and reduction of cigarette smoking remove certain carcinogens from the environment and reduce risk. Sunscreens block the carcinogenic wavelength of ultraviolet light. Vaccination for hepatitis B virus reduces the risk of hepatocellular cancer.

Other measures to control environmental carcinogens may be directed to the internal environment by nutritional modification and chemoprevention. A low-fat, high-fiber diet reduces risk of colorectal cancer and, possibly, breast and prostate cancer. Oral vitamin A analogues reduce leukoplakia and second cancers in the aerodigestive epithelium. Oral nonsteroidal anti- inflammatory drugs decrease rectal adenomas in patients with familial adenomatous polyposis. Antiestrogens reduce second cancers in the breast.

BIOLOGY OF MALIGNANT TRANSFORMATION

History

Cancer has been recognized as a disease for thousands of years. The first known mention of cancer is in the Ebers Papyrus, a medical treatise written in Egypt about 1600 b.c. The manuscript recommends surgical excision or cauterization for tumors. The scientific advances of the Greeks and Romans led to the understanding that cancer results from physiological processes. Galen (a.d. 129– ca. 199) defined cancer as “tumors against nature” and ascribed the cause of cancer to “humoral” imbalances. Paracelsus (a.d. 1493–1551) argued that cancers were caused by external agents—which is supported by current literature linking cancer development to environmental carcinogens. It was not until the 1850s that Rudolf Virchow, the father of cellular pathology, recognized cancer as an alteration of the native tissues. In the 1870s Julius Cohnheim argued that cancer was a failure of embryonic cells present in all tissues to mature properly, the first mention of carcinogenesis as “dedifferentiation.” Theodor Boveri, a professor of zoology at the University of Würzburg in Germany, reported in 1902 that his studies of mitosis in sea urchins led him to believe that cancer was due to abnormal chromosomes. Boveri's theory competed with the infectious disease theory of carcinogenesis, but the identification of the chicken leukemia virus by Ellerman and Bang in 1908 and Rous's identification of the chicken sarcoma virus in 1911 brought the infectious disease theory back to the forefront. Knudsen, in his 1971 description of familial retinoblastoma, suggested that a combination of inherited and acquired events govern cancer development. More recently Vogelstein and de la Chapelle, on the basis of their identification of an association between cancer and inherited defects in DNA repair, postulated that epithelial cancers result from a failure of the cell to maintain DNA fidelity during replication.

The common denominator in all theories of carcinogenesis is alteration of the cell's genome, either by direct damage from radiation or chemicals, by integration of viral genomic

sequences, or by an inherited defect in DNA repair capacity. The study of cancer etiology is focused on the molecular events required for malignant transformation, particularly the interplay between genetic and environmental influences in carcinogenesis.

Cellular Homeostasis

It is instructive to study normal regulatory processes to understand the derangements that occur with carcinogenesis. To achieve homeostasis in tissues, renewable cell populations must perform four related functions; they must (1) proliferate with proper timing and fidelity of DNA content, (2) differentiate in a pattern consistent with normal function of the tissue, (3) involute in a manner such that the proliferation and involution rates are balanced, and (4) repair any damages to their DNA resulting from exposure to mutagens such as radiation, toxins, and transforming viruses (Fig. 9-4). A defect in any of these functions can result in tumor formation.

Carcinogenesis

The term cancer refers to a group of diseases characterized by the autonomous growth of abnormal, “neoplastic” cells. Cancer results from a deregulation of critical aspects of cellular function, such as proliferation, differentiation, and apoptosis. Without the proper constraints on these processes, neoplastic cells reproduce in great numbers, invade adjacent structures, and develop metastatic colonies. The natural history of most cancers suggests that the development of these abnormal characteristics occurs in a progressive fashion. In describing this process, tumor *initiation* is defined as the exposure of cells to agents that induce an inheritable genetic change, i.e., agents that are genotoxic or induce critical mutations by binding of electrophilic carcinogenic metabolites to DNA. Tumor *promotion* is the exposure of initiated cells to agents that induce their proliferation. This proliferation may allow other spontaneous mutations to occur that culminate in expression of malignant phenotype (malignant transformation). Tumor *progression* describes successive development of increased local growth, invasion, and metastasis by transformed cells.

Cancer Phenotype

Progression of a tissue to malignancy disturbs host homeostatic mechanisms, as characterized by (1) unresponsiveness to normal growth regulators, (2) invasive phenotype, and (3) evasion of immune-mediated tumor destruction. Tumors are thought to be clonal in origin (i.e., all of the cells within a tumor arise from a single progenitor cell whose growth regulation has become deranged). Support for this clonal theory comes from the observation that tumors arising in women who are heterozygous for a gene encoding the enzyme glucose-6-phosphate dehydrogenase (G6PD) express only one of the two isoenzymes. In addition, all of the neoplastic cells in patients with chronic myelogenous leukemia whose tumor bears the Philadelphia chromosome (Ph1) contain Ph1. Some data from animal models, such as chemically induced murine fibrosarcoma, suggest that solid tumors may be multicellular in origin. Clonal dominance, however, has been demonstrated for both murine and human tumors. Despite their possible clonal origin, cancers, particularly the solid tumors, are heterogeneous in character. A cancer mass includes tumor cells and their supporting blood vessels and stroma. Within the tumor, abnormal regulation of cellular function leads to nuclear and cellular polymorphism, loss of cellular polarity, and variation in DNA content from cell to cell (aneuploidy). These processes are accelerated as cells lose control over DNA repair. As regions of tumor outstrip their blood supply, areas of inflammation and necrosis further contribute to tumor heterogeneity. As a result of loss of the fidelity of DNA replication, changes in the malignant cell population occur throughout the course of tumor progression. This is best demonstrated by a change in differentiation state or tumor antigen expression between primary tumors and their metastatic foci.

In an idealized model, the growth of a tumor proceeds exponentially in the early phases when the supporting tissues and nutrients are optimal, with a shortening of the doubling time as the tumor enlarges. This relationship between time and tumor size is referred to as *Gompertzian growth*, named for the eighteenth-century mathematician Benjamin Gompertz, who developed the model that describes it. The natural history of many human tumors is described by this model (Figs. 9-5 and 9-6).

Progression of a tissue to malignancy involves several stages. The earliest visible evidence of neoplastic transformation is dysplasia, a condition in which epithelial tissues exhibit altered size, shape, and organization. Dysplasia is a common reaction of tissue to chronic inflammation or exposure to environmental toxins or irritants. The degree of deviation from normal cellular and tissue architecture defines dysplasia as mild, moderate, or severe. In epithelial tumors, dysplastic cells are confined to the region above the basement membrane. Because dysplastic cells retain a measure of control over cellular proliferation, dysplasia is generally reversible once the inciting factor is removed. In most tissues, however, severe dysplasia is associated with progression to carcinoma if left without intervention.

The hallmark of a solid tumor carcinoma is the ability to invade the basement membrane and spread without regard to normal tissue boundaries. *Local* disease is the term used to refer to invasive tumor that is confined to the tissue of origin. Once the basement membrane has been breached, the next barrier to tumor dissemination is the network of draining lymph nodes. Tumor spread to the lymph nodes draining the tissue of origin is termed *regional* disease. The final stage of tumor progression is metastasis, whereby independent colonies of tumor are established in distant sites favorable to tumor growth. This type of tumor is commonly referred to as *distant* disease.

Carcinogens

In 1775 Sir Percival Potts, a surgeon at St. Bartholomew's Hospital in London, described the “soot wart,” a squamous cell carcinoma of the scrotum in chimney sweeps. This was the first recognition that cancer is a disease related to long-term exposure to associated environmental factors. Molecular studies link some known carcinogens to specific cancer-associated mutations, e.g., benzo[a]pyrene, a component of cigarette smoke, is a potent mutagen that preferentially induces damage of the p53 tumor suppressor gene at nucleotides that are common mutation sites in human lung cancer. Environmental factors implicated in carcinogenesis include radiation, chemical agents, and viruses. The common denominator among these factors is the ability to induce heritable change in cellular DNA.

Physical Carcinogens

Tumor induction by physical agents occurs by essentially two mechanisms: (1) induction of cell proliferation over an extended period of time, which increases the opportunity for events leading to transformation; and (2) exposure to physical agents that induce damage or changes in cellular DNA. Foreign bodies, particularly irritants, can induce tumors in animal models; however, it is difficult in humans to attribute the induction of a tumor solely to the presence of a foreign body. Foreign bodies may act as cocarcinogens or promoters, or may produce a chronic irritation that exposes tissue to carcinogenesis by other environmental agents. The higher risk of skin cancer in patients with burns or esophageal cancer after chemically induced irritations, such as that following lye ingestion, provides an example of the close link between tumorigenesis and the induction of cell proliferation. Cellular proliferation associated with chronic inflammatory conditions may contribute to the carcinogenicity of other agents or may increase the probability of genetic changes resulting in neoplastic transformation. An example is the increased colorectal cancer risk in inflammatory bowel disease.

The best known agent of physical carcinogenesis is radiation. There are two types of radiation: ionizing and non-ionizing. Ionizing radiation includes x-rays and gamma rays, and alpha and beta particles, while the most common form of non-ionizing radiation is ultraviolet (UV) radiation. Both types of radiation are associated with human cancers, but the two groups induce different types of tumor.

Ionizing Radiation

When administered in high doses, all forms of ionizing radiation induce tumors. The carcinogenic potential of x-rays was reported by Friebe in 1902, soon after they were discovered, when many radiologists had developed skin cancers. From 1913 to 1924 a radium-based paint was used to illuminate watch dials, and more than a thousand workers in a New Jersey plant were exposed to this alpha-particle emitter. By 1931 unusually high rates of aplastic anemia and osteosarcoma among radium workers were noted, alerting scientists to the carcinogenic potential of alpha particle exposure. Survivors of the nuclear bombs dropped on Japan in 1945 have an increased incidence of chronic myeloid leukemia and carcinomas of the lung, thyroid, and breast, with a 10- to 20-year latency before development of disease.

The results of radiation exposure are dose and time related. The carcinogenic effect of ionizing radiation is through induction of breaks in DNA strands. Cells most susceptible to this damage are those with a high mitotic activity, such as hematopoietic and epithelial tissues. A population with increased sensitivity to ionizing radiation and other DNA-damaging agents has been identified among individuals heterozygous for a gene mutation responsible for the recessive disorder ataxia telangiectasia (AT). Approximately 2 percent of the population are heterozygous carriers of a defective AT gene allele and demonstrate a four-fold increase in cancer incidence, including tumors of the stomach, breast, skin, ovary, brain, and hematopoietic cells. It is postulated that these individuals lack the ability to repair DNA, although the specific defect associated with AT gene mutation is unknown.

An understanding of the damage caused by ionizing radiation, the tissue penetration of different agents, and the advent of modern dosimetry have reduced the cancer risk associated with therapeutic radiation. Radiation therapy for conditions such as Hodgkin's lymphoma and breast cancer still carries a risk of treatment-related, second malignancies such as leukemia or soft tissue sarcoma.

Non-ionizing Radiation

The association between skin cancer and ultraviolet light was first observed in murine experiments by Hyde in 1906. UV light may be responsible for the induction or promotion of a number of human skin tumors, including basal cell carcinoma, squamous carcinoma, and malignant melanoma. UV radiation is absorbed by DNA and induces DNA damage, particularly the formation of thymidine dimers. DNA repair enzymes that are functioning normally are able to repair these defects. Individuals with xeroderma pigmentosa have a defective endonuclease and are unable to incise the strands damaged by UV exposure. Because UV-induced errors go unrepaired in these individuals, they develop multiple skin cancers. Melanin has a protective effect in absorbing UV radiation, and therefore fair-skinned individuals are at greatest cancer risk.

Cancer-associated DNA damage may also result from physical factors such as the foreign-body reactions induced by asbestos or through reactive oxygen species liberated at sites of chronic inflammation. Exposure to radiation may induce immunosuppression, contributing to carcinogenesis by a lack of immune surveillance. Clinical and experimental models suggest that physical irritants, such as asbestos, may act as cocarcinogens; thus, for example, a combination of asbestos exposure and cigarette use may be synergistic in producing mesotheliomas, lung cancer, and associated epithelial tumors. Observations such as these suggest that in the multistage process of carcinogenesis, physical agents may fulfill one or more of the critical steps necessary to induce a tumor.

Chemical Carcinogens

The first report of a chemical agent inducing cancer was Hill's description in 1761 of nasal carcinoma associated with the use of snuff. The correlation between cigarette smoking and lung cancer was demonstrated by Doll and Hill in 1950, and tobacco products remain the source of most chemically induced human cancers. Epidemiologic studies reveal that a substantial number of compounds are associated with chemical carcinogenesis. Like tobacco smoke, most presumed carcinogenic substances are a complex mixture of chemicals, rather than a single, pure agent. In addition, a number of known chemical carcinogens require metabolism from a procarcinogen into carcinogenic reactive electrophilic intermediates that alter cellular DNA. DNA damage by carcinogen metabolism depends on the balance between the rate of oxidation to carcinogenic intermediates and the rate of detoxification of these oxidative products via conjugation with glutathione and glucuronic acid.

There are several main classes of chemical carcinogens, including organic and inorganic substances. Polycyclic hydrocarbons are organic carcinogens that undergo metabolism in the host to an active form. The most extensively studied polycyclic hydrocarbon is benzo[a]pyrene, a component of cigarette smoke, fossil fuel combustion products, and smoked foods. The metabolic products of benzo[a]pyrene and related compounds are electrophilic epoxides that bind to intracellular proteins, such as DNA. Benzo[a]pyrene is converted to

its toxic metabolites through the action of the hepatic enzymes cyclooxygenase and cytochrome P-450 (Fig. 9-7). Aromatic amines, such as b-naphthylamine, benzidine, aminofluorenes, and dimethylaminoazobenzene (DAB), also undergo metabolic conversion to active forms and are associated with tumors of the urinary tract and liver. Inorganic carcinogens include heavy metal products of fossil fuel combustion such as nickel, cadmium, chromium, arsenic, and lead. Metal carcinogens are mutagenic, inducing DNA adducts and DNA cross-linking. Chronic occupational exposure to these carcinogens is associated with a number of tumors, e.g., nasopharyngeal carcinomas subsequent to chronic exposure to nickel-smelting products.

Viral Carcinogens

Viruses are packages of genetic information, in the form of either DNA or RNA, protected by a structural protein coat. Viruses may insert their genetic material into host cells and induce changes morphologically consistent with neoplastic transformation (Fig. 9-8). Much of our present understanding of carcinogenesis is derived from the study of the effects of viral modification of cellular function. RNA retroviruses isolated from chicken sarcomas demonstrated that sarcomas could be transmitted between chickens by a cell-free infiltrate. It is now recognized that both RNA and DNA viruses are capable of inducing tumors in humans, although only a small proportion of individuals infected with a cancer-associated virus develop tumors. Virus-associated cancers arise after an incubation period of years to decades, suggesting that other genetic or environmental factors contribute to virally induced carcinogenesis.

Observation of the effect of oncogenic viruses on cellular homeostasis suggests that the different oncogenic viruses use similar strategies to deregulate cell growth. Many of the oncogenic viruses encode proteins that interact with the same intracellular targets, particularly Rb and p53 proteins. The contribution of oncogenic viruses to carcinogenesis may lie in the inactivation of these proteins that are essential for regulation of the cell cycle. The most common tumor viruses are listed in Table 9-4.

DNA Tumor Viruses

Most of the human virus-associated tumors are the result of infection with DNA tumor viruses. Because of the worldwide prevalence of hepatitis B- associated hepatocellular carcinoma, DNA tumor viruses may be the most common inciting factor for malignancy.

Epstein-Barr Virus (EBV)

The prevalence of EBV infection worldwide is extremely high, with seropositivity for EBV antibodies approximately 90 percent. EBV infects epithelial cells and some B cells and produces a spectrum of disease from active, highly symptomatic forms such as acute infectious mononucleosis, to a chronic, indolent manifestation. Cancers develop in a small subset of patients infected with EBV, and the epidemiology of these cancers suggests that cofactors in the environment or genetic makeup of affected individuals are important for EBV-induced carcinogenesis. For example, Burkitt's lymphoma is almost entirely restricted to equatorial Africa, where malaria may be a cofactor. In the United States, extranodal EBV-associated B cell lymphomas occur in the setting of immunosuppression after transplantation or in individuals with acquired immunodeficiency syndrome (AIDS).

Hepatitis B Virus (HBV)

Infection with hepatitis B virus is common worldwide. One of the many manifestations of hepatitis B is a chronic hepatic infection which ranges in severity from a mild, essentially asymptomatic form, to severe, chronic, active disease resulting in cirrhosis. Cohort and case control studies in Southeast Asia and Africa suggest that HBV infection is associated with the development of hepatocellular carcinoma. The HBV transforming agent may be the HBV X gene, a segment of the HBV genome that is consistently found in HBV-associated hepatocellular cancers.

Human Papillomavirus (HPV)

The indication that squamous cell carcinoma of the cervix was associated with an infectious agent first came from epidemiologic data showing an increased incidence of this cancer in women with multiple sexual partners. Over 90 percent of cervical carcinomas contain HPV DNA, predominantly subtypes 16 and 18, which is integrated into the cellular DNA. HPV virus infects epithelial cells and induces their proliferation. In the setting of epidermodysplasia verruciformis, an autosomal recessive condition associated with impaired cellular immunity, HPV infection results in squamous cell carcinoma. The significant incidence of squamous cell carcinoma of the anus observed in homosexual males is also ascribed to the combination of HIV-induced immunosuppression and HPV infection.

RNA Tumor Viruses

In 1936 Bittner reported that an agent transmissible through milk was responsible for increasing the incidence of breast cancer in mice, resulting in the identification of the mouse mammary tumor virus. Since then, many other RNA viruses have been associated with tumors in animals. RNA tumor viruses are retroviruses, a class of viruses defined by the presence of an enzyme called reverse transcriptase. Using reverse transcriptase, the retrovirus produces a DNA copy of the viral RNA genome that can be integrated into the host cell DNA, leading to transformation. In human beings, the T cell leukemia viruses HTLV-I and HTLV-II are cancer- associated RNA viruses. Like HIV, these viruses specifically target CD4+ T lymphocytes, contribute to immunosuppression, and induce tumors of hematogenous origin.

Immunodeficiency and Cancer

The theory of immunological surveillance against cancer is that immune effector cells can eliminate cells that undergo malignant transformation. According to this theory, the development of a tumor is a failure of immune surveillance in maintaining tissue homeostasis. Despite advances in the understanding of carcinogenesis, the nature of immune surveillance and the role of the immune response cells in the progression of malignancy is unclear.

States of immunosuppression are associated with an increased risk of cancer. Patients receiving long-term immunosuppressive medication for prevention of allograft rejection have an increased incidence of skin cancers and lymphoid malignancies. The carcinogenic effect of ionizing and non- ionizing radiation may be due in part to radiation-related immunosuppression. Gamma rays and x-rays directly and indirectly affect the viability and function of lymphocytes. UV light induces immunosuppression indirectly, possibly through release of biologically active substances from cells in the skin. The coincidence of virally induced tumor formation and states of immunosuppression provides strong evidence that a normally functioning immune system acts to suppress carcinogenesis. For example, AIDS is associated with Kaposi's sarcoma, non-Hodgkin's lymphomas, and squamous cell carcinomas. AIDS- associated Kaposi's sarcoma and non-Hodgkin's lymphomas commonly carry fragments of the Kaposi's sarcoma-associated herpes-like virus (KSHV) genome, while AIDS-related squamous cell cancers are HPV- induced.

In experiments with carcinogen-induced murine tumors, loss of T lymphocytes does not significantly affect carcinogenesis but does diminish host response to transplantable tumors. Analysis of the immune cell participants in the surveillance against neoplastic progression reveals that in the normal host, several lymphoid cell compartments, including T, B, and NK lymphocytes, as well as macrophages, participate in the prevention and destruction of aberrant cells.

Genetic Alterations

The Multistep Hypothesis Cancer is fundamentally an alteration in the genes that control cellular function. It is clear that the development of a malignant phenotype is multifactorial. Some abnormal genes (termed cancer susceptibility genes) can be inherited at conception as germline defects. The known cancer susceptibility genes affect the cell's ability to detect and repair genetic damage, alter immune surveillance for tumors, modify cellular metabolism of carcinogens, or regulate the growth of specific cell types. Other genetic changes, known as somatic mutations, are acquired through interaction with agents that alter the cellular genome, such as radiation, mutagenic chemicals, or viruses. Although the exact combination of genetic changes required for carcinogenesis is not fully understood, evidence suggests that carcinogenesis requires the successive accumulation of genetic defects that result in the altered cellular growth and differentiation characteristic of a malignant phenotype. The genetic changes implicated in this "multistep hypothesis" of cancer development are best understood for colorectal cancer (Fig. 9-9). In 1988 Vogelstein and associates published a report describing specific mutations in colorectal cancer and defined their relationship to the adenoma-carcinoma sequence. This report led to wide acceptance of the multi-step hypothesis as the basis for malignant transformation and gave a genetic perspective to the processes of tumor initiation, promotion, and progression. Data suggest that not only are specific mutations essential for carcinogenesis, but also the order in which these defects are acquired is important. Although the sequence of events is not completely understood, the multistep hypothesis gives us a useful framework for defining the genetic nature of carcinogenesis.

Oncogenes

Oncogenes are genes that promote the transformation of normal cells into tumor cells, generally by activating growth-enhancing intracellular signaling pathways. Oncogenes can be found within mammalian cellular DNA (cellular oncogenes) and in viruses (viral oncogenes). Oncogenes are designated by three-letter names, which are usually derived from the tumors or the cell line in which the oncogene was first identified. For example, the first identified RNA virus, the Rous sarcoma virus, contains the *src* oncogene. Oncogenes derived from viral genomes are labeled with the prefix "v" (e.g., v- *src*); cellular oncogenes are labeled with "c" (e.g. c- *src*). Proto-oncogenes are normal components of the genome that function as oncogenes when altered or inappropriately expressed through processes such as chromosome rearrangement or viral transformation. Oncogenes encode proteins, sometimes termed oncoproteins, that alter cell cycle regulation, resulting in tumor formation.

The discovery of RNA retroviruses in the early twentieth century provided the foundation for our understanding of oncogenes and their precursors, proto-oncogenes. After infection, retroviral RNA is transcribed into double- stranded DNA by the viral enzyme reverse transcriptase. The retroviral DNA then is integrated into the chromosomal DNA of the host, forming a DNA provirus. The viral DNA is transcribed and translated by host cell machinery into viral RNA and viral proteins, which are assembled within the host cell. The new virus particles are released from the host cell by budding from the plasma membrane. Oncogenic viruses contain genetic segments that lead, on integration into the host genome, to neoplastic transformation of the host cell. Retroviruses also can induce tumors by activating host cellular proto-oncogenes. For example, the *src* gene encodes a membrane-associated enzyme responsible for phosphorylation of cellular proteins, and viral transformation through alteration of this gene results in abnormal intracellular signaling that contributes to tumor development.

Early genetic studies showed that tumors contain many chromosomal abnormalities, including gain or loss of chromosomes (aneuploidy), or alterations in individual chromosomes, such as translocations or amplifications. The role of the Philadelphia chromosome in human chronic myelogenous leukemia is an example of oncogene activation through chromosomal rearrangement. In the Philadelphia chromosome, a segment of chromosome 9, carrying the cellular oncogene c- *abl*, is attached to chromosome 22, within a gene known as *bcr*. The expression of the resulting *bcr-abl* fusion protein is important in the development of leukemia, an observation confirmed in animal studies showing that introduction of endogenous *bcr-abl* sequences causes leukemia (Fig. 9-10).

Oncogenes are divided into categories depending upon the role their proteins play in cellular function. These include growth factors, growth factor receptors, cytoplasmic protein kinases, *guanosine triphosphate (GTP)* -binding proteins, nuclear transcription factors, and cell cycle regulators (Table 9-5).

Tumor Suppressor Genes and the Inherited Cancer Predisposition Syndromes

The normal effect of tumor suppressor genes is to keep cellular growth in check. The loss of function of these genes leads to tumor formation (Table 9-6). The classic example of a tumor suppressor gene is the retinoblastoma gene (RB1). Each normal cell has two copies of the RB1 gene, and loss of RB1 gene function requires mutation of both copies. In

familial retinoblastoma, affected individuals inherit one defunctionalizing germline mutation in RB1 (Fig. 9-11). Expression of the RB1 mutation phenotype requires loss of the second allele by somatic mutation, a concept known as Knudson's "two-hit" hypothesis after Knudson's description of familial retinoblastoma in 1971. Most of the inherited cancer predisposition syndromes described to date involve inheritance of one mutant and one normal allele of a tumor suppressor gene. Analysis of tumors arising in individuals with germline mutations in tumor suppressor genes suggests that additional mutations, such as in the oncogenes *ras*, *c-myc*, etc., are required for expression of the cancer phenotype, an observation in keeping with the multi-step hypothesis of carcinogenesis. This theory is further supported by variability in phenotypic expression and in time to development of cancer among the members of these families. It is probable that modifier genes or environmental influences contribute to this variability.

Hereditary Retinoblastoma and the RB1 Gene

Retinoblastoma, a pediatric retinal tumor, occurs in both sporadic and familial forms. The sporadic retinoblastomas develop within the first 7 years of life and are generally unilateral. In contrast, familial retinoblastomas usually present within the first year of life and are characterized by multiple tumors involving both eyes. The penetrance of the RB1 mutation in these families is over 90 percent. The retinoblastoma gene product is a nuclear protein important for cell cycle regulation. The RB1 gene product (Rb protein) binds to, and sequesters, cyclin D as well as E2F, a transcription factor leading to the G₁-S cell cycle transition. Rb inhibits the ability of E2F to bind DNA and initiate transcription of the genes for DNA synthesis, such as *c-myb* and *c-myc*. A mutation in RB1 promotes unregulated cell growth through increased E2F activity.

Li-Fraumeni Syndrome and p53

In 1979, p53 was first identified as a cellular nuclear protein associated with the SV40 tumor virus. It was not until 1989 that p53 was recognized as a tumor suppressor gene and identified as a germline mutation associated with Li-Fraumeni syndrome, a familial clustering of breast cancer, soft tissue sarcomas, brain tumors, osteosarcoma, leukemia, and adrenocortical carcinoma. Affected individuals develop cancer by age 70 through somatic loss of the wild-type p53 allele.

Inactivation of the p53 gene is one of the most detectable genetic defects in tumors. The p53 protein plays a crucial role in preserving the integrity of the cell's genome by temporarily halting the cell cycle in response to damage, allowing adequate time for DNA repair prior to replication. In instances of severe damage, the p53 protein is capable of triggering programmed cell death, consequently eliminating damaged cells before replication can occur. By stimulating synthesis of nuclear proteins, such as Gadd45, p53 may indirectly facilitate DNA repair (Fig. 9-12). Given its importance in preventing replication of a damaged genome, p53 has been christened the "guardian of the genome"; intact p53 function is crucial for tumor prevention.

Familial Adenomatous Polyposis and the APC Gene

The *adenomatous polyposis coli (APC)* gene mutation was first localized in 1991 in patients with a rare autosomal dominant form of inherited colorectal cancer known as familial adenomatous polyposis (FAP). FAP is characterized by the development of multiple intestinal adenomas and nearly 100 percent progression to colorectal carcinoma within the life span of untreated individuals. FAP is a systemic disease with a phenotype that may include duodenal adenomas or carcinoma, desmoid tumors, mandibular osteomas, congenital hypertrophy of the pigmented retinal epithelium, and cutaneous epidermoid tumors. FAP results from a germline mutation in the *APC* gene, located on chromosome 5q21, leading to production of a truncated APC protein. Although the exact function of the APC protein is unknown, this intracellular molecule binds to, and induces, the degradation of b-catenin, a glycoprotein associated with both cell-cell adhesion and intracellular signaling. Mutations in the APC gene have been found in over 80 percent of sporadic colorectal cancers, suggesting that this mutation, like that of p53, is important in the pathogenesis of sporadic tumors.

Hereditary Malignant Melanoma

Studies of melanoma prone families (familial malignant melanoma) led to the localization of the responsible gene. This gene, identified on 9p21, encodes a protein known as p16, belonging to a family of proteins that inhibit the activity of *cyclin-dependent kinases (CDKs)*. Cyclin-dependent kinase inhibitors, like p16, modulate the mechanism that drives cells through mitosis and DNA replication. CDK inhibitor genes act as tumor suppressors, and defunctionalizing mutations in CDK inhibitor genes are associated with tumor development.

Genetic analysis of melanoma-prone Dutch kindreds revealed intermarriage between two families with germline p16 mutations. This provided the unique opportunity to study two individuals homozygous for p16 mutations at birth. One of these individuals survived to the age of fifty-five with no evidence of melanoma, and is thought to have died of an intraabdominal adenocarcinoma. The other individual developed three malignant melanomas by age fifteen. This unusual human experiment demonstrates that the penetration and expressivity of the p16 mutation is highly variable. The overall contribution of p16 mutations to melanoma incidence is low; studies of weakly familial and sporadic melanomas demonstrate a very low rate of p16 mutation.

Multiple Endocrine Neoplasia

The *multiple endocrine neoplasia (MEN)* syndromes are characterized by autosomal dominant inheritance of altered proliferation in specific endocrine glands. There are three distinct MEN syndromes: (1) MEN I, characterized by pituitary, parathyroid, and pancreatic endocrine tumors; (2) MEN IIA, characterized by pheochromocytoma, medullary thyroid cancer, and parathyroid tumors; and (3) MEN IIB, characterized by pheochromocytoma, medullary thyroid cancer, ocular and oral neuromas, gastrointestinal ganglioneuromatosis, and marfanoid body habitus. The gene for MEN I has been mapped to chromosome 11q13, although its specific location has not been identified. Pedigree and tumor tissue studies of MEN I suggest that this gene belongs to the tumor suppressor gene family. MEN IIA and IIB constitute genetically separate syndromes, which are governed by an oncogene rather than a tumor suppressor gene. MEN II families have dominant germline mutations in the *ret* proto-oncogene, which encodes a growth factor receptor.

Familial Breast and Ovarian Cancer

Cancer susceptibility genes associated with breast and ovarian cancer include BRCA-1 and BRCA-2, presumed tumor suppressor genes on chromosomes 17q21 and 13q12, respectively. In families with a high rate of breast cancer, i.e., at least four cases per family, approximately 50 percent of affected individuals have mutations in BRCA-1 and 30 percent in BRCA-2. In families with high rates of both breast and ovarian cancers, 75 percent are attributable to BRCA-1 and 23 percent to BRCA-2. BRCA-2 is most often associated with male breast cancer, and inherited mutations in BRCA-2 may be involved in 15 percent of all male breast cancer. Families with germline mutations in BRCA-2 also are at increased risk for prostatic malignancy.

In the high-risk families comprising the linkage studies of BRCA-1, inheritance of a BRCA-1 mutation was associated with a greater than 80 percent lifetime risk of breast cancer in the female family members. Studies of Ashkenazi Jewish families bearing a particular BRCA-1 mutation, 185delAG, demonstrate overall penetrance of this mutation at 38 percent by age forty, 69 percent by age fifty, and 85 percent by age sixty-five. The functions of the BRCA-1 and BRCA-2 gene products are unknown.

Epidemiologic studies suggest that mutations in the gene associated with ataxia telangiectasia (AT) are also associated with an increased risk of breast cancer. Approximately 2 percent of the population are heterozygous carriers of a defective AT gene allele, and the proportion of breast cancer attributable to AT gene carriers is approximately 4 percent.

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC) was first described by Aldred Warthin, a pathologist at the University of Michigan, in 1895. His seamstress died at an early age of cancer of the "female organs" and was a member of a family with a high incidence of colon, endometrial, and gastric cancer. In 1966 Henry Lynch described what he called the cancer family syndrome in a study of two large Midwestern families with a high incidence of colon cancer. In 1995 the International Collaborative Group on HNPCC proposed the Amsterdam criteria as a definition for HNPCC (Table 9-7).

The molecular basis for *HNPCC* was characterized by linkage studies of known colon cancer susceptibility genes, such as p53 and *APC*, in families that met the Amsterdam criteria. Although no linkage to these genes was found, researchers discovered a high rate of mutation in DNA microsatellites, which are short repetitive sequences of mono-, di-, or tri-nucleotides interspersed throughout the normal genome. They postulated that the HNPCC-associated mutations producing this "microsatellite instability" encoded factors required for DNA replication and repair. A 1993 study used microsatellite markers to map HNPCC to 2p15-16, and a subsequent study linked HNPCC to mutations on 3p. It is thought that over 70 percent of cases of HNPCC involve mutations in one of four identified mismatch repair genes. These genes encode proteins that recognize, excise, and repair mismatched nucleotides, preserving the integrity of the genome. A defect in mismatch repair theoretically sets the stage for accumulation of the multiple uncorrected mutations required for cancer development.

An inherited tendency to develop cancer is thought to be associated with 1 to 5 percent of all colorectal cancers, 5 to 10 percent of breast cancers, and 5 to 10 percent of ovarian cancers. Many of the inherited cancer predisposition syndromes involve germline mutations in genes that also contribute to the development of sporadic cancers, such as p53, *APC*, and MLH-1. Families with inherited cancer predisposition syndromes provide the most striking examples of tumor suppressor genes in action, but most tumors associated with tumor suppressor gene dysfunction are sporadic. These syndromes, however, present the opportunity to study carcinogenesis in models that are relevant to more common, nonfamilial malignancies.

Functional Alterations in Carcinogenesis

Tumor progression involves acquisition of several abilities by the malignant colony. These cells must be able to (1) invade the basement membrane and surrounding tissues through the production of proteases, (2) recruit blood vessels to support the growth of the tumor mass, (3) avoid destruction by effector cells of immune surveillance, such as NK cells, (4) move through tissues, a process that requires production and recruitment of cell adhesion molecules and chemotactic cytokines, and (5) travel to distant sites, adhere, and establish a new tumor colony. There are many parallels between fetal development and malignant transformation. During development, the behavior of individual cells is determined by regulated developmental programs that result in the formation of cohesive cell colonies. The process of tumorigenesis involves the disruption of these normal developmental programs. This principle is clearly illustrated in the development of a teratoma, where the resulting tumor attempts to recapitulate an intact organism.

Normal embryonic development and tissue homeostasis depend on specifically timed intracellular communication. Much of this communication results from the production and release of growth factors, such as *epidermal growth factor (EGF)*, as well as signals delivered by adhesion molecules through cell-cell contact. Tumorigenesis is characterized by the breakdown of these growth regulatory interactions, a process that involves both the activation and expression of proto-oncogenes, and the inactivation of suppressor genes. Although tumors have long been thought of as autonomous tissues, it is clear that a tumor could not exist without its surrounding stroma. Certain tumors require particular environments in which to grow, as evidenced by the characteristic metastatic locations of many solid tissue tumors. An obvious example of a tumor-host dependency is angiogenesis, but there are many other possibilities for tumor growth regulation by the microenvironment of a tumor. The result of carcinogenesis is the disruption of the normal homeostatic relationship between the transformed cell and its surrounding normal tissues.

Relationships Between Tumors and Normal Host Tissues Local Invasion

During the transition from in situ to invasive carcinoma, tumor cells must cross the basement membrane and enter the surrounding stromal tissue. The intact basement membrane, a dense matrix of collagen, glycoproteins, and proteoglycans, does not contain pores large enough for intact cells to penetrate, and hence tumor invasion must involve partial destruction of this barrier. On the other side of the basement membrane is the tissue stroma, a collection of fibroblasts, myofibroblasts, and other stromal cells. These cells actively

participate in tumor invasion. The process of local tumor invasion can be divided into three steps: tumor cell adhesion, matrix dissolution, and migration.

Tumor Cell Adhesion

The growth of normal tissues is characterized by cell-cell adhesion, a process linked to cellular proliferation and differentiation, such that a cell losing this contact undergoes involution. During carcinogenesis, the requirement for cell-cell adhesion is lost, and the single cell infiltrates local tissues in a relatively independent manner. Cell-cell adhesion and the growth regulation provided by this contact are mediated by cell adhesion molecules (CAMs), which are complex transmembrane glycoproteins present on the surface of both epithelial and stromal cells. These adhesion molecules also interact with the surface of the basement membrane, which contains receptor glycoproteins such as laminin, type IV collagen, and fibronectin.

CAMs are divided into four main classes according to their structure and general function. These include the cadherins, the integrins, the selectins, and the immunoglobulin superfamily receptors. In addition, other cell surface molecules, such as the *major histocompatibility (MHC)* molecules and CD44, contribute to tumor cell adhesion (Fig. [9-13](#)).

Cadherins

Cadherins are transmembrane glycoproteins that mediate calcium- dependent homophilic cell-cell adhesion. There are three major classes of cadherins: E-cadherins, mediating adhesion between epithelial cells, N- cadherins, controlling adhesion in nerve, cardiac, and pulmonary tissues, and P-cadherin, providing adhesion in intestinal, cardiac, and pulmonary tissues. The intracellular portion of the cadherin is associated with the actin cytoskeleton as well as with molecules involved in transmitting growth regulatory signals to the nucleus. Analysis of human epithelial tumors reveals a consistent loss of E-cadherin expression, and cell line transfection studies suggest that reintroduction of E-cadherin into tumor cells inhibits their invasive ability.

Integrins

Integrins are heterodimeric transmembrane glycoproteins that mediate adhesion between epithelial cells and extracellular matrix proteins. More than 20 different types of integrins have been identified, many of them with tissue specificity. Integrins commonly recognize extracellular matrix proteins by a tripeptide sequence of Arg-Gly-Asp present in fibronectin, vitronectin, and a variety of other adhesion proteins. The surface expression of integrins and their interaction with extracellular proteins can be modulated by cytokine factors such as *tumor-necrosis factor (TNF)*, interferon-gamma (IFN-g, or *transforming growth factor- b*1 (TGF-b1). The binding of integrins to their ligands results in transmission of signals for cellular proliferation and differentiation. The process of tumor invasion or metastasis may involve loss of appropriate integrin-mediated adhesion and signaling, resulting in cellular activation and establishment of tissue-specific metastatic colonies.

Selectins

Selectins are adhesion molecules present on endothelial cells and hematopoietic cells. These cell surface molecules govern the processes of leukocyte adhesion and homing. Three types of selectins have been described: (1) E-selectin, or endothelial-leukocyte adhesion molecule-1, (2) P-selectin, or granule membrane protein 140, and (3) L-selectin, or leukocyte-specific selectin. E-selectin and P-selectin are expressed on activated endothelial cells and mediate the binding of leukocytes to endothelial cells. L-selectin, found on the surface of leukocytes, controls the homing of leukocytes to lymphoid organs. E-selectin has demonstrated an ability to recognize Le ^x (SLX) antigen, a complex carbohydrate that is expressed at high levels in metastatic colorectal cancers. Altered expression of cell surface carbohydrates may be one of the mechanisms of tumor progression.

Immunoglobulin Superfamily

The Ig superfamily is characterized by an immunoglobulin-like extracellular domain, and fibronectin type III repeats. These molecules mediate homotypic and heterotypic cell-cell interactions. Neural cell adhesion molecule (N-CAM) is one example of the Ig superfamily. The protein product of the DCC gene, located on chromosome 18q, shows significant homology to N-CAM. This gene is mutated in metastatic colorectal cancers, suggesting that normally functioning DCC protein is important in preventing cell invasion and/or metastasis.

Several other cell surface molecules contribute to the cell-cell interactions governing normal tissue behavior. These include major histocompatibility (MHC) molecules, particularly MHC class I. MHC class I molecules complex with endogenously processed peptides, such as viral proteins, and target abnormal or infected cells for destruction by immune effector cells. One of the ways that abnormal tumor cells hide from immune surveillance is by altered expression of MHC molecules. Another cell surface molecule with a special role in tumorigenesis is CD44, a protein present in various isoforms created by alternative mRNA splicing. The CD44 splice variants are thought to facilitate lymphocyte recirculation and homing to lymphoid tissues. In addition, CD44 is present on the surface of epithelial cells, and particular isoforms are overexpressed on both primary and metastatic tumors.

Matrix Dissolution

After adhesion of tumor cells in experimental models of tumor infiltration, a localized zone of lysis is produced in the basement membrane near the point of tumor cell contact. This matrix lysis occurs from 2 to 8 hours after tumor cell attachment as a result of enzymes secreted directly by the tumor cell and by stromal fibroblasts. These enzymes belong to a family known as the metalloproteinases (MMPs). Examples of these enzymes include interstitial collagenases, type IV collagenases, and stromelysins. Natural protease inhibitors, known as tissue inhibitors of metalloproteinases (TIMPs), produced either by the host or by the tumor itself, can counteract this process. Once the basement membrane barrier is lysed, tumor cells are free to migrate into the surrounding stromal tissue (Fig. [9-14](#)).

Migration

In addition to adhesion and proteolysis, active tumor motility is required for the invasion and metastasis of tumors. In a dramatic in vivo study by Wood in 1958, microcinematography was used to observe directly the migration of rabbit carcinoma cells from the vasculature of the rabbit's ear. Like most cellular functions, tumor cell motility involves both fixed cell surface interactions and soluble factors. Morphologic studies show that, like leukocytes, tumor movement is characterized by ameba-like pseudopod extension. This movement requires coordination of multiple steps, including cellular protrusion and new adhesion formation at the leading edge and release of old adhesive interactions at the trailing edge. A variety of cytokines stimulate motile responses in tumor cells. These include tumor cell-derived cytokines, such as autocrine motility factor, autotaxin, and scatter factor (Table [9-8](#)). Many adhesion molecules, particularly those found in the extracellular matrix, such as laminin, collagen, fibronectin, and thrombospondin, serve as tumor cell attractants in motility assays.

Angiogenesis

Angiogenesis, or the formation of new blood vessels, is important for all phases of tumor progression (Fig. [9-15](#)). Without new vessel growth, tumors would quickly outstrip their local nutrient supply and would be unable to form new colonies after distant metastasis. Like all aspects of tumor growth, the process of angiogenesis involves complex signals delivered between the tumor cell and the host environment. At the initiation of angiogenesis, endothelial cells in vessels near the tumor site are stimulated to degrade the extracellular matrix. This is followed by migration of endothelial cells into the perivascular stroma in the direction of the angiogenic stimulus, initiating a capillary sprout that eventually forms a tubular vessel. Growth of a tumor colony beyond 1 cm ³ in size requires vascularization of the tumor through angiogenesis. Angiogenesis is partially mediated by soluble locally secreted factors. These factors include: basic fibroblast growth factor (bFGF), acidic FGF (aFGF), vascular endothelial growth factor (VEGF), platelet-derived endothelial cell growth factor (PD- ECGF), transforming growth factors a and b (TGF-a and -b), angiogenin, *TNF*-a, and interleukin-8 (IL-8) (Table [9-9](#)).

Tumor angiogenesis is a complex process, only partially explained by the presence of angiogenic factors secreted by tumor cells. Tumor cells themselves do release angiogenic factors such as VEGF and FGF as well as several that have not yet been completely purified or characterized. Tumor angiogenesis may occur through down-regulation of normally secreted angiogenesis inhibitory substances, such as thrombospondin. Tumors may be able to recruit macrophages and then activate them to secrete angiogenic factors such as *TNF* and IL-8.

The development of angiogenic potential in a tumor may be an important indicator of its biologic behavior. For example, the presence of increased vascularity in early (Stage I or II) breast cancer specimens indicates a significantly higher chance of tumor recurrence. Angiogenesis in early stage breast cancer is also correlated with the presence of lymph node metastasis during initial operative staging, indicating that angiogenesis is closely linked with metastatic potential. It has also been suggested that development of metastatic potential is acquired at a critical density of blood vessels in a primary breast cancer lesion. These observations raise the possibility that antiangiogenesis agents, such as analogues of the fungus-derived angiogenesis inhibitor fumagillin, might prove beneficial in the treatment of malignancy.

Metastasis

Metastatic tumors develop as clones arising from a heterogeneous primary tumor. It is assumed that when a cell within a tumor reaches a particular stage of virulence, it acquires the ability to metastasize. Recent evidence suggests that tumor cell metastasis requires multiple host-tumor interactions, and the process of metastasis probably begins early in the growth of the primary tumor. The metastatic cell must be able to do more than simply grow and divide in a new location; it must also break away from the original tumor population, invade through the basement membrane into a blood vessel, travel and adhere to a distant site, and induce angiogenesis. These activities require coordinating the processes of proteolysis, motility, adhesion, growth factor responsiveness, and angiogenic activity. Since all of these processes are naturally occurring functions of growth and development, the basic defect of metastasis must lie in the aberrant regulation of these processes.

Adhesion is an obvious component of metastatic behavior, both in the initial loss of attachment to the primary tumor cell mass and in the preference of certain tumors for metastatic sites. Despite advances in our understanding of the mechanisms of cellular adhesion, it is still difficult to define the adhesion requirements for metastasis. Many of the adhesion events previously described are implicated in the development of metastatic lesions. An example of this is the interaction of fibronectin, collagen, and laminin in the extracellular matrix with tumor cell receptors of the integrin and nonintegrin varieties. Some organ-specific adhesion events have been identified, supporting the hypothesis that specific adhesion is the reason for the preferential metastatic sites of certain tumors. Both in vitro and in vivo studies show that interfering with adhesion molecules can inhibit metastasis.

The development of metastatic potential in a tumor cell clone is correlated with the presence of proteolysis, a process already described for its role in tumor cell invasion and migration through tissue. Blockade of certain proteases, such as urokinase-type plasminogen activator, prevents establishment of metastasis. Compared with nonmetastatic cells, metastatic human melanoma cells express higher levels of tissue factor, the major cellular initiator of the plasma coagulation protease cascades. Tissue factor may promote metastasis by allowing increased tumor-endothelial cell adhesion as well as facilitating transmigration of tumor cells across the endothelium.

Metastasizing tumors have a predilection for selected organ sites (Table [9- 10](#)). In human beings, colon tumors frequently metastasize to the liver, renal cell carcinoma to the lung, melanoma to the lung and brain, prostate cancer to the bone, breast cancer to the lung, liver, brain, and bone, and ocular melanoma to the liver. Selection of a metastatic site by a particular tumor is probably governed by the adhesion and growth factor characteristics of the metastatic site and the requirements of the metastatic tumor. For example, metastatic melanoma cells express more of the integrin VLA-4 than do nonmetastatic cells, suggesting that this adhesion molecule and its ligand, V-CAM, may have some role in determining the specific endothelium for locating the metastatic deposit (Fig. [9-16](#)).

The role of the regional lymphatics in neoplasia in general and in metastasis in particular is as controversial as it is important. Early theories of cancer progression postulated that

regional lymph nodes provided a filter that was an effective, but temporary, barrier to the spread of tumor cells. It is now thought that the properties of the tumor cells themselves, rather than the filtration capacity of the lymph nodes, determine whether neoplastic cells are trapped within nodes or allowed to disseminate. The regional nodes may also be involved in the initiation of systemic immunity to tumors. For example, adoptive transfer of lymphoid cell populations derived from regional lymph nodes has been shown to induce tumor allograft immunity in normal animals. Among the many tumor metastasis models, however, there are substantial differences in the quality and quantity of immune responses to tumors, and the functional contribution of regional nodes to systemic tumor immunity is unclear.

Tumor cell entrapment in the capillary bed of distant organs is a necessary prelude to secondary tumor growth. Although the morphologic aspects of tumor cell entrapment are studied extensively, little is known about the dynamics of the process. Exposure of the capillary basement membrane is a result of the normal and continuous physiologic process of endothelial cell- shredding and may allow adhesion of tumor emboli. Platelet adherence to damaged regions of the basement membrane, followed by degranulation, causes further retraction of endothelial cells and augments attachment of tumor emboli or platelet-tumor cell emboli. Fibrin deposits around a tumor embolus are frequently observed, but the role of fibrin in tumor cell entrapment and metastasis is uncertain. Theoretically, a protective coat of fibrin surrounding the tumor embolus shields the neoplastic cells from the host immune response and blood turbulence. Increased coagulation is commonly observed in patients with cancer and may be related to the increase in thromboplastin found in tumors. Some neoplasms produce large quantities of procoagulant-A, which directly activates factor X of the clotting cascade. A reduced rate of blood flow in the vicinity of the tumor leads to increased trapping of circulating tumor cells and contributes to the survival of already trapped cells. The use of anticoagulants in the control of metastasis is based on these observations.

Studies using oncogene transfection provide a model for activation of the cellular responses that are required for tumor metastasis. Many oncogenes, when transfected into appropriate recipient cells, such as fibroblasts and epithelial cells, are capable of inducing metastatic ability. Some of these “metastatic” oncogenes include mutated *ras*, *v-src*, *v-fes*, *v-fms*, and p53. Lack of expression of the “metastasis suppressor” gene, *nm23*, may also be responsible for the development of metastatic disease. This gene was first identified for its decreased expression in murine melanoma tumor lines. Decreased expression of *nm23* is also associated with metastasis in breast, colon, renal cell, hepatocellular, lung, and squamous cell carcinomas. Although there is no definite proof that lack of *nm23* expression results in metastasis, this conclusion is supported by research showing that transfection of *nm23* into melanoma cell lines results in decreased tumor incidence, metastatic potential, and cytokine responsiveness. The exact mechanism of metastasis suppression by *nm23* is unknown, but evidence suggests that this gene is important for signal transduction during development.

Metastasis is a multistage process in which tumor cells acquire more and more autonomy regarding growth factor and adhesion requirements. A complex process with no universally applicable mechanism, metastasis is dependent on the characteristics of the tumor (the “seed”), and the microenvironment of its implantation site (the “soil”).

Autocrine Mechanisms Production of Tumor Growth Factors

The autocrine model of tumorigenesis holds that tumor formation, like the process of embryogenesis, occurs through a coordinated series of cellular signaling events, regulated by growth factors. Transformation of normal cells to malignant behavior may result from either increased production of stimulatory growth factors or decreased production of inhibitory growth factors. In 1896 Sir George Beatson in Glasgow demonstrated that oophorectomy could produce tumor regression in patients with breast carcinoma, suggesting that secreted steroid hormones support tumor growth. The molecular characterization of tumor growth factors began with the observation that polypeptides secreted by a variety of retrovirally, chemically, or oncogene-transformed cell lines could induce tumor growth or cellular transformation. The first correlation between an oncogene and a normal cellular protein was demonstrated when the amino acid sequence of the *sis* oncogene product displayed significant homology to the b chain of platelet-derived growth factor (PDGF).

One example of the interplay between stimulatory and inhibitory growth factors is that of the transforming growth factors TGF- α and TGF- β . TGF- α and TGF- β were originally named for their ability to reversibly induce anchorage-independent growth in fibroblasts. TGF- α belongs to a family of growth-stimulatory cytokines, all of which share a common receptor with epidermal growth factor (EGF). As expected, these cytokines have similar activities, which include regulation of the growth and differentiation of normal and neoplastic epithelial cells. TGF- β , on the other hand, is an inhibitor for cells responding to growth factors of the TGF- α family. This protein normally provides autocrine growth inhibition of epithelial cells and also inhibits the in vitro growth of some tumor cell lines. Recent data suggest that the development of malignancy can be correlated with increased autocrine growth stimulation by TGF- α , or decreased autocrine growth inhibition by TGF- β .

Other growth factors reported to be involved in tumorigenesis include insulin-like growth factor-1 (IGF-1), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), hepatocyte growth factor (HGF), fibronectin, transferrin, amphiregulin (a member of the *EGF* family), and interleukin-6 (IL-6) (Table [9-11](#)). IL-6 may be an inhibitor of tumor growth in early tumor stages, switching to a stimulatory factor for metastatic lesions. In one study, melanoma cells obtained from primary tumors exhibited growth inhibition upon in vitro culture with IL-6. Growth of metastatic melanoma cells, however, was stimulated significantly by culture in IL-6. Acquisition of the ability to proliferate in response to cytokines such as IL-6 may be one of the cellular events leading to metastatic disease.

Constitutive Activation of Growth Factor Receptors

In some tumors, loss of normal growth regulation occurs as a result of altered expression of growth factor receptors (Fig. [9-17](#)). Either constitutive activation of a growth factor receptor or an increase in growth factor receptor number would have the same effect as an increase in levels of the corresponding growth factor, e.g., an increase in receptors for epidermal growth factor (EGFR) may contribute to tumor growth in skin, colon, and breast cancers. The *erbB* oncogene product is a transmembrane receptor similar to the EGF receptor except that it is constitutively activated, i.e., able to generate a mitogenic signal in the absence of EGF binding (Fig. [9-18](#)). Expression of this oncogene is associated with poor prognosis in breast cancer. Several other receptors encoded by oncogenes, such as *kit*, *ros*, *met*, *ret*, and *trk*, demonstrate deletions of ligand-binding domains. The *MEN* IIA and IIB syndromes are associated with dominant activating germline mutations of different regions of the *ret* proto-oncogene. Murine embryo studies demonstrate that this gene encodes a growth factor receptor found on subsets of cells in the central and peripheral nervous system. In addition, *ret* is consistently expressed in both familial and nonfamilial neuroblastomas, pheochromocytomas, and medullary thyroid carcinomas as well as in normal thyroid and adrenal glands.

An interesting demonstration of the cumulative effect of mutations on tumorigenesis is provided by the relationship between mismatch repair defects and *TGF- β* activity. As described previously, a characteristic of deficient mismatch repair is alteration of microsatellite DNA. The gene encoding the epithelial cell receptor for TGF- β , the TGF- β receptor type 2 (TGF- β RII), contains a microsatellite site consisting of a string of ten adenosine repeats. In individuals with *HNPCC* and mismatch repair defects this gene is commonly mutated and the resulting TGF- β RII is dysfunctional. This results in loss of TGF- β suppression of epithelial cell growth, and contributes to tumor formation.

Intracellular Signal Transduction

Binding of a ligand to a cell surface receptor results in an intricate cascade of intracellular reactions, ultimately inducing transcription of appropriate cellular genes. This complex process is known as intracellular signal transduction. Any alteration in the network of signals responsible for ordered cell growth can contribute to carcinogenesis, and most oncogenes or tumor suppressor genes encode proteins essential for intracellular signal transduction. Oncogenes can be roughly divided into groups according to their cellular function. The small subset of oncogenes comprising growth factors or growth factor receptors has already been discussed. The other oncogene categories include signal transducers such as cytoplasmic protein kinases and *GTP*-binding proteins, transcriptional regulators, and regulators of programmed cell death (apoptosis).

Signaling Through Growth Factor Receptors

Engagement of a receptor by an appropriate ligand induces the assembly of the primary second messenger proteins at the inner surface of the plasma membrane near molecules such as *ras* that are involved in subsequent branching pathways of signal transduction (Fig. [9-19](#)). Growth factor receptors, also known as receptor tyrosine kinases, consist of three domains: (1) a large amino-terminal extracellular ligand binding domain; (2) a short transmembrane helix; and (3) an intracytoplasmic carboxyl terminus that is a ligand-activated tyrosine kinase. Binding of a ligand growth factor to the extracellular domain results in receptor dimerization and phosphorylation of the intracellular portion of the receptor. This triggers recruitment of intracellular substrates characterized by *src* homology 2 (SH2) domains to the receptor phosphotyrosine residues. An example of such a substrate is the protein Grb2, which, when associated with the appropriate phosphotyrosine of an activated growth factor receptor, recruits the *Sos* protein, a nucleotide exchange factor. *Sos* then engages the *ras* protein and assists in its activation by exchanging *guanosine diphosphate (GDP)* for *GTP*. This activation is assisted by yet another factor, a GTPase-activating protein (GAP).

Once *ras* has been activated, it triggers a cascade of serine-threonine kinases, such as members of the *raf* gene family, and a group of cytoplasmic enzymes known as *mitogen-activated kinases (MAP kinases)*. These kinases mediate the reactions that bridge the gap between the cell membrane and the nucleus. Activation of the MAP kinases results in phosphorylation of nuclear transcription factors, such as the c- *fos* and c- *jun* products, which are components of a transcriptional activator named AP-1. c- *fos* and c-*jun* induce transcription of the proto-oncogene c- *myc*, a direct regulator of the cell cycle, and stimulate the cell to progress from G₁ into S phase, thus committing the cell to a round of DNA replication.

The signaling pathway of growth factor receptors is one of several different mechanisms leading to cellular activation. Receptors that lack intrinsic kinase activity transmit their signal through association with intracellular protein kinases, such as the product of a gene called *lck*. *ras* belongs to a family of proteins known as G proteins that transmit signals from cell surface ligands to effectors, such as adenylate cyclase or phospholipase A2, through conversion of *GTP* to *GDP*. Regulation of the activation states of *ras* and related proteins is a crucial point in signal transduction. To participate in signaling, *ras* protein must attach to the inner surface of the plasma membrane by linking to an isoprenyl group, a process known as farnesylation. Strategies to inhibit the *ras* farnesylation reaction, such as through inhibition of the enzyme farnesyl protein transferase (FPTase), are under investigation as new chemotherapy agents.

A *ras*-independent signaling pathway has been proposed whereby receptor engagement activates a phospholipase that hydrolyzes inositol phospholipids in the plasma membrane and activates two additional second messengers: (1) inositol triphosphate, which triggers a signaling cascade through intracellular calcium flux, and (2) diacylglycerol, a membrane-associated lipid that activates another protein kinase called protein kinase C (PKC). Activated PKC is then able to activate *raf*, producing *MAP* kinase activation and leading to transcription of c-*fos* and c-*jun*.

A recurring theme in studies of signal transduction is the involvement of protein kinases. Intracellular second messenger proteins must be phosphorylated by a tyrosine kinase in order to amplify and distribute signals for cellular growth and differentiation. Although the roles of these kinases in signal transduction are not well understood, studies of cellular activation associate both receptor and nonreceptor kinase activity to multiple cellular processes, such as proliferation, metabolism, and cytoskeletal function. Many more pieces of the puzzle are needed to fully understand the complex regulatory mechanisms governing signal transduction.

Cell Cycle Control

Cells take their cues for proliferation and differentiation not only from external sources such as growth factor receptors but also according to an internal program. The cell cycle encompasses the progression from G₁ phase through mitosis and is coordinated by nuclear proteins called cyclins. The passage of a cell through the cell cycle is tightly regulated by a network of controls that act on the transcription of cyclin genes, the degradation of cyclin proteins, and the modification of cyclin-dependent kinases by phosphorylation. It is

now recognized that the cell cycle is a dynamic process that includes periods of arrest of cell proliferation when DNA damage occurs, presumably to allow time for DNA repair to occur. Provisions are made within the cell cycle program for apoptosis in circumstances in which the cell's genome has undergone irreparable damage.

Coordination of the cell cycle is achieved through a network of cyclin- dependent kinases (CDKs), which undergo programmed changes in activation state (Fig. 9-20). When in an activated state, each CDK is a combination of a cyclin and a kinase as well as a variety of other associated proteins. After activation of mammalian cells, a succession of kinases, known as CDK4, CDK2, and CDC2, are expressed in conjunction with a series of cyclins (cyclins D, E, A, and B) as the cell progresses from G₁ to mitosis. Each of the cyclin genes is transiently transcribed during a particular phase of the cell cycle, its mRNA translated, and then the protein is rapidly degraded such that its residence time during the cell cycle is brief. The elements of control over the cell cycle include redundant systems for regulating each step of this process. In addition to mechanisms allowing passage of cells through the cell cycle in response to mitogenic stimuli, negative controls on cell cycle progression, known as cell cycle checkpoints, are important for cell differentiation and senescence (Fig. 9-21). Defects in these negative controls are associated with carcinogenesis. At least two checkpoints detect DNA damage: one at the G₁-S transition, and one at the G₂-M transition (Table 9-12).

Alterations at the Cell Cycle Checkpoints

At the transition from G₁ to S phase, the main target of the activated kinase is the Rb protein (Fig. 9-22). The Rb protein is bound to the transcription factor E2F during G₁. Upon phosphorylation, Rb releases E2F, which in turn activates the transcription of genes required for S phase. Loss of function of the Rb protein leads to unregulated entry of a cell into S phase.

Upstream of Rb-E2F, several proteins control the G₁-S transition. One of these is the p53 gene product. Damage to the cellular DNA induces production of p53 protein, which in turn activates p21, a protein that inhibits all of the cyclin- CDK complexes (Table 9-13). This results in a delay in the transition from G₁ to S that allows time for DNA replication to occur. A cell with deficient p53 will enter S phase without sufficient DNA repair and replicate uncorrected mutations. An additional cell cycle check is provided by p27, a protein induced by binding of TGF- β to the cell. p27 is also an inhibitor of cyclin-CDK complexes. Finally, p16 is a cyclin-dependent kinase inhibitor and regulator of G₁-S transition whose activation stimulus is not yet known; germline mutations in the gene encoding p16 are associated with familial malignant melanoma.

The G₂-M cell cycle transition is also incompletely understood, but it appears to involve the product of the ataxia telangiectasia (AT) gene. Individuals with AT exhibit a high frequency of chromosomal breaks after irradiation, and their cells do not undergo proper arrest in G₂ after radiation. Individuals carrying a germline mutation in the AT gene are at an increased risk for cancers, presumably through loss of the tumor suppressor function of the AT gene product.

Evidence for another type of cell cycle regulator comes from examination of specialized nucleoprotein structures known as telomeres. Telomeres are located at the ends of chromosomes and are essential for maintenance of chromosomal stability. In immortalized cell cultures, telomere length is maintained by the enzyme telomerase. Telomerase is absent, however, in almost all normal human cells. With repeated replication of the chromosome, the telomere ends are lost, causing telomeres to undergo progressive shortening in normal human cells. This process leads to a limited life span for normal cells, as cells lacking telomeric sequences, unable to replicate, become senescent. Telomeres are thought to represent an internal clock by which the life span of somatic cells is measured. Studies of human tumors show no loss of telomere size with repeated replication and an increase in telomerase activity, suggesting that escape from the regulation caused by telomeric shortening may be important in tumorigenesis.

Regulation of Apoptosis

In order for tissues to maintain a normal state, cells subject to renewal must involute so that the proliferation and involution rates are balanced. This “programmed cell death” is known as *apoptosis* and, in contrast to cell necrosis, is characterized by cytoplasmic shrinking, nuclear chromatin condensation, and DNA fragmentation. Defects resulting in loss of normal apoptosis are associated with tumor formation. For example, the *bcl-2* oncogene was identified in follicular lymphomas and found to promote cell survival rather than proliferation. A family of genes whose products interact with one another to regulate cell death by apoptosis includes *bcl-2* (Fig. 9-23). BAX, a protein identified by its association with the *bcl-2* gene product, counteracts the survival-promoting effects of *bcl-2*. Although many different stimuli are able to induce apoptosis, most result in involvement of the BAX/*bcl-2* interchange; for instance, p53 may serve as a cellular surveillance factor by inducing either growth arrest or cell death, depending upon the cellular circumstances. Transcription of BAX protein is inducible by p53. Therefore, p53 causes growth arrest through activation of the p21 gene, or apoptosis through induction of BAX. Other regulators of apoptosis include TNF-R1, a cell surface receptor that promotes apoptosis when activated by its ligand, TNF- β , and the interleukin-1 β - converting enzyme (ICE) family, a group of cysteine proteases capable of inducing apoptosis. Finally, various growth factors and cytokines such as IGF-1 may act on the apoptotic pathway to promote cell survival.

SURGICAL MANAGEMENT OF PRIMARY TUMORS

General Considerations

The surgeon's role in the treatment of tumors varies with the type of cancer but includes diagnosis, clinical staging (Table 9-14), operative resection for cure and local disease control, pathologic staging or palliation, and the management of medical conditions common to the cancer patient (Table 9-15). The major goal of treatment is to provide the best chance for cure with the best functional and cosmetic result. Primary curative operations may be performed on patients with breast, lung, uterine, and large-bowel cancer. In other forms of cancer, such as lymphoma, the surgeon's role may be diagnostic, with a possible contribution to staging; in patients with leukemia, the only surgical role may be provision of vascular access for long-term administration of chemotherapy or the management of associated complications. Knowledge of clinical and pathologic staging is important; accurate diagnosis and assessment of the extent of tumors are essential to appropriate treatment. Pathologic staging gives insight into the natural course of the neoplasm, which is necessary to determine further treatment plans and to evaluate their efficacy (Tables 9-16 and 9-17).

The surgeon uses physical examination, roentgenography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) techniques to determine if the neoplasm is potentially curable by surgical removal (Table 9-18). Studies to preclude metastases are indicated when they are cost-effective and would substantially alter surgical treatment. The asymptomatic patient with a 1 cm breast mass and clinically negative regional lymph nodes should not require liver or bone radionuclide scan or abdominothoracic CT scans, as these tests would not be cost- effective. However, the use of CT scans of the chest in a patient with lung cancer can effectively help to stage the disease and to ascertain whether surgery with operative resection is appropriate.

Surgical resectability is also determined by the tumor's relation to, and degree of invasion into and around, vital structures. Invasive and noninvasive radiologic studies are extremely helpful in outlining the goals of operative management and defining the operative approach in specific patients e.g., portal vein combined with hepatic/splenic artery occlusion denotes nonresectability in patients with carcinoma of the pancreas, although surgical bypass may be necessary for biliary or gastric outlet obstruction.

The surgeon has a major role in disease prevention and patient/family counseling. The extent of an operation may be related to the presence of additional precancerous lesions or to a strong family history of site-specific cancers. For example, a patient with cancer of the colon and numerous colonic adenomas may be treated by a total abdominal colectomy rather than simple excision of the cancer-affected segment of large bowel.

In some circumstances, surgical removal of the contralateral breast may be used as a form of cancer prevention in a breast cancer patient who is at high risk for subsequently developing cancer in her other breast. The presence of lobular carcinoma in situ and breast cancer family syndrome are two circumstances in which contralateral mastectomy may be justified as a form of cancer prevention.

Operability and treatment decisions must take into account the patient's medical status and ability to tolerate the proposed operation. Assessment of cardiopulmonary status, hepatic and renal function, and nutritional status is vital to determining operative risk and to assessing needs for hospital and home rehabilitation.

An important but often underemphasized goal of cancer management is restoring the patient's physical, emotional, social, and employment status. The rehabilitation for a woman with breast cancer might be directed toward minimizing scarring and swelling of the tissues of the chest and arm, regaining strength and mobility in the shoulder after axillary lymphadenectomy, and restoring contour and symmetry of the breast. For some women an external prosthesis is satisfactory; other women significantly benefit from breast reconstructive surgery. Similarly, patients with extremity sarcomas may be considered candidates for limb salvage surgery or prosthesis use to maximize function (Fig. 9-24).

Most patients expect to understand and participate in the decision-making process, but many are confused by conflicting input from family, friends, and even other physicians. Anxiety and uncertainty about the life-threatening nature of cancer and the prospects of physical disfigurement may make it difficult for them to understand treatment issues and to contribute to the decision-making process. The physician should combine empathetic listening with a clear and comprehensive 20- to 30-minute discussion of treatment options. The use of patient education materials (written and videotaped) and counseling by nurses or physician assistants can facilitate the decision- making process and increase the patient's level of comfort and information about treatment planning.

Clinical Diagnosis

A complete history and physical examination is indispensable before further judgments can be made regarding laboratory testing and treatment. Common symptoms in the cancer patient may include dysphagia, nausea, anorexia, vomiting, hematemesis, abdominal pain, melena, and hematochezia in patients with gastrointestinal cancer; productive cough and hemoptysis in lung cancer; or an enlarging tender mass in breast and soft-part tumors. Symptoms generally correspond to the sites involved, but nonspecific symptoms, such as night sweats and weight loss, may be the initial manifestations of an underlying neoplastic tumor. The duration of symptoms may indicate the aggressiveness of the cancer or early case finding. The degree of physical impairment also influences treatment decisions regarding palliation.

The patient's past medical history often lends clues to the diagnosis. Diethylstilbestrol hormone use by the patient's mother during pregnancy, thymic irradiation for asthma, skin irradiation for acne in childhood, or a history of chronic inflammatory bowel disease are historical factors known to be associated with the later development of cancer. The medical history can also reveal environmental factors such as smoking, alcohol ingestion, or exposure to asbestos or aniline dyes, which can be related to organ-specific sites of tumor development. A thorough medical history provides an important index of operative risk for the patient and medications that may require adjustment in their dosage and frequency.

Inquiry into family history may reveal findings that support an initial diagnosis, suggest additional associated lesions, or influence the extent of surgical treatment. A patient with a thyroid nodule may have relatives with episodic hypertension, renal stones, or an “adrenal tumor” suggesting a multiple endocrine neoplasia syndrome. A patient with relatives who developed large-bowel cancer before the age of forty should be screened for polyposis syndromes. Without a thorough history, these and other genetically influenced diseases will be missed.

Asymptomatic patients who are at high risk for development of certain types of cancer by virtue of age, family history, or personal history of disease should be systematically screened. They should have appropriate examinations as indicated, using mammography, fecal occult blood testing, flexible sigmoidoscopy, cervical cytology examination, etc., as indicated. Simple screening examinations, such as uterine cervical Pap smear and fecal occult blood testing, should be performed routinely. Often the surgeon is asked to evaluate

a patient with a mass in a regional lymph node area, such as the neck, axilla, or groin. Usually this mass represents one or more lymph nodes enlarged secondary to an inflammatory process, originating in the area drained by the regional nodes. Lymphadenitis is often multiple and tender, and the primary area of inflammation is usually obvious. If the mass represents a solitary lymph node or several distinct enlarged painless nodes with no obvious cause, the question of biopsy to diagnose cancer is raised. Open excisional biopsy of lymph nodes should be deferred until a thorough search for the source of a primary tumor has been made, but fine-needle aspiration and cytology examination can be done without causing regional tissue contamination with cancer cells.

Excisional biopsy of lymph nodes containing metastatic cancer can release viable cancer cells into the biopsy wound because efferent and afferent lymphatics containing such cells are divided in the process of excising the lymph node. The incision of a node or group of nodes containing metastatic tumor may increase the risk of seeding the wound with cancer cells and violates the surgical principle of en bloc resection of the primary cancer, regional lymphatic channels, and regional lymph nodes. Once neoplastic disease is growing free in connective tissue and is no longer contained within the lymphatics or lymph nodes, operative eradication of the tumor becomes difficult because the anatomic limits of the area containing cancerous tissue are broadened. If adenopathy is present in the head and neck region, then the oral cavity, larynx, and pharynx should be thoroughly investigated. If the mass is in the axilla or groin, the breast and the skin of the corresponding extremity and portion of the trunk should be examined. The patient should be queried about previous removal of skin lesions, particularly moles, that may represent melanoma.

Laboratory and Radiologic Studies

In addition to the routine laboratory tests such as complete blood count, coagulation profile, multichannel serum biochemistry profile, and chest x- ray, other studies are useful in determining the prognosis in patients with malignant disease (Table [9-19](#)).

Evaluation of the patient with a suspicious breast lesion should include bilateral mammography. Roentgenographic characteristics may support the clinical diagnosis and reveal occult lesions in the contralateral breast. Clinically occult lesions may undergo mammographically directed stereotaxic needle biopsy or needle localization for open biopsy. The patient with breast cancer who has abnormal liver function tests or palpable hepatomegaly should undergo a CT scan; those with skeletal symptoms should receive a radionuclide technetium 99m bone scan. Metastatic lesions 1 cm or more in diameter can be detected in the liver using unenhanced and enhanced CT scans with 3–5 mm slices.

Patients who have symptoms or signs attributable to the gastrointestinal tract should receive an air contrast upper or lower barium study. Air contrast barium studies show greater mucosal detail than barium studies without air contrast and are more sensitive to small lesions. Endoscopy can also be used for both diagnosis and tissue examination. CT scans of the chest are useful in evaluating suspicious lesions noted on chest x-ray and skeletal and soft tissue lesions. Ultrasound and CT scanning can be particularly useful in the detection of hepatobiliary cancer. Invasion of vascular structures and dilated extrahepatic and intrahepatic ducts secondary to extrahepatic biliary obstruction by a neoplasm can be demonstrated. Coexisting ascites also may be noted. Magnetic resonance imaging is valuable in determining the location and extent of soft tissue and bone tumors and their relationship to adjacent structures. By quantitative imaging, the physical characteristics of tumors often can be determined.

Serum markers, such as *carcinoembryonic antigen (CEA)*, *CA19-9*, *beta- human chorionic gonadotropin (beta-HCG)* , and *alpha-fetoprotein (AFP)* are useful in the management of patients with specific tumors (Table [9-20](#)). CEA is a tumor-associated glycoprotein found in several different solid tumors such as breast, lung, gynecologic, and gastrointestinal cancers and sarcomas. Plasma CEA levels are not sensitive or specific enough to be of great value in screening for cancer, particularly for early lesions. Elevated plasma levels are correlated with increasing tumor size, stage, and the extent of positive lymph node metastases in patients with large-bowel cancer. When surgical removal of the primary tumor is complete, measuring circulating CEA levels may be useful during the follow-up period as an early marker of recurrent systemic disease.

Surgical Pathology

The importance of accurate pathologic diagnosis in the proper surgical treatment of cancer patients cannot be overstated. Determinations of the presence of cancer, the histologic grade, the site of the primary or metastatic foci, and surgical resection margins provide critical information.

Fine-needle aspiration cytology of a solid lesion can be performed with a 22-25-gauge needle to assess the cytology of palpable tumors. Diagnosis using fine-needle aspiration techniques concurs with surgical pathologic diagnosis in 97 percent of tested lymph nodes and 77 percent of breast tumors examined. This technique is rapid, minimally traumatic, and highly accurate for diagnosis of a clearly palpable mass or a radiographically visible lesion (Fig. [9-25](#)). False-positive results are rare; false-negative results may occur because of small sample size, site of the lesion, degree of tissue necrosis, and tumor type. With the use of fine-needle aspiration techniques in combination with roentgenography and ultrasonography, deep, nonpalpable lesions are amenable to diagnosis with minimal morbidity, e.g., transthoracic aspiration of lung nodules using CT scan and CT-directed aspiration of pancreatic masses. Fine-needle aspiration cytology is particularly useful in the diagnosis of palpable masses in the breast and thyroid, as well as palpable suspicious nodes in the neck, axilla, or groin.

Aspiration cytology cannot be completely depended on for grading of solid tumors, for subdividing types of lymphoma, or for accurate diagnosis after radiation treatment, but a positive diagnosis greatly facilitates diagnostic and treatment planning. Use of immunohistochemical markers may be of additional diagnostic value (Table [9-21](#)).

When an accurate diagnosis of tumor type and grade is necessary, an incisional or excisional biopsy is required. Care should be taken in the planning of a surgical biopsy so as not to jeopardize later surgical extirpation or the use of skin flaps. In general, large soft-tissue lesions (5 to 7 cm) that are deeper than the superficial fascia are best sampled by incisional biopsy (Fig. [9-26](#)). Small (<2 cm) superficial lesions can be managed by excisional biopsy with a view toward further treatment depending on tumor type, grade, and depth of invasion. Frozen section diagnosis should not be relied on to provide histologic grade of the tumor and information about depth of invasion. Surgical margins of resection can and should be evaluated by frozen section examination. In some instances, such as malignant rectal polyps, local excisional therapy is all that is required if permanent histopathology determines only superficial invasion, adequate resection margins, low-grade differentiation, and absence of vascular or lymphatic invasion.

Decision for Operation

A decision for curative operation presupposes that the tumor is localized or confined regionally, that the area of the tumor can be encompassed by regional excision, that evidence of distant metastases cannot be found, and that the tumor is appropriately treated by operation.

Given a decision for a curative operation, the extent of the surgical procedure must be defined. In principle, an en bloc resection should be performed, encompassing the primary tumor, regional lymph nodes, and intervening lymphatic channels. This principle is perhaps best illustrated by operations for large-bowel cancer, in which the regional lymphatics of the colon (but not the rectum) course in one direction with the major arteries and veins. This principle is less applicable in the rectum, where lateral spread and the limiting confines of the lateral pelvic wall may preclude a wide margin. Similarly, the principle is less applicable for breast cancer, for which multiple pathways of lymphatic spread are well recognized (e.g., internal mammary and retropectoral nodes, axillary and supraclavicular nodes).

As a result of these variables, and partly due to emergence of earlier stage disease, the extent of various operations for cancer is undergoing change. This “remodeling” is best illustrated in breast cancer, for which the trend is toward local excision of the primary tumor with radiation therapy and adjuvant chemotherapy. The therapeutic value of regional node dissection has been questioned by some. Performed properly, it is of clear prognostic value and could establish the database for precise staging for other adjuvant treatments.

Surgical procedures may be performed solely for staging purposes. An example is staging laparotomy in Hodgkin's disease, in which multiple lymph node biopsies, liver and bone marrow biopsies, and splenectomy are performed. In a variety of settings, operative intervention is used for palliative treatment. Bypasses are performed around obstructed viscera, and gastrojejunostomy is done for obstructing carcinoma of the stomach. Choledochoduodenostomy or jejunostomy procedures are used as bypass procedures for periampullary carcinoma of the pancreas obstructing the common bile duct. Intraluminal stent tubes may be inserted through an obstructing esophageal carcinoma to allow the patient to take oral nourishment, and colon diversion (bypass or colostomy) may be performed for obstructing large-bowel cancer.

The use of cytoreductive surgery is controversial. This approach may be most relevant in ovarian cancer, for which deliberate removal of as much ovarian tumor as possible may enhance the patient's response to subsequent chemotherapy or radiation therapy. Cytoreductive operations also may be valid in the treatment of some childhood tumors, such as neuroblastoma. Rarely is cytoreductive surgery (“debulking”) applicable in other circumstances.

The extent of an operation should be dictated by precise staging. With precise staging, and with the presence of effective chemotherapy, operative intervention may be more limited. For example, the traditional management of non-seminoma germ cell tumor of the testis has been radical orchiectomy and retroperitoneal lymph node dissection extending to the renal vasculature. The predictability of normal levels of b- *HCG* and *AFP* with normal CT scans and ultrasound, backed by effective chemotherapy should dissemination occur, now may permit only radical orchiectomy without node dissection in those patients who are normal by these determinants. This approach results in fewer patients suffering adverse consequences from retroperitoneal node dissection and resultant nerve damage with impotence and retrograde ejaculation. More precise pretreatment planning of tumors traditionally treated by operation is a main objective of current research. Research in areas such as lymphoscintigraphy and the use of radiolabeled monoclonal antibodies is being explored to achieve greater precision of staging.

Preoperative Preparation

Appropriate preoperative preparation includes knowledge of the natural history of the patient's disease, evaluation of operative risk, decisions relevant to the need for and timing of operative intervention, estimate of the physiologic stress potentially imposed by the operation, and the quantitative assessment of the patient's physiologic status. Comprehensive preparation of a patient for operative therapy requires both physiologic and psychologic support. In the preoperative preparation of the surgical patient, the physician should consider potential abnormalities such as acid-base disorders, malnutrition, infection, respiratory insufficiency, hepatic and renal dysfunction, anemia, and clotting abnormalities.

The major aims of preoperative therapy should be to prepare the patient to withstand the stresses of operative therapy and to minimize the risks of the surgical procedure. The appropriate duration of the preoperative period depends on the urgency of the operative procedure. The length of time feasible for correction of preexisting deficits may be *short* (hours), as in the case of massive gastrointestinal hemorrhage or free perforation of an obstructed colon; *intermediate*, as in complete but nonstrangulated bowel obstruction; or *prolonged* (days), as in jaundice due to pancreatic carcinoma. Determination of the urgency of a particular operative procedure requires knowledge of the operative risk and the natural history of the disease without immediate operative intervention. Included in this evaluation are factors such as the age of the patient (chronologic and physiologic), degree of physiologic derangements and nutritional deficits, presence of organ system failure or insufficiency, and stage of the primary disease. Although the urgency of operative intervention may limit the length of preoperative preparation and the methods available for correcting preexisting abnormalities, partial repair of deficiencies should be initiated promptly with plans made for more complete correction during and after operative therapy.

Months of chronic undernutrition cannot be corrected in a matter of hours, but anemia, dehydration, and electrolyte abnormalities can be ameliorated by early initiation of intensive intravenous support, guided by appropriate laboratory monitoring.

Anemia is common among patients with cancer and should be corrected with packed red cell transfusions to a hematocrit level of 30 percent or more before major operative intervention when much bleeding is anticipated. When possible, patients should autodonate one or two units of blood within 4 weeks of surgery to decrease the risk of viral transmission from nonautologous blood transfusions.

Clotting abnormalities can usually be determined by an adequate patient history, physical examination for evidence of hemostatic problems, and routine laboratory investigation (prothrombin time, partial thromboplastin time, and platelet count). Ascertainment of drug ingestion (especially aspirin, phenylbutazone, or indomethacin) is important because some medications result in qualitative platelet deficiencies, leading to serious clotting abnormalities. Aspirin ingestion should be avoided for at least 1 week before elective hospital admission. Some medical conditions are also associated with platelet dysfunction, such as uremia, leukemia, and hepatic failure. The template bleeding time is a useful screening test for patients with suspected platelet dysfunction. It is generally agreed that a count of 50,000/mm³ functionally active platelets is sufficient for major operative procedures.

After major elective operations, wound infection rates have varied from 0.5 percent to 20 percent depending on whether the procedure was “clean” or “contaminated” (Table 9-22). Besides the added morbidity and potential mortality, surgical infection increases the average duration of hospitalization by at least 10 days, resulting in a large increase in hospital costs. Resistance to infection (immune function), dose and virulence of the invading bacteria, and the presence of foreign body, dead tissue, or anaerobic conditions are all factors that determine the probability of wound infection.

Antibiotic prophylaxis is used to reduce the incidence of postoperative wound infection in patients undergoing contaminated operations. Chemoprophylaxis is useful to cancer patients who are undergoing head and neck surgery, chest surgery, abdominal gastrointestinal surgery, and pelvic surgery, such as hysterectomy.

The use of antibiotics in these situations should be: (1) timed to allow adequate wound antibiotic levels before contamination; (2) administered only for a short time during the perioperative period; (3) specific for the most likely infecting organism(s); and (4) safe, i.e., it should present minimal additional hazard to the patient.

Cancer Operations

Local Resection

Wide local resection that removes an adequate margin of normal tissue with the tumor mass may be adequate for certain low-grade neoplasms that do not metastasize to regional nodes or widely infiltrate adjacent tissues. Basal cell carcinomas, thin melanomas (i.e., less than 1.0 mm), and mixed tumors of the parotid gland are examples of such neoplasms. Some normal tissue surrounding the tumor should be excised to prevent local recurrence.

Radical Local Resection

Neoplasms, such as soft tissue sarcomas and esophageal and gastric carcinomas, may spread widely by infiltration into adjacent tissues. In such cases it is necessary to remove a wide margin of normal tissue with the neoplasm. The wide margin of normal tissue between the line of excision and the tumor mass also acts as a protective barrier against tumor cell spill into the severed lymph and blood vessels. The greater the width of normal tissues between the plane of dissection and the tumor, the greater the likelihood of a complete local excision.

If the tumor was previously explored, but not removed, or if an incisional biopsy procedure was performed, a segment of skin and the underlying muscles, fat, and fascia must be removed far beyond the limits of the original incision because tumor cells may have been implanted in the incision during the initial operation.

Malignant neoplasms are not well encapsulated. A pseudocapsule composed of a compression zone of neoplastic cells may surround the tumor. This apparent encapsulation offers a great temptation for simple enucleation, because the tumor may be easily dislodged from its bed. The surgeon must cut through normal tissue at all times and should never disrupt the neoplasm during its removal. Dissection should proceed with meticulous care to avoid tumor cell spill. The surgeon should resect as far as possible from the gross extent of the tumor on all sides, including the deep aspect. Skin, subcutaneous fat, and some muscles may have to be sacrificed, but usually this causes little functional loss. Sacrifice of tumor- involved major vessels, nerves, joints, or bones may be necessary to obtain a curative result. The extent of operation is also determined by functional integrity.

Radical Resection with En Bloc Excision of Lymphatics

Since many neoplasms commonly metastasize by way of the lymphatics, operations have been designed to remove the primary neoplasm and the regional lymph nodes draining that area in continuity with all the intervening tissues. Conditions are best for this type of operation when the collecting nodes of the lymphatic channels draining the neoplasm lie adjacent to the primary site or when there is a single avenue of lymphatic drainage that can be removed without sacrificing vital structures. It is important to avoid cutting across involved lymphatic channels because such action can increase the possibility of local disease recurrence.

En bloc regional lymph node dissections such as those undertaken in modified radical mastectomy and radical total gastrectomy should be performed when there is clinical involvement of lymph nodes by metastatic tumor. In many cases the tumor has already spread beyond the regional nodes, and the likelihood of cure after such procedures may be quite low. En bloc removal of the involved nodes offers the only chance for cure and provides significant palliation and local control.

Lymphadenectomy

There are some general principles common to lymph node dissection (LND) at various anatomic sites, particularly the neck, axilla, and groin (Fig. 9-27).

- (1) The surgeon must thoroughly understand the anatomy of the lymph nodes in each area of the body and should incorporate all the draining nodes at risk into the surgical specimen.
- (2) The goals of LND must be clearly defined as cure, local disease control (i.e., palliation), and/or staging. LND may be curative in some patients with bulky nodal metastases, or palliative in certain patients with large, symptomatic nodal metastases in the presence of distant metastases. Staging to determine whether metastatic disease is present in the regional lymph nodes will assume increased importance with the availability of effective adjuvant therapies.
- (3) An incomplete LND is generally not acceptable except when the goals of surgery are strictly palliative. When the intent is curative, as in a patient with regional metastases from a primary cutaneous melanoma, complete LND is vital. But a partial axillary dissection (levels I and II) is satisfactory for breast cancer, because the goals are staging and local disease control.
- (4) The incision providing access to the underlying regional nodes should be placed to minimize the risk of dividing lymphatic vessels that could contain malignant cells.
- (5) For dissections of lymph nodes in the neck, axilla, or groin, closed- suction catheter drains are important to evacuate blood and serum and keep the tissues in apposition, minimizing the risk of seroma formation. One or two large catheters may be inserted percutaneously through the lower flap and placed in a dependent part of the wound. Although there are no objective data on the best time to remove these devices, the incidence of seroma formation increases if they are removed too early, and the incidence of wound infection increases if they are kept in too long (especially longer than 10 days). Catheters probably should be removed when the drainage is less than 40 mL per 24 h, or 8 days after surgery, whichever comes first.
- (6) The use of prophylactic antibiotics is controversial. The incidence of wound infection is highest after a groin dissection and lowest after a neck dissection. Staphylococci and streptococci are the most common organisms isolated from these wound infections. The use of prophylactic antibiotics is probably justified on an empirical basis for groin and axillary lymphadenectomies, but this must be confirmed with controlled clinical trials.
- (7) In patients with bulky nodal metastases, especially with invasion and fixation into surrounding tissues, such as in the axilla for metastatic breast cancer and in the neck for metastatic melanoma, the risk of regional recurrence is greater than 20 percent. Data from prospective clinical trials indicate that adjuvant radiotherapy might be considered to improve regional disease control.

Elective Lymph Node Dissection (LND)

The high rate of local cancer recurrence after surgical resection when lymph nodes are grossly involved and the high error rate when palpation is used to assess the extent of the involvement have led to elective or prophylactic dissection of clinically normal regional lymph nodes close to the primary tumor. Microscopic examination of these excised lymph nodes reveals evidence of tumor spread in 20 to 40 percent of carcinomas and melanomas. A higher 5-year survival rate was reported for patients undergoing excision of lymph nodes with microscopic rather than clinically evident tumor involvement.

This concept of elective LND has been challenged because it is not clear whether cure rates are improved if the nodes are removed before they are palpable. Controlled clinical trials directed toward this question in many types of neoplasms are currently under way. Regardless of direct therapeutic benefit, foreknowledge of tumor in regional nodes can affect staging, treatment, and prognosis. For example, patients with breast cancer who have metastases to regional nodes may benefit considerably from adjuvant chemotherapy or hormonal therapy. Also some patients with deep melanomas (> 4 mm) may become candidates for investigational adjuvant trials only if lymph node metastases are present. Furthermore, a comparison of experimental results from different institutions depends on accurate staging when therapy is initiated.

Selective Lymph Node Dissection

Morton and colleagues recently described a promising technique for detection of the regional draining lymph nodes most likely to contain metastatic tumor cells spreading from a primary cutaneous melanoma. Their technique of intraoperative lymphatic mapping and selective sentinel LND is currently under investigation in a phase III multicenter trial for melanoma and is also being applied to breast carcinoma and other neoplasms. Initially the technique relied on injection of a vital blue dye at the tumor site and visual tracking of this dye along the lymphatics to the nodal basin. Sentinel node mapping has been facilitated by adding a radiolabeled isotope to the dye and monitoring its path by a handheld gamma probe.

Extensive Surgical Procedures

Some slow-growing primary tumors can reach enormous size and may locally infiltrate widely without the development of distant metastases. Radical operative procedures can be undertaken for these extensive and nearly inoperable tumors, with occasional cure. Advances in surgical techniques, anesthesia, physiologic monitoring, and supportive care (blood transfusions, antibiotics, and fluid and electrolyte management) have permitted the development of more radical and extensive operative procedures that have significantly improved the local control rates for certain neoplasms. These extensive surgical procedures sometimes offer a chance for a cure that is not possible by other means and are

justified in selected situations when extensive laboratory workup shows no evidence of distant metastases. These operations should be undertaken only by experienced surgeons who can select those patients most likely to benefit. The surgeon considering extensive procedures such as pelvic exenteration, hemipelvectomy, forequarter amputation, or radical operations for head and neck carcinomas must be willing to accept the responsibility for the patient's postoperative emotional rehabilitation.

Pelvic exenteration is a well-conceived operation capable of curing patients with radiation-treated recurrent cancer of the cervix and certain well- differentiated and locally extensive adenocarcinomas of the rectum. This operation removes the pelvic organs (bladder, uterus, and rectum) and all soft tissues within the pelvis. Bowel function is restored with colostomy. Urinary tract drainage is established by anastomosis of ureters into a segment of bowel (ileum or sigmoid colon). The 5-year relapse-free survival after pelvic exenteration is 25 percent.

Hemipelvectomy (resection of the lower extremity and iliac bone) can sometimes be curative for skeletal sarcomas limited to the head of the femur or acetabulum or to one-half of the pelvic structures and for some slow-growing soft tissue sarcomas of the upper thigh and buttock that recur locally but metastasize slowly. Forequarter amputation (resection of the upper extremity and scapula) can offer similar results when the neoplasm is limited to the bones of the scapula and upper humerus or to the soft tissues of the shoulder girdle.

Surgery of Recurrent Cancer

Surgical resection of localized, recurrent, low-grade, slow-growing malignancies may produce a long period of remission. Surgical procedures are frequently successful in controlling recurrent soft tissue sarcomas, anastomotic recurrences of colon cancer, certain basal and squamous cell carcinomas of skin, and breast cancer recurring after lumpectomy. However, surgical resection of the recurrent neoplasm in the patient with metastatic disease is usually unsuccessful and rarely indicated, unless the entire tumor mass can be completely removed.

The results of routine second-look operations to detect early recurrence of colon cancer have not been impressive, but tumor markers, such as *CEA*, have been extremely useful for selecting patients most likely to benefit from reoperation. In general, a local recurrence can be treated surgically or with radiation. The surgeon must decide which form of treatment will achieve local control with the lowest morbidity.

Specific Organs Breast

In the United States breast cancer is the most common malignancy in women and second only to lung cancer in cancer-related mortality in women. In 1995 more than 180,000 women were diagnosed with invasive breast cancer, and the probability of a woman's developing breast cancer at some point during her life was estimated at 1 in 9.

The increased incidence of breast cancer has increased awareness of the disease. Screening mammography is used more commonly, because clear benefit has been shown in large prospective studies of women over the age of 50 years. The benefit has occurred in diagnosing more malignancies at in situ or early stages compared with women who are self-diagnosed and those outside of screening programs. Women should be screened for breast cancer with a baseline mammogram between the ages of 30 and 40 years, a mammogram every two years between ages of 40 and 50 years, and yearly thereafter. Education regarding breast self-examination and timed physical examinations by a physician should also be done.

In “early” cases, a woman presents to the physician with an “abnormal” mammogram showing microcalcifications, asymmetry, a mass with or without skin thickening, or other signs of potential malignancy. Alternatively, the patient may present with a palpable breast mass, nipple discharge, or signs of more advanced disease such as skin retraction or inflammatory skin changes. Physical examination should be carried out to look for local regional metastases.

A diagnostic algorithm may be developed, determined by the primary site and size of the suspicious lesion. Palpable lesions initially may be diagnosed by fine-needle aspiration in the outpatient setting. If this cytologic examination is positive, there should be a thorough discussion with the patient of treatment options and definitive therapy initiated. In cases in which a breast-conserving procedure can be done, the primary lesion is excised, with pathologic confirmation of the adequacy of tumor margins, and tumor tissue is prepared for estrogen and progesterone receptors. A limited axillary dissection is performed at that time, with the entire procedure done under general anesthesia. In the case of an equivocal or nondiagnostic fine-needle aspiration, the breast mass can be excised under local anesthesia with a margin of normal breast tissue (frozen section is done for diagnosis and tissue is processed for hormone receptors). The axillary dissection can be done at a subsequent date. If the lesion is not palpable but is mammographically defined, a needle localized biopsy or stereotactic core needle biopsy is done for diagnosis.

The responsibility of the surgeon is to provide the patient with the best chance for cure, for local chest wall control of tumor, and for minimal morbidity. If axillary lymph nodes are not clinically palpable, dissection of the lateral axilla (level I and II lymph nodes) is performed, with the lateral border of the pectoralis minor muscle as the medial limit of the dissection.

The management of these patients has evolved toward breast conservation surgery (lumpectomy, axillary dissection, and breast irradiation). This coincides with the trend toward smaller cancers associated with greater public awareness and increased use of breast screening using physical examination and mammography. In patients with larger primary tumors (>4–5 cm) or those who have high-risk features that might compromise local control, a modified radical mastectomy with or without primary reconstruction can be done. In the past, there was greater emphasis on irradiation of lymph node regions (internal mammary nodes, supraclavicular nodes), but the long-term survival benefit of adjuvant radiation therapy has not been shown.

Other approaches have been used to treat patients with small (<2 cm) cancers of the breast. Veronesi and associates (1981) compared radical mastectomy with quadrantectomy, axillary dissection, and radiotherapy in 701 patients with breast cancers measuring less than 2 cm in diameter. Local chest wall or ipsilateral breast recurrences and patient actuarial survival were similar in both groups.

In the National Surgical Adjuvant Breast and Bowel Project (NSABP) trials, Fisher and colleagues (1989) reported that among patients with negative nodes, 12 percent of those who underwent irradiation and 37 percent of those who did not undergo irradiation have a recurrence of breast tumor during the 8 years of follow-up ($p < .001$). The probability of a recurrence in those with positive nodes (all of whom received chemotherapy) was only 6 percent with irradiation and 43 percent with no irradiation. Irradiation of the breast obviously is important to decrease local recurrence and the need for subsequent mastectomy.

In situ intraductal or lobular breast cancer is seldom associated with lymph node metastases. In situ ductal breast cancer may be treated by local excision with or without radiation therapy or by total mastectomy with immediate reconstruction. The choice of therapy is often dictated by the extent of the in situ disease, the presence or absence of multifocal lesions, the histologic type, the patient's desires regarding treatment, cosmesis, and future risk.

Sixty percent of recurrent breast cancer occurs within two years after mastectomy. If the initial local treatment for breast cancer is adequate, local chest wall recurrence rates should be less than 5 percent in stage I disease and less than 10 percent in stage II disease. Breast reconstruction can be performed simultaneously with mastectomy in women with invasive breast cancer. The major criticism of breast reconstruction is the potential for delay in diagnosing local chest wall recurrence, but this risk is small. The best defined role for immediate breast reconstruction may be in the treatment of in situ breast cancer.

Esophagus and Stomach

Operative therapy for carcinomas of the esophagus has been associated with substantial morbidity attributed to patient factors, such as preexisting cardiopulmonary disorders and malnutrition, and to anatomic factors, such as the location of the primary tumor and the local, regional, and lymphatic spread.

In addition to intensive preoperative nutritional and pulmonary support to reduce postoperative complications, adjunctive radiotherapy and/or chemotherapy have been administered in an attempt to reduce local recurrence and increase patient survival. Randomized trials with preoperative irradiation alone have not shown survival benefit.

Preoperative combination chemotherapy, consisting of cisplatin, bleomycin, and vindesine, results in tumor shrinkage in nearly half of all patients. In addition, the surgical resectability rate is increased in patients given preoperative chemotherapy and radiation treatment.

In the event that resection for cure is impossible, resection of the tumor for palliation should be performed. If a patient can ingest adequate nutrients by mouth, the quality of remaining life is improved and the opportunity for further palliation from chemotherapy and radiation therapy is increased. In patients with large tumors, surgical palliation may include bypass by colon interposition. The risk of producing a major postoperative complication by doing a palliative resection must be weighed against the potential benefits. The operating surgeon must consider life expectancy and quality of remaining life in deciding between palliative resection or bypass and nonoperative treatment.

The surgical treatment of gastric cancer is based mainly on operative and pathologic observations. Carcinoma of the distal portion of the stomach (restricted to pylorus and antrum) should be treated by subtotal gastrectomy, omentectomy, and removal of subpyloric, hepatic arterial, and preaortic lymph nodes. Tumors located in the body of the stomach have been treated by subtotal or total gastrectomy with the choice based on tumor location; little difference in overall survival rate is noted between these two procedures.

Pancreas

If evidence of distant or regional metastases from carcinoma of the pancreas or periampullary region cannot be identified, the patient in good medical condition is a candidate for pancreaticoduodenectomy (see Chap. 30). The malnourished patient should receive either enteral or parenteral nutritional support during preoperative preparation, unless deteriorating liver function secondary to biliary obstruction necessitates immediate biliary decompression. Elevated levels of serum bilirubin and alkaline phosphatase in a well-nourished patient with normal hepatocellular function are not by themselves contraindications to surgery.

Liver

Advances in anesthesia, blood replacement, and surgical technique have made major hepatic resection feasible with low mortality. Patients with primary hepatoma and certain solitary metastatic cancers, e.g., from carcinoma of the colon, should be evaluated for possible curative resection.

Hepatic ultrasound or abdominal CT scanning combined with plasma *AFP* and *CEA* levels are the most effective tests for screening patients for liver disease, but their sensitivity is limited. Arteriography outlines the arterial blood supply to the liver. CT and intraoperative ultrasonography are sensitive tests that identify small metastatic deposits and can detect tumor in the lateral segment of the left hepatic lobe.

At exploration, metastases limited to one hepatic lobe should be considered for resection either by wedge excision or lobectomy. If the cancer is unresectable, hepatic arterial devascularization and/or chemotherapy infusion may be performed.

Large Bowel

Preoperative preparation of the patient with colorectal carcinoma requires thorough assessment by physical examination, radiographic methods, and endoscopic techniques to determine the size, mobility, and histology of the primary tumor. Synchronous cancers of the large bowel are noted in approximately 4 percent of patients. In the absence of obstruction, all patients should undergo a thorough mechanical bowel preparation with laxatives and enemas preoperatively. Oral neomycin and erythromycin is one antibiotic prophylactic regimen that is used along with mechanical bowel preparation on the day before operation to reduce intraluminal bacterial content.

In colonic resection, the mesentery of the cancer-bearing bowel should be removed as completely as possible to avoid local recurrence and obtain adequate lymph node removal for staging and attempted surgical cure.

Good surgical judgment is necessary when operating on any part of the colon, but it is required most when dealing with carcinoma of the rectum and rectosigmoid. The surgeon should provide a combination of the best opportunity for cure and local control of disease with the least chance of postoperative morbidity, mortality, and loss of function. Sphincter-saving procedures should be performed if the chance for local control is not jeopardized. Cancerous lesions within 2 cm of the anal verge that invade through the muscularis propria (T3) usually should be removed by abdominoperineal resection. A tumor cephalad to this level often can be managed with a low anterior resection or pull-through procedure. Preoperative radiation therapy with chemotherapy may be helpful to permit tumor shrinkage, destroy peripheral tumor micrometastases, and allow a sphincter-sparing procedure.

Local excision can be done for *early* cancer of the rectum in lesions that undergo complete excision with low-grade histology and with tumor confined to the submucosal plane of the bowel wall without lymphatic or vascular invasion. This approach is preferable to electrosurgical diathermy, which destroys histologic markings and makes staging impossible. Electrocoagulation is useful as palliation for selected patients. Adjunctive radiation and chemotherapy treatment may be indicated because surgical therapy alone yields high recurrence rates in Duke's C lesions with high- grade histology, size greater than 4 cm, and distance within 5 cm of the dentate line compared with other rectal tumors.

Preoperative radiotherapy and chemotherapy combinations may increase resectability, prevent seeding, and destroy cancer cells outside the operative field. Postoperative radiotherapy “spares” those patients with more favorable pathologic lesions and can be given to a surgically “defined” area, but complications such as small bowel radiation enteritis are more frequent.

Melanoma

Treatment of malignant melanoma is based on depth of skin invasion, location on the body, and areas of potential metastatic spread. Punch biopsy may be satisfactory for histologic diagnosis, but excisional biopsy, including a small amount of subcutaneous fat, is preferable in order for the pathologist to define accurately the depth of invasion and tumor thickness. Pathologic staging should be done on permanent sections, because interpretation of frozen-section preparations can be misleading.

Thin, radial growth phase melanoma that has not penetrated through the papillary dermis (Clark's levels I and II) or is less than 0.76 mm thick seldom metastasizes or recurs locally and has a 95 percent chance of initial cure by adequate local excision. Adequate local excision usually can be achieved by wide excision of the biopsy scar with 1 cm margins sufficient to allow primary closure of the wound. Some lesions, particularly the superficial spreading type, may be too large for excision and primary closure, and flap rotation or skin grafting may be necessary. Similarly, skin grafts may be needed in areas of the body where skin is not easily mobilized, e.g., the sole of the foot.

Thick vertical growth phase lesions that have penetrated to the reticular dermis (level III), into the reticular dermis (level IV), or through it and into the subcutaneous fat (level V) have a much higher potential for metastasis. This risk is directly proportional to the depth of invasion (especially when greater than 1.5 mm in thickness) and to the location on the body (the risk in head and neck tumors is greater than that in trunk tumors, which is greater than that in tumors of the extremities). All regional node-bearing areas and the area between the primary melanoma and the regional lymph nodes should be carefully evaluated for clinical regional lymph node metastases or in-transit metastases coursing to the regional lymph nodes through the intradermal or subdermal lymphatics.

Surgical treatment of all thick (1.5 to 2 mm) melanomas must be directed to eradication of the primary tumor, areas of potential in-transit metastases, and the regional lymph node-bearing areas. Treatment of the primary lesion should include a wide excision with 1 cm margins. Treatment of regional lymph nodes also must be practical. A thick melanoma in the middle of the trunk may potentially metastasize to the axillary, inguinal, or supraclavicular lymph node areas on either side; prophylactic lymph node dissection of each of these locations would be impractical.

Adult Soft Tissue

Soft tissue sarcomas in adults may grow to a large size without detection, as they are often deeply situated. Prognosis has been shown to be correlated with tumor size, site, histologic type, and degree of differentiation. Tumors that are small (less than 5 cm), superficial (not extending beyond the superficial fascia), and low grade are grouped together as tumors with a favorable prognosis. Tumors that are large (more than 5 cm), deep (extending beyond the superficial fascia), and high grade have a poorer prognosis.

Traditionally, soft tissue sarcomas have been treated surgically (Fig. 9-28). Experience has shown that excision of only the tumor results in a local recurrence rate of 90 percent because of the “pseudocapsule,” an outer sheath of viable tumor cells that is stripped away and left behind after simple excision. Local recurrence rates are around 40 percent after more extensive resection and 10 to 25 percent after radical muscle group soft- part resection or amputation.

In a prospective randomized trial comparing amputation with wide local excision plus radiotherapy, local recurrences occurred in none of 16 patients treated with amputation, and 4 of 26 undergoing combined treatment. Eilber and associates reported a 3 percent local recurrence rate for extremity sarcomas treated with preoperative chemotherapy and radiotherapy, followed by en bloc resection of primary tumor with limb salvage.

Modifications of the protocol (e.g., reduction of radiation dose to a total of 2800–3000 cGy) are associated with excellent tumor control and reduced wound toxicity. Adjunctive radiation therapy, with or without chemotherapy, decreases local recurrence after a conservative surgical approach that *completely* removes the tumor with adequate surgical margins. The surgeon and radiation therapist ideally should plan their approach together. All areas of the operative site should be irradiated to minimize local recurrence.

RADIATION THERAPY

The effectiveness of radiation therapy, like surgical therapy, must be assessed by comparing local and regional tumor control with treatment- induced morbidity. Ionizing radiation is effective in the management of a wide variety of malignant tumors and is part of the treatment for 50 to 60 percent of patients with cancer. The radiation oncologist should be involved in the selection of patients and their evaluation before, during, and after treatment.

With radiation, tumors can be destroyed while anatomy is preserved. Often function and cosmesis can be preserved if the anatomy is intact before treatment. Concurrent medical problems have less influence on radiation therapy than on surgical or chemotherapy, although treatment-related sequelae may be more frequent or more severe in patients with certain systemic illnesses, such as diabetes or collagen vascular disease.

The differential effect of radiation on tumors and normal tissues results in a favorable therapeutic ratio in most clinical situations. Radiation can, however, have immediate and delayed side effects on normal tissues. The incidence and severity of late sequelae, which may progress over many years, are highly dependent on treatment technique. The type of equipment used, field arrangement, accuracy of tumor localization and field placement, treatment schedule, and expertise of the treating physician all influence outcome. The appearance of late sequelae may be the unfortunate consequence of treatment techniques long abandoned.

Physical Basis

Ionizing radiations are characterized by their capacity to ionize (and excite) atoms and molecules in an absorber such as tissue. Electromagnetic radiations can be produced artificially in kilovoltage radiation therapy units and linear accelerators by impinging energetic electrons on a target (e.g., tungsten). The energy of the resulting x-rays is related to the energy of the accelerated electrons as they reach the target material. Electromagnetic radiations of characteristic energy (gamma rays) are also produced by the radioactive decay of naturally occurring radioisotopes (e.g., radium 226) or artificially produced isotopes (e.g., cobalt 60). According to quantum physics, x-rays and gamma rays can also be represented as particles called *photons*. Removal of the target in a linear accelerator results in an emitted beam of high-energy electrons that have different absorption characteristics from photons and are very useful in the treatment of relatively superficial malignancies. Other types of particulate radiations (e.g., protons, neutrons, pi mesons, and helium ions) are produced by very powerful linear accelerators, or *cyclotrons*, and have been used therapeutically, primarily in investigative settings. Because the basic physical mechanisms of action of all ionizing radiations are the same, the different effects observed with equal physical doses result from differences in spatial or temporal distributions.

For decades, doses at the point of interest, such as the tumor or spinal cord, were grossly extrapolated from skin reactions or doses measured in air (in roentgens). Today clinical specification of radiation doses is derived from direct measurements of absorbed doses within the patient (using thermoluminescent dosimeters) or from doses calculated within a tissue phantom that simulates the human being. Phantom measurements are adapted for precise clinical application through the use of computer programs. Recent technological advances have made it possible to correct for tissue inhomogeneities (air cavities and bone) within the treatment volume using CT-based treatment planning.

Until 1980, absorbed radiation doses were quantified in rads, with 1 rad equal to 0.01 joule per kilogram of the absorber. According to the 1980 recommendations of the International Commission on Radiological Units, doses should be quantified in gray (Gy) units, with 1 Gy = 100 rad = 1 joule per kilogram of the absorber, and 1 cGy = 1 rad.

The availability of modern radiation therapy was initially facilitated by widespread distribution of cobalt 60 teletherapy units, dating to 1949, and the later versatile 4 to 6 MeV linear accelerators. Linear accelerators that produce a range of photon and electron energies between 4 and 25 MeV are available and are useful in a wide variety of clinical situations. Modern equipment provides deeply penetrating beams, short treatment times, isocentric patient setups, improved skin sparing, decreased bone absorption (compared with kilovoltage units), and sharp beam margins with less side scatter than the cobalt 60 units.

In some clinical situations, brachytherapy, or the direct placement of radioactive sources within tissue, may permit delivery of tumor doses higher than those achievable with external beam radiation therapy. Because the dose delivered falls off in a manner proportional to the square of the distance from the source, very high doses can be delivered to tissues immediately adjacent to the implant with relative sparing of surrounding normal tissues. A variety of artificially produced radioisotopes, including iridium 192, cesium 137, and iodine 125, are used in the treatment of cancers of the breast, prostate, brain, lung, head and neck, gynecologic organs, soft tissues, and eye. High-dose-rate (HDR) remote afterloaded brachytherapy, a new delivery technique that is gaining greater clinical acceptance, involves the delivery of several grays in minutes. Low-dose- rate (LDR) brachytherapy may require several days of hospitalization, but HDR can be delivered in a fractionated manner as an outpatient procedure. In HDR remote afterloading, a high-activity source is driven to a predetermined series of positions for specific periods. Because of the small source size, smaller-diameter catheters can be applied to interstitial and intraluminal sites, such as

the bronchus, esophagus, and bile duct, which previously could not be easily treated with LDR techniques. This computer- operated remote afterloading technique optimizes the dose distribution. These brachytherapy techniques have led the radiation oncologist into the operating room and into closer cooperation with the surgeon.

Biologic Basis

Radiosensitivity is the susceptibility of cells to injury by ionizing radiation. This injury may cause reproductive cell death by interrupting the cell's capacity to replicate indefinitely. Radiation can kill cells by interfering with critical cell functions unassociated with cell replication (“interphase death”); this is an important mechanism of radiation-induced cell death in lymphocytes and in normal salivary gland. The inherent radiosensitivity of most normal and transformed mammalian cells is remarkably similar, with doses of 110 to 240 cGy consistently reducing reproductive cell survival to 37 percent ($D_{0.37}$ dose). Therefore, differences in the rapidity and completeness of response of human tumors and normal tissues must be based on other factors, such as the capacity to repair sublethal damage, tissue oxygenation, cell cycle time and distribution, and repopulation.

Radiocurability is the ability of radiation to control a tumor permanently, allowing survival of the host. Tumor type, size, site, and extent have a greater influence on radiocurability than cellular radiosensitivity. *Radioresponsiveness*, or the rapidity of a tumor's response to radiation, may not correlate well with radiocurability. Epidermoid carcinomas of the oral cavity, larynx, skin, and cervix and adenocarcinomas of the breast, cervix, and prostate may be radiocurable despite relatively slow responses to radiation, and undifferentiated carcinomas often respond rapidly to radiation treatment but usually are not cured because of widespread tumor dissemination. However, differences in radioresponsiveness of tumors of a specific type and site may correlate with local tumor control.

Normal tissues have a greater capacity to repair injury than do tumor cells. Fractionation, or the division of a radiation dose into multiple smaller doses, allows recovery of this damage between radiation fractions. Laboratory and clinical studies indicate that an interfraction interval of at least 4 to 6 hours is necessary to permit maximal repair of sublethal injury. Because of their greater repair capacity, slowly dividing normal tissues usually are spared more than tumor cells by the use of relatively small fraction sizes, but rapidly dividing stem cell populations, such as bone marrow and mucosal surfaces, have less capacity for repair. The use of small doses per fraction improves the therapeutic ratio by reducing the late normal tissue effects of radiation more than the tumor effects. Although some protraction of treatment is necessary to permit repopulation of acutely responding normal stem cell populations and avoid intolerable acute normal tissue effects, treatment protraction also permits repopulation of tumor cells and should not be excessive. Empirical evidence suggests that daily fractions of approximately 2 Gy optimize the balance between these effects. Clinicians have been investigating the use of altered, hyperfractionated schedules that use two or three small fractions per day in an effort to further decrease late normal tissue complications without increasing the overall duration of treatment.

For similar reasons, cell killing can be modified by changes of the dose rate. To achieve tolerable individual treatment durations, external beam radiation therapy usually is delivered at a dose rate of 2 to 5 Gy/min. As the dose rate decreases, cell killing per unit of dose decreases. Low dose rates (i.e., less than 10 cGy/min) may favor repair in normal tissues. This effect is exploited clinically to improve normal tissue tolerance (particularly of the lung) in total-body irradiation and to allow delivery of very large total doses with low-dose-rate interstitial and intracavitary brachytherapy techniques.

Radiation-induced cell killing can be modified in other ways. Because molecular oxygen must be present for maximal cell killing by ionizing radiation, tumor cellular hypoxia can decrease the effectiveness of radiation therapy by as much as a factor of 3. This “oxygen effect” may explain the postirradiation persistence of tumor cells when there is necrosis or fibrosis.

The intrinsic radiosensitivity of cells can be increased by altering the target DNA, such as by replacing thymidine with halogenated pyrimidine analogues (BUdR, IUdR) during cell replication. Cell killing can be increased by inhibiting postirradiation repair processes. For example, the repair of DNA strand breaks can be inhibited by actinomycin D and doxorubicin and by heat (42 to 45°C). Unfortunately, current methods of altering the target DNA and inhibiting postirradiation repair are not selective for tumor cells and may not improve the therapeutic ratio.

Clinical Basis

Table 9-23 is a partial list of tumors that are treated with radiation. Irradiation may be the only anticipated treatment or may be combined with surgery and/or chemotherapy. The intent of treatment may be curative or palliative. In some clinical situations, surgery and radiation provide comparable rates of local tumor control with qualitatively different side effects. In these cases, the choice of treatment only can be made by a patient who has been carefully informed by a surgeon and radiation oncologist. Whenever curative treatment of malignancy is being considered, it is important that all the specialists (medical, surgical, and radiation oncologists) are involved before initiation of therapy. Previous surgical and chemotherapeutic management can significantly influence the therapeutic ratio of subsequent radiation therapy. Close cooperation from the beginning of therapy can often improve treatment outcome significantly. For example, careful marking of the margins of a tumor during surgery can help the radiation oncologist define a more accurate target volume and decrease the morbidity of therapy. Awkward placement of a surgical incision can dramatically increase the volume, complexity, and morbidity of subsequent irradiation. In some cases, the radiation oncologist can obtain valuable information by observing the operative field.

Decisions about the utility of radiation therapy are based on tumor-related factors (type, site, extent, typical natural history) and host factors (general condition, status of local and regional tissues). In almost all cases, definitive tissue diagnosis should be obtained before treatment to avoid inappropriately morbid treatment of benign conditions that mimic malignancy. On rare occasions when biopsy poses an unreasonable risk to the patient (e.g., tumors of the brainstem and optic tract), treatment may be initiated on the basis of strong radiologic diagnostic evidence. The introduction of CT and MRI should reduce diagnostic errors in these situations.

Histologic tumor type and grade may be useful pretherapeutic predictors of biologic behavior and radiocurability. The potential for local and regional tumor control is closely related to tumor size and the primary site. In most cases, radiation dose is limited by the tolerance of surrounding normal tissues. The probability of controlling a tumor with a tolerable dose of radiation is inversely proportional to its size and the number of proliferating clonogens that must be eliminated. Surgical tumor debulking procedures that leave gross residual disease are sometimes necessary to relieve tumor-related symptoms; they usually reduce the number of clonogens by less than one log, may increase tumor hypoxia, may decrease the tolerance of adjacent normal tissues, and rarely improve radiocurability. Large tumors are more likely to have spread regionally, sometimes requiring treatment of a larger volume with a consequent reduction of normal tissue tolerance.

The primary tumor site predicts biologic behavior and dictates which normal tissues will be affected by treatment. For example, small tumors of the glottic larynx rarely spread to regional nodes, and more than 90 percent of these tumors are cured with moderate doses of radiation to a small local field. By contrast, tumors of similar size originating a few millimeters away in the supraglottic larynx have a richer lymphatic supply, are associated with a greater likelihood of regional spread, and often require treatment with relatively large fields encompassing the regional lymph nodes. Even fairly large tumors of the cervix can be controlled locally with minimal risk of serious morbidity because of the high radiation tolerance of the uterus and vagina and the ability to deliver high doses with intracavitary therapy. Carcinomas of similar size in the upper abdomen are rarely controllable with radiation therapy alone because surrounding normal tissues such as liver, kidney, bowel, and spinal cord limit the deliverable doses of external beam radiotherapy. Intraoperative radiotherapy (the delivery of external beam radiotherapy directly to a tumor exposed during an operation) is currently being investigated as a possible means of increasing the radiation dose that can be delivered in such situations.

Goals

If the cancer is curable, a prolonged treatment course and a moderate risk of serious treatment-related morbidity are often accepted in an effort to overcome life-threatening disease. If the objective is palliation of cancer- related symptoms, treatment must be designed to minimize morbidity and inconvenience and maximize symptom relief. Even when seemingly indicated, radiation therapy could be inappropriate because of host factors. Debilitated or disoriented patients may not tolerate daily treatment. Local tissue changes induced by comorbid disease may cause the risk of curative treatment to outweigh the chance of benefit.

Dosage and Delivery

Treatment planning and delivery require close cooperation among health professionals, including medical physicists, dosimetrists, radiation therapy technologists, radiation therapy nurses, and radiation oncologists. The radiation oncologist begins by defining a target volume based on the patient's medical history, physical examination, radiologic studies, operative description, and pathology reports. This determination also considers the natural history of the disease, its anatomic routes of spread, and possible interactions among radiation, surgery, chemotherapy, and intercurrent disease. The therapeutic approach is designed to maximize the chance of tumor control and minimize the risk of treatment-related morbidity. In most cases, the primary tumor and adjacent area at risk for regional spread are graphically displayed and incorporated in a planned target volume.

Radiation can be delivered by multiple beams of photons or electrons, sometimes augmented by interstitial or intracavitary applications. Beam- shaping devices may be used to alter depth dose distributions and to shape the radiation field. The dosimetry data are incorporated in computer- assisted programs that allow rapid, accurate calculations of the desired options. The chosen treatment fields are simulated on the patient using a specialized machine built to the geometric specifications of the treatment machine but fitted with a diagnostic x-ray head and fluoroscope. The patient can be fitted with immobilization devices to improve the reproducibility of treatment. Marks on the patient's skin make it possible to reproduce the simulated fields during treatment. With careful immobilization and field localization, repetitive treatment delivery can be accurate to within a few millimeters.

Different sites in the same patient can be treated with different doses according to risk and the amount of tumor involvement. A relatively large volume including the primary tumor and surrounding areas at risk for harboring microscopic disease may be treated using a moderate dose. The primary tumor, grossly involved lymph nodes, or positive surgical margins may then be “boosted” to a higher dose with smaller external beam fields or with brachytherapy.

When the goal of treatment is palliation, the treatment dose and schedule are chosen to achieve symptom relief as quickly as possible, with little or no treatment-related morbidity. Because the dose is usually not pushed to normal tissue tolerance and the patient is not expected to survive to experience late effects of radiation, relatively large daily fractions may be used to shorten the overall treatment time. Treatment is given only to relieve symptoms or occasionally to prevent imminent problems (e.g., to prevent fracture in tumorous weight-bearing bones). Occasionally, aggressive radiotherapeutic treatment of hematogenous metastases may be indicated, particularly if the lesion is solitary and presents after a long disease-free interval.

Combination Modalities

Radiation therapy alone is curative in many clinical situations. Aggressive local or locoregional treatment yields high cure rates in many types of head and neck cancer, gynecologic malignancies, anal cancer, prostate cancer, Hodgkin's disease, and other neoplasms. In other cases, radiation is used in combination with surgery or chemotherapy. Radiation and surgery may be directed to the same site, e.g., when resection of a cancer of the hypopharynx is followed by irradiation, or when irradiation of a soft tissue sarcoma in an extremity is followed by surgery. Combined modalities may decrease the morbidity associated with either modality alone. Local tumor excision plus radiation therapy is an alternative to mastectomy for breast cancer. Treatment of soft tissue sarcomas with wide local excision and preoperative or postoperative irradiation achieves local control rates comparable to amputation but with preservation of the limb. In some cases, radiation and surgical treatment are directed to different sites, e.g., when orchiectomy is followed by irradiation of the retroperitoneal lymph nodes, or when a neck dissection follows interstitial irradiation of a cancer of the oral tongue.

Postoperative radiation improves local and regional control rates in many postsurgical situations. Because patients selected for postoperative therapy tend to be those with unfavorable clinical or histologic features, retrospective studies usually do not compare similar groups of patients and do not answer important questions about the influence of postoperative treatment on survival. However, even when the survival benefit of postoperative radiation is uncertain, treatment may be indicated to prevent local recurrence.

When surgery and radiation therapy are directed to the same site, the interval between them depends on a range of factors. Moderate-dose irradiation of a soft tissue sarcoma may be followed by resection in 10 to 14 days; rectosigmoid resection should be delayed 4 to 6 weeks after pelvic irradiation to allow for regression of edema and hyperemia. Most postoperative radiation therapy is delivered with relatively high doses directed to sites at high risk for persistent tumor. The optimal timing of postoperative radiotherapy depends on the type of surgical procedure, patient recovery, wound healing, and tumor characteristics and should be decided by the surgeon and radiotherapist. Unnecessary delays may allow time for tumor regrowth and decrease the efficacy of radiotherapy.

Planned combined treatment should not be confused with the use of one method after failure of another approach that often reduces the effectiveness of the second method. For example, irradiation of a tumor regrowing in tissues altered by surgery is likely to be ineffective because of decreased vascularity and increased tumor volume. It may have a higher morbidity because of abdominal adhesions that fix segments of bowel within the high-dose volume. Conversely, an aggressive course of radiation therapy that leads to fibrosis, loss of tissue planes, and decreased vascularity increases the incidence of complications from subsequent major surgery.

Side Effects

Any effective anticancer therapy can produce undesirable and occasionally dangerous side effects. Acute radiation-induced side effects can be distressing but can usually be managed conservatively and are almost always self-limited. The nature of these effects, summarized in Table 9-24, depends on the tissues included within the target volume.

The clinically important late sequelae of radiation therapy may not be apparent until months or even years after completion of treatment. The risk of late complications can usually be minimized (but not eliminated) by careful technique. In many situations, an effort to eliminate a small-to- moderate risk of major complications by reducing the radiotherapy dose will increase the risk of tumor recurrence.

The risk of second malignancies induced by ionizing radiation is small. In studies of more than 2,000 patients with head and neck cancer and 2,000 patients with cancer of the breast, no increase in the incidence of second cancers could be demonstrated in patients treated with radiotherapy. The increased incidence of leukemia in patients treated for Hodgkin's disease was strongly correlated with exposure to alkylating agents, although many of the patients also received radiation therapy. A very slight increase in the incidence of myelogenous leukemias (observed:expected = 1.4) was noted in 29,493 patients observed for 60,000 person-years after radiation for cervical carcinoma.

MANAGEMENT OF CANCER AT DISTANT SITES

Clinical Evaluation and Screening

If an initial screening appraisal indicates the need for a more extensive metastatic survey, then the presence and extent of metastases should be assessed by a comprehensive but cost-effective diagnostic evaluation. Components of this evaluation depend on the signs and symptoms of disease in a particular area (Table 9-25) and the goals of treatment (cure versus palliation). Laboratory tests, except for screening, should not be ordered unless the results would change the treatment plan. Other factors to be considered are the cost and availability of further tests, prognostic factors, and the natural history of the disease.

These principles are also important postoperatively in determining how long and how often to follow the patient and what types of screening tests should be used. In general, the patient should be evaluated every 3 to 4 months for the first 2 years, at 6-month intervals to the fifth year, and then at least once a year indefinitely. Chest x-rays and/or laboratory tests are obtained initially at 6-month intervals and then yearly or as indicated. The exact frequency of screening depends on the risk of recurrent metastatic disease; patients with very early cancer (e.g., melanomas less than 1.0 mm) might be evaluated at 6-month to 12-month intervals from the beginning, but those at high risk for metastases should be evaluated every 2 to 3 months during the first 2 years. Because a large proportion of recurrences are detected by the patients themselves, high-risk patients should be briefed on possible symptoms and urged to seek immediate medical attention should they appear.

History and Physical Examination

A hallmark of metastatic disease is a symptom complex that progresses in intensity or frequency. A careful history and physical examination are the most sensitive, specific, and cost-effective means of evaluating possible metastatic disease, short of a biopsy.

Laboratory and Radiological Tests

The chest x-ray should be used routinely for screening. Whole-lung tomograms or CT scans of the chest are useful for evaluating suspected pulmonary, pleural, or mediastinal metastases (Fig. 9-29). Serum liver function tests, including lactic dehydrogenase level, are important screening tools for metastatic disease. An isolated elevation of the serum alkaline phosphatase or lactic dehydrogenase level is presumptive evidence of metastatic disease. A CT or ultrasound scan of the abdomen should be obtained if physical examination or abnormal liver chemistry suggests intraabdominal metastases.

Some solid tumors produce circulating tumor secretory products that represent marker molecules. These tumor markers can be used to monitor for recurrence or assess the response to treatment (see Table 9-20). Marker molecules are not infallible, however, and a tumor cell population may emerge that fails to secrete the marker being monitored.

Bone and brain scans are not indicated for routine screening of occult metastatic disease because their diagnostic yield is low, except for those cancers that frequently relapse first in the bone, such as breast cancer and prostate cancer. A radionuclide bone scan is the most sensitive test for skeletal metastatic disease, but a careful history and directed radiographs are necessary to ensure that areas of uptake do not represent areas of old trauma or inflammation.

Positron emission tomography (PET) has become a widely used investigative and clinical tool for cancer detection and diagnosis, cancer staging, and cancer treatment monitoring. This use of PET technology is based on the observation that malignant transformation of cells is associated with an increased glycolytic rate (even in the presence of oxygen), which is correlated with uptake of fluorine-18 deoxyglucose (FDG). PET scanning can detect tumors as small as 10 mm. It is useful for detecting brain tumors, metastatic melanoma, and metastatic malignancies of the head and neck, breast, lung, and colon.

Pathologic Tests

The definitive diagnosis of metastatic disease is made by biopsy analysis. An excisional or needle biopsy procedure is relatively easy when the suspected metastasis is superficial. Deeper lesions may also be approached with a fine-needle biopsy. In many circumstances, a clinical diagnosis made by radiologic studies is sufficient, especially if metastases involve more than one site at the same time and the abnormality was absent on previous studies.

Cytologic examination of urine, sputum, cerebrospinal, peritoneal, or pleural fluid, or of bone marrow also may yield a diagnosis of metastatic disease, especially with specific symptoms referable to these areas. A common problem in the diagnosis of metastatic cancer is distinguishing a metastatic lesion from a primary anaplastic, undifferentiated carcinoma or lymphoma, e.g., when an anaplastic lung lesion appears in a patient who had a primary anaplastic or undifferentiated carcinoma or lymphoma. When an anaplastic lung lesion appears in a patient who had a primary melanoma removed 5 years previously and is a heavy cigarette smoker, should this be diagnosed as a metastatic melanoma or a lung carcinoma? Electron microscopy and immunostaining with antibodies of cytologic specimens and tissue specimens can be crucial in aiding the pathologist in the diagnosis.

General Principles of Treatment

The treatment of a patient with advanced cancer depends on the number and sites of metastases, their rate of growth, types of, and responses to, previous treatment, and the patient's age, overall condition, and desires. For example, vigorous treatment might be appropriate for a slowly growing solitary metastasis, but only symptomatic treatment, or none at all, might be used in a debilitated patient with multiple metastases for whom prior treatment has failed. The option of no treatment is particularly important in patients who are asymptomatic, terminally ill, or very old. For example, a physician may choose to observe an asymptomatic patient with slowly growing tumors in sites such as the lung. Quality of life is maintained in this instance, and treatment can be instituted when the size or number of metastases increases or when the patient develops symptoms. A patient should never be denied treatment when there is a reasonable expectation of success and an acceptable risk of toxic effects.

The number of organs or tissues containing metastases is the most significant factor predicting survival in patients with distant metastases. For example, the median survival is 7 months for melanoma patients with metastasis to one site, 4 months for those with metastases to two sites, and only 2 months for those with metastatic disease at three or more sites. The location of the metastases is also important. Sites associated with relatively favorable outcomes for melanoma and breast cancer include (in approximately descending order of frequency) the skin, subcutaneous tissue, distant lymph nodes, bone, and lung. Unfavorable outcomes are associated with metastases to the liver and brain. Metastases in favorable sites are associated with long-term survival (i.e., 2 to 5 years) in a small but measurable proportion of patients. If the patient has received previous therapy, such as chemotherapy or surgery for a systemic metastasis, the survival time is likely to be shorter. Patients in a debilitated state are less likely to withstand vigorous treatments than those who are not suffering symptoms of metastatic disease.

Defining the Goals, Benefits, and Risks of Treatment

The first goal of treatment is relief of symptoms. Treatment to relieve symptoms is worthwhile, especially when the benefit of symptom relief exceeds the risk of toxic effects and morbidity. Its efficacy can be monitored by subjective and objective assessment of the symptoms caused by the metastases.

The second goal of treatment is to prolong life. This has not been achieved in most patients with advanced cancer. One exception is the surgical removal of solitary metastases from skin and subcutaneous tissues or visceral sites such as the lung or brain (see Fig. 9-27). Curative surgical excision of solitary metastases of melanoma in visceral organs can lead to 5-year survival rates exceeding 40 percent.

Table 9-26 presents the treatment modalities for patients with metastatic disease. The choice of treatment should consider potential toxicity, requirements for hospitalization, frequency of treatments, and median time necessary to attain antitumor response. The physician must understand the potential risks of each treatment as they apply to a particular patient. Patients who have a good performance status (who are able to care for themselves and have no debilitating symptoms from their disease), good cardiac and pulmonary function, and adequate white blood cell and platelet counts are usually candidates for clinical trials. Available effective methods for relief of symptomatic disease should be considered first.

Patient Counseling

One of the greatest causes of anxiety for the cancer patient is uncertainty. Patients should be counseled so that they can participate in treatment decisions, cope with their disease

realistically, and arrange their personal lives. Although some patients do not want a full presentation of the facts, some discussion is warranted because it is difficult to initiate treatment without explanation. If the physician and the patient do not communicate honestly and openly, the patient could lose trust in the physician and might not accept subsequent treatment recommendations.

When counseling patients and their families, the physician must be sympathetic, realistic, and hopeful about the results of treatment. Patients need hope, and even in grim situations treatment can achieve certain goals, if only the relief of symptoms. In other words, the physician should continue treating the patient even when it is no longer possible to treat the cancer. The approach depends on the patient's prognosis, physical condition, and emotional stability. The patient's desires should be strongly considered when choosing among alternative forms of palliative treatment.

Surgery

Curative Procedures

Once a neoplasm has metastasized to a distant site, it should no longer be curable by surgical resection, but removal of metastatic lesions in the lung, liver, or brain has occasionally produced a clinical cure (Fig. 9-30). Therefore, in selected patients with slowly growing neoplasms, curative resection of the metastatic lesions may be indicated, especially if the metastasis is solitary. Observation for several weeks or months sometimes provides relevant information about the rate of tumor growth and the possibility of metastases emerging at other sites. All patients considered for curative resection must undergo an extensive workup to rule out metastatic spread. Among the components of this workup are a complete blood count and serum chemistry panel, applicable serum tumor markers, MRI of head, CT of chest, abdomen, and pelvis, and a bone scan, if applicable. Newer whole-body imaging studies, such as *PET* scanning, may eventually replace conventional radiologic techniques. Curative resection should be attempted only if the lesions are accessible and the procedure can be performed safely.

Palliative Procedures

Surgical procedures are sometimes indicated to relieve the symptoms or reduce the severity of disease, or to prolong a useful, comfortable life without attempting cure. A palliative operation that improves quality of life by relieving pain, hemorrhage, obstruction, or infection is justified when it can be done safely without great discomfort to the patient. Surgery that only prolongs a miserable existence does not benefit the patient. Some examples of palliative surgical procedures are colostomy, enteroenterostomy, or gastrojejunostomy to relieve obstruction; chordotomy to control pain; cystectomy for infected, bleeding tumors of the bladder; amputation for painful infected tumors in the extremities; simple mastectomy for carcinoma of the breast, even in the presence of distant metastases, when the primary tumor is infected, large, ulcerated, and locally resectable; colon resection in the presence of hepatic metastases; and biliary bypass procedures. Additionally, gastrostomy or jejunostomy may be undertaken to improve nutritional intake and administration of medications. Cerebral metastases that are not resectable by conventional surgical techniques can be ablated by stereotactic radiosurgery using a “gamma knife” that delivers focused radiation to specific brain lesions.

The decision to use palliative surgery depends on the site of the disease and the duration of anticipated survival. If the patient's life is measured in weeks, the surgical ablation of a metastasis is not justified, but longer anticipated survival may render excision of gross disease worthwhile.

Radiation Therapy

Irradiation has a role in the treatment of patients with advanced cancer, particularly those with symptomatic lesions. It is used as palliative treatment for patients with bone or brain metastases and for symptomatic lesions located in the skin, subcutaneous tissues, or lymph nodes. Radiation therapy using high-energy beams relieves the pain of bone metastases, often within 1 week. Cranial (whole-brain) and spinal cord irradiation is used for central nervous system metastases. Irradiation from high-energy proton beams using a linear accelerator also can effectively treat superficially located metastases in the skin or soft tissues.

Chemotherapy

Modern use of chemotherapy began in the 1940s with the administration of hormonal therapy using androgens and estrogens and the use of the alkylating agent nitrogen mustard. Throughout the 1950s, chemotherapy was given on empirical grounds, using doses and scheduling previously found to be successful in antimicrobial therapy. Daily oral administration of fixed drugs was generally used. Although responses were occasionally seen, clinical relapse was universal. In the early 1960s, Skipper founded the principles still used in designing chemotherapeutic trials:

- (1) A single cancer cell can grow into a lethal tumor mass.
- (2) The rate of tumor growth (tumor doubling time) slows with increasing tumor burden in the later stages of tumor growth.
- (3) Most chemotherapeutic agents exhibit log cell kill kinetics, and the same increment of log cell kill is seen with subsequent doses.
- (4) Tumor burden is inversely related to curability by chemotherapeutic agents.

The comparison of antimicrobial therapy for bacterial infections and chemotherapy for malignant disease has major limitations. An immunocompetent host recognizes bacterial antigens as foreign and mounts a defense. Antimicrobial therapy will kill bacteria or arrest bacterial proliferation until host antibodies and immune effector cells expand to eliminate remaining viable bacteria. By contrast, a cancer patient's immune system may not recognize tumor cells as foreign because tumors arise from normal cells through mutational events that uncommonly lead to significant cell-surface alterations. Even after significant cell kill by chemotherapy, the host's immune system may not recognize and attack the remaining viable tumor cells, allowing their regrowth (Fig. 9-31).

Systemic or regional delivery of diffusible pharmacologic agents can destroy or arrest tumor cells capable of proliferation. Currently available drugs are not selective for tumor cells; they affect all dividing and some quiescent cells. Since most agents act on one or more stages of cell cycle, cells and tissues with the highest growth fraction will be most affected. Chemotherapy attempts maximal tumor cell kill with minimal and acceptable toxicity to normal host tissues.

The primary target of chemotherapeutic agents is the tumor stem cell. Complete destruction of all tumor stem cells is essential for cure. Pioneering studies with L1210 murine leukemia, which has a 100 percent growth fraction, fostered the concept of log tumor killing. If a single dose of drug reduces the tumor cell number by 99 percent (a 2-log kill), then subsequent identical drug doses will decrease tumor cell number by the same log decrements. If a 1 cm tumor contains approximately 10^9 cells, then even a 99.999 percent cell kill (a 5-log kill) will leave 10^4 viable tumor cells. The so-called clinical complete response, defined as disappearance of all measurable disease, usually results in recurrent disease because several million viable, but undetectable, proliferating cells may still be present in one or more sites.

Chemotherapy was initially attempted to cure patients with macrometastatic disease. Although chemotherapy is still important for gross metastatic disease and may produce dramatic clinical responses, cures are rare and limited to some pediatric malignancies, hematologic malignancies, Hodgkin's and some non-Hodgkin's lymphomas, testicular neoplasms, and choriocarcinoma. Equal attention is being directed toward preoperative chemotherapy and postoperative treatment for presumed micrometastatic disease. Most human tumors do not undergo exponential growth in vivo but demonstrate a slowing of growth with progressive tumor size. The growth fraction peaks well before clinical detection. Smaller-volume disease is presumed to be more responsive to drugs active against proliferating cells and provides the rationale for treatment in a postoperative or adjuvant setting.

Resistance to Chemotherapeutic Agents

The concept of tumor cell log kill presumes that all cell subpopulations within a tumor are chemosensitive. Clinical drug resistance is responsible for the majority of chemotherapy failures. Resistant subpopulations of cells may exist de novo within tumors or may arise by spontaneous or induced mutations. Chemoresistant cells probably do not emerge until a tumor reaches a critical mass of approximately 10,000 to 10 million cells. This may take several years for many solid tumors. Above this mass, the likelihood of one or more chemoresistant clones increases exponentially with subsequent tumor growth. It is extremely important to begin chemotherapy as early as possible.

There appear to be several different general mechanisms of drug resistance for different classes of chemotherapeutic agents (Table 9-27). Tumors are often resistant to several agents that may be structurally unrelated. This *multidrug resistance (MDR)* can also occur by several different mechanisms. An MDR gene has been identified; its protein product, P-glycoprotein, causes the efflux of several different drugs from the intracellular space of target host cells in vitro. Drugs affected by overexpression of the MDR gene include several natural products, such as the anthracycline doxorubicin, the vinca alkaloids vinblastine and vincristine, actinomycin D, and the epidophyllotoxins, such as etoposide (VP-16). High levels of P-glycoprotein are found in normal cells lining the luminal spaces of the gastrointestinal tract, liver, and kidney, where this gene product is presumed to induce an active efflux of environmental toxins from the body. The efflux pump can be blocked in vitro by calcium channel blockers, such as verapamil, which is currently undergoing clinical study. Other compounds that are effective in reversing MDR include tamoxifen, cyclosporin A, a nonimmunosuppressive analog of cyclosporin (SDZ PSC 833), and an antifungal triazole (itraconazole).

The search for potent, selective modulators of *MDR* will promote a new generation of agents. Compounds that are active in vitro and in vivo include: RS-33295-198, SR33557, a new quinoline derivative (MS-209), a novel triazolinopiperidine (S9788), and an acridonecarboxamide derivative (GF 120918). Other mechanisms of MDR include: alterations in drug-conjugating enzymes, such as glutathione S-transferase; alterations in components of the cytochrome P-450 enzyme complex, such as aryl hydrocarbon hydroxylase; or alterations in drug transport enzymes, such as glucuronyl transferase. Additionally, MDR may involve allosteric alterations in DNA through interference with activity of topoisomerase II, an enzyme responsible for maintaining DNA's secondary and tertiary structure. Molecular probes are being developed to identify additional genes involved in MDR. Antibodies against P-glycoprotein are available and under investigation for diagnostic and therapeutic use. A new marker for MDR has been described. Specific glycosylated lipids appear to be expressed in high levels in drug-resistant cells and tumors. Detection of these lipids may signal the need for aggressive chemotherapy in combination with the new MDR modulators.

Classification of Chemotherapeutic Agents

Anticancer drugs may kill tumor cells, but the majority act by preventing cell division and cell proliferation. Most drugs affect one or more components of the cell cycle. The classification of anticancer drugs as non- cell cycle-specific, cell cycle-specific, or phase-specific is relative rather than absolute. DNA synthesis can be prevented by blocking the availability of purine and pyrimidine nucleotide precursors. DNA may be damaged by cross-linking with unstable alkyl groups. DNA transcription can be prevented by direct binding of drug to DNA. Mitosis can be arrested through binding of tubulin and prevention of mitotic spindle formation. Drug combinations are often based on the complementary effects of phase-specific agents on rapidly dividing cells, and non-cell cycle-specific agents on dividing and nondividing cells.

Alkylating Agents

Alkylating agents are non-cell cycle-specific agents that contribute an unstable alkyl group to cross-link nucleic acids (primarily DNA). The major effect is on cells in G1 or mitosis, but high doses may also have cytotoxic effects on cells in G0. Alkylating agents have antitumor activity against Hodgkin's and non-Hodgkin's lymphoma, leukemias, multiple myeloma, and carcinomas of the breast, endometrium, testis, and lung. Cyclophosphamide and cisplatin (CDDP) are used in a variety of solid tumors. Dacarbazine (DTIC) and ifosfamide have documented antitumor activity against soft tissue sarcomas and other neoplasms.

Nitrosoureas are a subgroup of alkylating agents with increased lipid solubility, and better central nervous system penetration. They also may act by carbamoylation, affecting DNA and RNA. They do not exhibit cross- resistance with other alkylating agents. There is a small but important incidence of secondary malignancies (especially leukemias) several years after therapy with nitrosoureas.

Antimetabolites

These agents interfere with DNA and RNA synthesis and are phase-specific for the synthesis phase of the cell cycle. An exception is *5-fluorouracil (5-FU)*, which is phase-specific and cell cycle-specific. Antimetabolites are most active in rapidly proliferating tumors such as the hematologic malignancies but also have wide applicability in many solid tumors, especially breast cancer and gastrointestinal malignancies. These drugs may include structural analogues of metabolites essential in normal growth and proliferation that become incorporated as a false message, such as the pyrimidine analogue cytarabine (Ara-C). Other actions include reversible or irreversible binding to key or rate-limiting enzymes in the synthesis pathways, such as the relatively irreversible binding of methotrexate to the enzyme dihydrofolate reductase (DHFR). Leucovorin (folinic acid or citrovorum factor) is the most stable form of folic acid and may be given to replenish the intracellular folate pool. It can be administered after a high- dosage methotrexate regimen to “rescue” normal tissues by repleting folate and bypassing the block at DHFR. If given in combination with 5-FU, leucovorin potentiates the antitumor effect of 5-FU by stabilizing the covalent bond of 5-FdUMP (the active metabolite of 5-FU) to the enzyme thymidylate synthase.

Plant Alkaloids

Derivatives of the periwinkle plant include the vinca alkaloids vinblastine, vincristine, and vindesine. All three inhibit mitosis by binding microtubules and causing arrest in metaphase. The vinca alkaloids have antitumor activity against Hodgkin's and non-Hodgkin's lymphomas, acute leukemias, breast, testicular, head and neck, renal, and cervical carcinomas, and other solid tumors. Although these three compounds share a similar chemical structure, they have a wide spectrum of clinical activity and toxicity.

Derivatives of the mandrake plant, the epidophyllotoxins etoposide (VP-16) and teniposide (VM-26), may act through inhibition of nucleoside transport and incorporation into DNA and RNA. These drugs show phase-specific activity for cells in G2 and late S phase. Clinical activity has been seen against lymphomas, leukemias, lung, bladder, prostate, and testicular carcinomas, hepatomas, and other solid tumors.

The plant alkaloids are prominent targets for the P-glycoprotein product of the *MDR* gene, resulting in clinical drug resistance.

Antibiotics

A wide spectrum of antitumor drugs have been isolated from microorganisms. These drugs are generally considered non-cell cycle- specific agents and appear to interfere with the synthesis and/or function of nucleic acids. Doxorubicin, bleomycin, mitomycin C, and dactinomycin are examples that have wide clinical application.

Doxorubicin was derived from *Streptomyces* species and has demonstrated activity against many solid tumors, such as soft tissue sarcomas, carcinomas of the breast, lung, esophagus, stomach, liver, bladder, prostate, head and neck, testis, and endometrium, among others. The mechanism of action appears to involve intercalation into DNA with triggering of topoisomerase II-mediated DNA cleavage to alter the tertiary structure of DNA. A close analogue, daunomycin, has shown antitumor activity against acute lymphoblastic and myeloblastic leukemia.

Bleomycin was derived from a *Streptomyces* species and causes single- and double-strand breaks in DNA but not RNA. It has antitumor activity against squamous cell carcinomas, lymphomas, testicular and lung carcinomas, malignant melanoma, soft tissue sarcomas, and mycosis fungoides.

Mitomycin C is a non-cell cycle-specific antitumor antibiotic that acts as an alkylating agent to cross-link DNA and inhibit DNA and RNA synthesis. Antitumor activity has been demonstrated against many gastrointestinal malignancies and breast, lung, cervix, and bladder carcinomas.

Dactinomycin (actinomycin D) is an antitumor antibiotic derived from a *Streptomyces* species. It prevents DNA and RNA synthesis by binding to the deoxyguanosine moieties of DNA. Single-stranded DNA breaks have also been demonstrated. It has antitumor activity against malignant melanoma, testicular tumors, choriocarcinoma, Wilms' tumor, neuroblastoma, retinoblastoma, and several sarcomas.

Miscellaneous

Tamoxifen citrate is a nonsteroidal antiestrogen with cytostatic effects mediated through competitive inhibition of the estrogen receptor (ER) and several other emerging non-ER pathways. Tamoxifen has a clear role in the therapy of hormone-dependent tumors of the breast and prostate. Recent large studies have demonstrated antitumor activity against hormone receptor-negative breast carcinoma and possible protection against contralateral and recurrent breast carcinoma. Additionally, some beneficial claims have been made regarding the possible prevention of osteoporosis and atherosclerotic heart disease through an ER effect. Although the ER- mediated mechanisms of tamoxifen have become more complex and confusing, the clinical applications have expanded as a result of the apparent benefits and the relatively low toxicity of outpatient oral therapy.

Levamisole is an antihelmintic drug recently used as an antitumor agent because of reported immunorestorative activity for functionally impaired macrophages and T lymphocytes. Two large, randomized, prospective trials have shown a survival benefit in levamisole combined with *5-FU* in the adjuvant treatment of modified Duke's C adenocarcinoma of the colon. Levamisole also is being used in combination with other agents for rectal carcinoma.

Drug Selection

The National Cancer Institute (NCI) has established three phases for testing new drugs prior to general availability. Phase I clinical trials are designed to determine the maximal tolerated dose (MTD) of drug, drug toxicity, and schedule for use in phase II trials. Phase I trials usually are limited to patients whose advanced disease has not responded to standard treatments. Schema frequently include three patients at each escalating dose until toxicity is observed. Patients are informed that the likelihood for a major clinical response is small, but responses are monitored and documented.

Phase II clinical trials attempt to estimate the response rate of specific tumor types to a particular drug. Fifteen to 25 patients with a specific tumor type are initially entered. If no responses are seen, the study is usually terminated. Phase II trials may or may not randomize patients. Patients with a good performance status and a minimum of previous treatment are preferred, to allow the highest probability of showing a favorable effect. Response to the drug must be measurable to allow quantitative assessment. Phase II trials assess the activity but not the efficacy of a particular drug. A minimal response rate of 20 percent is generally required to proceed to phase III trials.

Phase III trials determine whether a drug with known activity contributes significantly to the treatment of a disease. A comparative study with new treatment versus standard treatment(s) is used to determine the efficacy of the new treatment. The standard treatment may consist of no treatment or other chemotherapeutic agents. Large numbers of patients, long follow-up, and extensive clinical and biostatistical resources usually are required. Patients in different treatment groups must be comparable in every way, including stratification for known or suspected prognostic variables, such as sex, age, and tumor stage. A randomized, controlled trial does not use historical controls. It may have several treatment arms, but each patient is randomly assigned to only one arm. As the number of treatment arms increases, so does the number of patients required for statistically valid comparisons. Patient eligibility and entry, the timing and method of randomization, and the endpoints to evaluate response and toxicity are determined before the start of the study. The end point of many phase III trials is overall survival, but other common study end points included disease-free survival, tumor response rates, and palliation of symptoms. Phase III trials often require multi-institutional participation to accrue sufficient numbers of comparable patients over a reasonable period. Intra- and interinstitutional quality control is required to reach valid conclusions.

Dose and Timing

To achieve maximal tumor cell kill, the highest tolerated dose is given over the shortest possible time. The dosage is based on the MTD derived from phase I and II studies and must be tailored to a patient's performance status, medical illness, or organ dysfunction.

Drug dosing was traditionally described in milligrams per kilogram (mg/kg). The current, and more reliable, standard of drug dosing is in terms of body surface area, described as milligrams per square meter (mg/m²). There are many nomograms to convert mg/kg to mg/m². A simple and relatively accurate conversion multiplies the mg/kg dose by 40 to yield the mg/m² dose. Alterations are often made for patients whose actual weight is markedly different from their ideal weight, e.g., obese patients or patients with large volumes of “third-spaced” fluid collections, such as pleural effusions, ascites, or edema. These alterations must consider the drug's pharmacology and volume of distribution.

The interval between doses depends on a drug's toxicity. For most chemotherapeutic agents with bone marrow toxicity, leukopenia and thrombocytopenia become evident on a complete blood count by day 9 or 10 and are most pronounced between days 14 and 18. Recovery usually begins by day 21 and is approximately 90 percent by day 28. This provides the rationale for a 28-day course or cycle of marrow-suppressive agents. Bone marrow recovery time may be delayed in onset or prolonged because of previous chemotherapy, radiation therapy to marrow-producing bone, or inherent toxicities of a few specific drugs, but an interval that is long enough to assure the safe recovery of bone marrow production may also allow recovery and repopulation of remaining tumor cells. Administering combinations of drugs can overcome the problems of single-drug toxicity and drug-resistant cell populations.

Combination Therapy and Dose Intensification

Single-agent therapy has produced cures only in choriocarcinoma and Burkitt's lymphoma. The best strategy is to treat as small a tumor as possible, as early as possible, using a combination of drugs to minimize the emergence of resistant clones during therapy. Combination chemotherapy is an attempt to provide antitumor therapy to all resistant cell populations at the earliest possible time without increasing the toxicity to normal tissues. Combination therapy usually uses only those drugs that are also effective as single agents against a particular tumor. Drugs with cell cycle and non-cell cycle specificity can be combined to target both dividing and quiescent tumor subpopulations. Nonoverlapping toxicities are essential to avoid life- threatening injury to normal tissues.

Dose intensification has been promoted to allow comparisons of the relative effectiveness of each drug used in combination therapy and to optimize drug dose delivery during a course of combination chemotherapy. Relative dose intensity (RDI) is the proportion of drug delivered per unit of time (usually 1 week) relative to an arbitrary standard dose of that drug over the same interval. For example, during a 28-day cycle of combination therapy, a cyclophosphamide standard dose of 80 mg/m²/day by continuous infusion (a dose

intensity of 560 mg/m²/week) is compared with a cyclophosphamide test regimen of 100 mg/m²/day given only on days 1 to 14 (a dose intensity of 350 mg/m²/week). The RDI of the test regimen is 350/560 = 0.63. The test dose of cyclophosphamide is higher during the first half of the 28-day course, but the overall total dose per course is less than the standard dose.

The importance of optimizing dose intensification has been documented in laboratory animal models bearing curable tumors, in which as little as a 20 percent decrease in dose intensity of an effective drug can result in a 50 percent decrease in cure rate. Comparisons of dose intensity in combination drug trials for breast, ovarian, and colon carcinomas and for lymphomas have demonstrated a strong correlation between dose intensity and response rates.

Induction, Adjuvant, and Neoadjuvant Chemotherapy

Induction chemotherapy is the use of chemotherapy as the sole form of treatment for advanced disease. The patient usually has multiple sites of metastatic disease and is not a candidate for locoregional treatment by surgery or radiation. If induction chemotherapy is unsuccessful, a change to other chemotherapeutic agents or combinations, or salvage therapy, is considered.

Adjuvant chemotherapy is the use of regional or systemic chemotherapy after locoregional tumor elimination by surgery or radiation therapy. Adjuvant therapy attempts to eliminate residual micrometastatic disease and usually is limited to patients at moderate-to-high risk for local or distant recurrence. Since there is no tumor visible at the time of treatment, response can be evaluated only by monitoring rates of recurrence, disease-free survival, and overall survival. The choice of agents is based on response rates seen with advanced disease of the same histologic type. Therapy is intensive but limited in duration; any benefit against microscopic disease is most likely to occur during the first few courses, as long as adequate cytotoxic doses are given. Few studies show any added benefit to “maintenance” adjuvant chemotherapy.

Neoadjuvant or primary chemotherapy is the use of chemotherapy as the first treatment for localized solid tumors such as breast, gastrointestinal, and pediatric carcinomas, extremity sarcomas, and localized lymphomas, among others (Fig. 9-32). It has several advantages. First, it may reduce the size of large or locally advanced tumors, allowing a safer resection that spares surrounding normal tissues, as in breast conservation surgery, anal sphincter preservation with mid-to-low rectal tumors, and limb preservation with extremity sarcomas. Second, tumor responsiveness to chemotherapy can be determined while grossly or radiologically visible tumor is still present; agents that produce an initial complete or major partial response will be continued postoperatively. A third potential advantage is immediate treatment of possible micrometastatic disease. On the other hand, unsuccessful neoadjuvant chemotherapy can delay locoregional interventions, and tumor progression during this time may preclude safe resection or require sacrifice of additional normal surrounding structures to obtain adequate resection margins. Preoperative chemotherapy may confuse pathologic staging of resected tissues, complicating future treatment decisions and prognosis.

Drug Delivery

Intravenous administration, the most common route for chemotherapeutic agents, delivers uniform doses of one or more drugs to all capillary beds and end organs with known or presumed metastatic disease. Regional arterial chemotherapy and intraperitoneal chemotherapy are other common routes of delivery. Less common applications include intravesical bladder therapy, topical therapy of skin tumors, intrathecal therapy for meningeal disease, and intrapleural drug instillation for malignant pleural effusions.

Intraperitoneal Administration

Intraperitoneal chemotherapy delivers relatively high doses of a chemotherapeutic agent to the serosal surfaces of the peritoneal cavity. The use of soft, indwelling peritoneal catheters connected to a subcutaneous access port has greatly diminished the risk of catheter-related infections. Intraperitoneal chemotherapy might be considered when peritoneal metastasis or liver metastasis is the dominant pattern of failure. It has been used in abdominal neoplasms that demonstrate abdominal carcinomatosis or malignant ascites, such as ovarian, colorectal, pancreatic, and gastric carcinomas, retroperitoneal sarcomas, pseudomyxoma peritonei, and abdominal mesotheliomas.

The depth and rate of diffusion of chemotherapeutic agents through peritoneal serosa and into peritoneal tumor depends on their size, lipid solubility, and charge. A large molecule with a low lipid content and a positive or negative charge will have a lower rate of peritoneal surface absorption and a longer exposure to peritoneal surfaces. Drugs for intraperitoneal administration should have known tumoricidal activity, low peritoneal permeability to maximize the duration of peritoneal drug exposure, and rapid plasma clearance. Cisplatin is one of the most commonly used agents.

The drug must be evenly distributed throughout the peritoneal cavity to optimize exposure and prevent excessively high drug concentrations in focal fluid loculations. Equal drug distribution requires the absence of adhesions, necessitating the administration of therapy perioperatively and a duration of therapy limited to days. Additionally, studies of peritoneal cavity fluid distribution after transperitoneal catheter infusion using water-soluble contrast or radionuclides have demonstrated the need for instillation of 1 to 2 liters of crystalloid to assure equal distribution.

Intraperitoneal chemotherapy has been investigated for several years in the treatment of minimal residual disease in ovarian carcinoma, but an overall survival advantage has been difficult to demonstrate because of the lack of randomized, controlled clinical trials. The efficacy of this therapy in other intraabdominal, abdominal, and pelvic malignancies is under investigation. The ideal setting for intraperitoneal chemotherapy is at the time of laparotomy or laparoscopy in a patient with positive peritoneal cytology obtained by lavage. Intraperitoneal chemotherapy is a good option for patients with smaller tumor masses or patients at high risk for recurrence.

Regional Artery Administration

Regional arterial drug therapy to specific organ sites has been used for several primary and metastatic solid tumors, including head and neck carcinomas, primary and recurrent gastrointestinal and pelvic malignancies, extremity sarcomas, in-transit metastatic melanoma, and primary or metastatic hepatic tumors.

Limb perfusion in extremity melanoma employs vascular isolation of an affected extremity through external iliac or axillary arterial and venous cannulation and placement of a proximal limb tourniquet to minimize systemic drug leakage. A high concentration of drug with or without limb hyperthermia then can be perfused over approximately 1 h and extracted via an extracorporeal dialysate pump oxygenator before reestablishment of normal limb perfusion. The maximal drug dosage is limited by limb tissue toxicity and not by systemic drug levels, and the procedure is accompanied by the considerable additional morbidity associated with operative limb vascular access and compromised wound healing.

Chemoembolization, used in the treatment of primary hepatomas or neuroendocrine tumors that have metastasized to the liver, delivers drug-impregnated pellets or sponge spheroids that temporarily or permanently occlude end-arteries selectively supplying tumor-bearing liver, slowing tumor blood flow, and increasing the time of drug exposure to the tumor. The same decrease in flow has been accomplished with internal or external, surgically placed, temporary hepatic artery occlusion catheters, which can be manipulated to cause tumor ischemia after hepatic arterial infusion of drug.

The high tissue extraction of some drugs by hepatic parenchyma has also been exploited. The fluoropyrimidines demonstrate high hepatic extraction, with removal of more than 90 percent of floxuridine (FUDR) and 75 to 85 percent of 5-FU on a single pass after hepatic artery bolus infection. Clinical trials using hepatic arterial FUDR have demonstrated that biliary sclerosis (apparently irreversible) and elevation of hepatic enzymes represent the dose-limiting toxicities seen with hepatic intraarterial FUDR administration.

Drugs such as doxorubicin and mitomycin C that have some demonstrated tumoricidal activity against primary hepatomas and metastatic colon carcinoma may also be given by hepatic arterial infusion. Systemic toxicity, however, becomes dose-limiting because the hepatic extraction of these drugs is approximately 25 percent and 12 percent, respectively. Attempts to increase the extracorporeal extraction of these and other drugs from the venous effluent of the liver and other regional infusion sites is under investigation using regional venous filtration techniques.

Measuring Response

The clinical response to adjuvant chemotherapy for micrometastatic disease is determined by the rates of recurrence, disease-free survival, and overall survival. The clinical response to induction or neoadjuvant chemotherapy for visible, palpable, or radiologically measurable tumors is determined by the change in tumor mass. A *partial response* is generally a 50 percent or greater reduction in summed measurable tumor mass. Each tumor mass is measured as the product of the two greatest perpendicular diameters. A partial response is occasionally subdivided into minor responses (less than 50 percent size reduction) and major responses (more than 50 percent size reduction, but less than a complete response). This subdivision is clinically insignificant because only a complete response has the potential for cure. A *complete response* requires total disappearance of tumor on physical examination and radiologic studies for at least 4 weeks. A complete clinical response is likely to be followed by early relapse if chemotherapy is not continued long enough to eliminate any micrometastatic disease. *Tumor progression* is defined as a greater than 50 percent increase in summed measurable tumor mass. *Stable disease* indicates no change in tumor mass, size reduction less than a partial response, or any increase in size less than progression.

Lack of change in tumor size does not always indicate a lack of tumor response. Many large tumors may undergo necrosis, fibrosis, or granuloma formation with marked destruction of viable tumor cells, but minimal or no change in size. The increasing use of neoadjuvant chemotherapy has enabled histologic evaluation of pretreated tumor and normal tissue. The biologic tumor response to chemotherapy is estimated by the percentage of visibly unaffected tumor cells identified through histologic examination of sectioned tumor.

Side Effects and Toxicity

Some degree of drug toxicity during the administration of chemotherapy is not only expected but often is desirable because it indicates a cellular damage response. With rare exceptions, the maximal tolerated dose of most chemotherapeutic agents is sought to achieve the highest tumor cell kill. Close attention to normal tissue injury is essential to optimize the risk/benefit ratio and assure that the treatment is not worse than the disease.

Patterns of organ toxicity have been well described for the different classes of drugs (Table 9-28). The degree of toxicity depends on drug concentration, duration of exposure, and host response. Anticipated drug toxicity is based on the nonspecific damage caused by most chemotherapeutic agents to rapidly proliferating normal tissues, such as bone marrow stem cells, gastrointestinal crypt lining cells, and hair follicles. Within the same class of drugs, differential organ injury may be seen. Rare idiosyncratic systemic drug reactions within any drug category may cause unexpected and occasionally life-threatening toxicity.

Objective and subjective measurements of toxicity are serially recorded to allow the delivery of maximal tumoricidal drug doses with minimal and reversible injury to normal tissues. The Eastern Cooperative Oncology Group (ECOG) and other groups have developed scales that attempt to standardize toxicity criteria for measurement and reporting in clinical trials. The severity of signs, symptoms, and alterations in laboratory tests are graded for all major organ systems. Grade 0 denotes no toxicity, and grade 4 usually denotes life-threatening toxicity. The duration, chronicity, and reversibility of toxicity are also important. Clinical trials often have provisions for dose reduction or cessation of drug therapy for toxicity higher than grade 2 or 3, depending on the organ system affected.

Biologic Therapy

Biologic therapy is the administration of any biologic molecule or multimolecular complex and includes immunotherapy and gene therapy. The most common type of biologic therapy for cancer is administration of recombinant cytokines, such as *interleukin-2 (IL-2)* and *interferon-alpha (IFN- α)* , alone or in conjunction with chemotherapy (biochemotherapy). Of increasing interest are cancer vaccines, a form of active specific immunotherapy, and gene-based interventions. Biologic therapy of cancer is generally used in a multimodal regimen to increase the efficacy of surgery, radiation, or chemotherapy. For example, biologic agents may be administered preoperatively to patients with measurable and surgically resectable metastatic disease; this allows the clinician to determine clinical response in a measurable tumor, compare pathologic response to clinical response, and examine the in vivo effects of biologics on host-tumor relationships. Alternatively, biologic agents can be administered after curative resection to destroy residual micrometastatic disease and prevent recurrence.

Considerable effort has been devoted to immunotherapy of cancer. Immunotherapy assumes that cancer progression results from failure of the host immune defenses to recognize and reject the tumor. Biologic agents augment the immune response with the goal of blunting tumor progression. Theoretically, the immune system may be activated or reactivated to attack and destroy tumor specifically, leaving normal tissue largely unaffected.

Implicit in the ability of the immune system to recognize and attack neoplastic cells is the existence of immunogenic tumor-associated antigens. Evidence that human tumors are immunogenic comes primarily from investigations using melanoma, which is one of the most immunogenic solid tumors. Blood from melanoma patients contains antibodies against tumor antigens as well as cytotoxic T cells (CTL) that can destroy tumor cells in vitro. Clinical studies indicate that approximately 3 to 15 percent of all cutaneous melanomas are first diagnosed as lymphatic or visceral metastases without evidence of a primary tumor, which suggests that the immune system has caused complete regression of the primary melanoma. Histopathologic evidence of regressive changes has been reported in up to 58 percent of primary melanoma specimens. On rare occasions, there has been spontaneous, complete regression of metastatic disease.

In most experiences, induction of antitumor antibody affords little protection. In rodent models, immunity to solid tumors cannot be transferred to normal syngeneic hosts using serum or purified antibody preparations. By contrast, T lymphocytes play a critical role in the rejection of solid tumors in these models. In addition to the adoptive specific immunity afforded by T lymphocytes, natural killer (NK) cells can lyse a wide variety of tumor and virus-infected cells without the antigen-specific receptors used by T or B cells.

Rapidly emerging advances in the basic mechanisms of cell-mediated immunity provide new strategies for biologic therapy based on the prospect that the host immune system may be manipulated either in vivo or ex vivo to reject neoplastic outgrowth. Molecular biology and cell cloning enable investigation of a new level of the biology of host-tumor relationships and development of biologic agents to administer to cancer patients. No single possibility has universal application, but as our understanding of the host immune response to autologous tumor antigens in various neoplastic diseases improves, the strategies for biologic approaches to treatment will improve vastly.

Recombinant Cytokines

Table 9-29 lists the cytokines currently in use for biotherapy of cancer. Early trials with nonrecombinant interferon in patients with advanced melanoma demonstrated a major response rate of 14.4 to 22.6 percent. Subsequent trials using recombinant *IFN-a* for metastatic melanoma showed a major response rate of about 23 percent (range 14 to 28 percent). *IL-2*, the T cell growth factor, induces a major response, particularly in patients with metastatic melanoma and metastatic renal cell carcinoma, but not in patients with breast cancer, colon cancer, or lymphoma.

The treatment of melanoma was significantly changed when Kirkwood and associates reported that high-dose *IFN-a-2b* significantly prolonged both relapse-free and overall survival rates after surgical resection of high-risk primary melanoma (American Joint Committee on Cancer (AJCC) stage II-B) or regional lymph node metastases (AJCC stage III). IFN-a-2b administered intravenously (20 million U/m²/day) for 4 weeks and then subcutaneously (10 million U/m² three times a week) for 48 weeks increased median disease-free survival by 1 to 1.7 years and median overall survival by 2.8 to 3.8 years, compared with observation. Interferon treatment also increased the rate of 5-year survival by 24 percent.

This important study was the first randomized controlled trial to show a significant benefit of adjuvant therapy in prolonging relapse-free and overall survival of high-risk melanoma patients. On the basis of the results of the study, the Food and Drug Administration approved *IFN-a-2b* for postoperative adjuvant therapy in melanoma patients at high risk of systemic recurrence.

The intravenous administration of the cytokines is not without significant toxicity, however, and it is clear that they trigger a cascade of effects that results in other lymphocyte activities as well as the direct effects of *IL-2* on other tissues. Some of the side effects are similar to those seen with septic shock. Concern over the toxicity of intravenously administered cytokines has promoted the development of methods to target cytokines and reduce systemic effects. Cytokines are administered aggressively and frequently because of their short half-life in the blood. In addition, cytokines are not always distributed to all areas of the body and often do not traverse the blood-brain barrier. An innovative approach is the incorporation of interferon and adjuvants into liposomes that direct the cytokine to a specific host cell population. In animal models, liposomes are ingested by macrophages. Degradation of the “packaged” therapy results in intracellular release of adjuvants, such as *muramyl tripeptides (MTP-PE)* , and the interferon, which activates macrophages to become cytotoxic against cancers in vitro and in vivo. A randomized study in dog osteogenic sarcoma showed significantly greater response and survival rates in animals that received the MTP-PE liposomes as compared with those that received empty liposomes. This novel approach has been extended to human studies, beginning with a pilot study of patients with osteogenic sarcoma and melanoma.

Combination biologic therapy is now in clinical trials for treatment of most major human cancers. The multiagent concept is plausible because: (1) multiple immune abnormalities are most likely to occur in cancer patients; (2) there is heterogeneity in immune response (nature of lymphocytes, role of antibody, presence of macrophages) relative to the site of the metastases; and (3) combinations of agents with different mechanisms of action are more likely to augment individual aspects of immune response additively or synergistically in a diverse population of cancer patients. For example, combinations of *IL-2* and *IFN-a* elicit a higher rate and more durable response time for metastatic melanoma than either cytokine alone. Combinations of tumor antigen, lymphokines, and cyclophosphamides are intended to activate tumor-specific immunity, promote effector T cell proliferation, and down-regulate suppressor T cells.

Biochemotherapy uses cytokines such as *IL-2* and *IFN-a* in combination with chemotherapeutic agents such as *5-FU* with the goal of enhancing antitumor activity. Various biochemotherapeutic regimens are being examined in patients with metastatic colorectal cancer, lung cancer, renal cell carcinoma, and melanoma. Cytokines also have been used as supportive therapy to allow higher doses of chemotherapy. For example, *granulocyte-macrophage colony-stimulating factor (GM-CSF)* has been administered with erythropoietin to allow acceleration and dose escalation of chemotherapy with cyclophosphamide, epidoxorubicin, and 5-FU in patients with advanced breast cancer.

Immunotherapy

Immunotherapy is a logical adjunct for the treatment of subclinical microscopic disease after definitive cancer surgery, radiation therapy, or chemotherapy for the following reasons: (1) patients who have only small foci of cancer cells remaining after destruction of the major tumor bulk are the most likely to benefit from immunotherapy, because the tumor mass that must be destroyed is smallest at that time; (2) the specificity of the immune response provides a possible therapeutic tool that has selectivity for small numbers of cancer cells not possible with any other therapeutic modality; (3) patients with disease in earlier stages are more likely to respond to immunotherapeutic maneuvers, since the cancer patient's general immune competence is greatest when the disease is localized and is often impaired after metastasis; and (4) immunotherapy should complement rather than interfere with currently available methods of cancer therapy. Because both irradiation and chemotherapy are immunosuppressive, the use of immunotherapy in combination with these therapeutic modalities must be carefully controlled.

Table 9-30 describes the types of immunotherapy. The rational application of these immunotherapies to human cancer will depend on a better knowledge of tumor-associated antigens in human neoplasms and methods for increasing the immune response against these agents. Their use should be limited to cancer facilities, where the effects of this form of treatment can be scientifically evaluated.

Active Specific Immunotherapy (Cancer Vaccines)

The clinical use of cancer vaccines was initiated at the turn of the century, prompted by the success of vaccines against infectious disease. Unlike vaccines against infectious disease, which are administered prophylactically, cancer vaccines are generally administered after the advent of disease. Both types of vaccine utilize attenuated whole cells, cell walls, specific antigens, or nonpathogenic strains of living organisms to stimulate the patient's immune system to fight the disease. The specific goals of active immunotherapy with cancer vaccines are to overcome the immunosuppression produced by tumor-derived factors, to stimulate specific immunity that will destroy tumor cells, and to enhance the immunogenicity of tumor-associated antigens (TAA).

Several observations support the potential value of active specific immunotherapy for the treatment of cancer. These include (1) vaccine- induced immunity against cancer in animal models, (2) the regression and eradication of tumors injected directly with immunostimulants, (3) occasional regression of noninjected tumors after the intralesional injection of *bacille Calmette-Gu érin (BCG)*, and (4) the development of antitumor antibodies.

The goals of active immunotherapy are to combat the decreasing immunocompetence that results from interaction of tumor-related products with components of the immune system and to eliminate the diverse clones within a tumor cell population by augmenting cellular and/or humoral immunity. Unlike chemotherapy, vaccine immunotherapy has no direct cytotoxicity on tumor cells; its clinical effect depends on the immune system and is slower in onset but tends to be more durable (Table 9-31).

Adoptive Immunotherapy

In adoptive immunotherapy, immune lymphoid cells are transferred to a recipient to mediate tumor destruction. Rosenberg and colleagues pioneered the study of adoptive immunotherapy using lymphokine- activated killer (LAK) cells, which are cytolytic lymphocytes generated in the presence of *IL-2*. These cytolytic cells can kill a wide range of fresh and cultured human cancer cells, but not normal cells. Human LAK cells do not have T cell markers and are not *MHC-* or antigen-specific in their killing.

Clinical trials using autologous LAK cells (obtained by repeated leukopheresis and in vitro IL-2 expansion) and systemically administered IL-2 produced clear, objective responses in some patients with bulky metastatic cancer. Some evidence suggests that LAK cells may be more important in renal cell carcinoma than in melanoma. Subsequently, the method was developed for isolating *tumor-infiltrating lymphocytes (TIL)* from human melanoma and renal cell carcinoma; after proliferation ex vivo in the presence of IL-2, the TIL were returned to the patients and IL-2 therapy administered concurrently. In preliminary studies, response rates of up to 40 percent were obtained. Unlike LAK cells, the TIL may have an important role in the therapy of local and regional disease, while LAK cells may remain useful in the treatment of hematogenous dissemination and some renal cell carcinomas. TIL-based immunotherapy is an active area of research, and TILs also are being investigated in conjunction with gene therapy.

Nonspecific Immunotherapy

Certain substances, such as mixed bacterial toxins and fractions of the tubercle bacillus, nonspecifically enhance host resistance to most viral, fungal, and bacterial agents. Although the exact mechanism is unknown, these agents appear to stimulate immune response to a wide variety of antigens, including tumor antigens.

Interest in a nonspecific immunotherapy was revived more than 20 years ago using attenuated bovine tuberculosis bacillus (bacille Calmette-Guérin, BCG). Some tumor regressions were observed, but consistent responses in any one treatment group were difficult to achieve. There are several possible mechanisms to explain tumor regression following BCG injection; specific and nonspecific immune reactions were probably involved. The tumor cells may be killed as “innocent bystanders” during the delayed cutaneous hypersensitivity reaction that occurs when lymphocytes and macrophages attack BCG dispersed throughout the tumor nodule. This is supported by the observation that the intratumor injection of BCG works only in patients who can be sensitized to BCG, as shown by their delayed cutaneous hypersensitivity reaction to purified protein derivative.

In addition to the nonspecific effect, a specific immune response to melanoma-associated tumor antigens occurs in some patients because an associated rising titer of antimelanoma antibody is observed after BCG immunotherapy. Sequential biopsies of tumor nodules taken after BCG inoculation reveal that the regression of these nodules is associated with granulomatous infiltration of lymphocytes, monocytes, and fibroblasts surrounding and infiltrating the melanoma cells. The regression of melanoma nodules not injected with BCG is accompanied by the appearance of lymphocyte infiltrates within the regressing melanoma tumor nodules. The specific antitumor effect may result from more lymphocytes and macrophages coming into contact with the tumor cells and promoting antigen presentation. Conversely, it may work via the effector limb of the immune response by bringing greater numbers of stimulated and unstimulated lymphocytes to the tumor.

Other nonspecific agents include *Corynebacterium parvum*, *Bordetella pertussis*, *MTP-PE*, methanol-extractable residue of BCG, bacterial endotoxins, and polynucleotides. Another form of nonspecific immunotherapy involves the use of agents capable of restoring depressed immune responses. Several agents have been proposed, including thymic hormones, such as thymosin, and the antihelminthic drug levamisole.

Passive Immunotherapy

The systemic use of tumor-specific antiserum is laden with theoretical and practical problems. Passive immunotherapy is effective only in suppressing small numbers of tumor cells and must work in concert with host effectors (e.g., complement, macrophages, antigen-dependent cellular cytotoxicity) to effect a cytotoxic action on target cells. In addition, only antibodies of certain classes and subclasses can interact effectively with certain cellular effectors. Most of the better-characterized human tumor-specific antisera are murine monoclonal antibodies that, because of their antigenicity, have limited applications in human beings.

Immunotoxins are tumor-specific antibodies that are attached to toxic molecules. This concept, first proposed by Ehrlich a century ago, uses the antibody molecule to preferentially localize anticancer agents in the vicinity of tumors. It obviates the need for the host to supply effector cells or complement to mediate tumor destruction. Monoclonal antibodies are preferred to heterologous antiserum because they permit the use of homogeneous, purified antibodies of defined specificity. A wide range of toxic molecules has been tested in vitro and includes radioactive isotopes, traditional cancer drugs, and plant and bacterial toxins. Recombinant DNA technology now permits the creation of hybrid or chimeric immunotoxin molecules in which the Fc fragment of the immunoglobulin molecule has been replaced by a polypeptide toxin sequence. Immunotoxins are currently undergoing clinical trials, although their overall therapeutic efficiency in clinical oncology is unproved.

Gene Therapy

Gene cloning has introduced a new era of biologic therapy that will have an impact on human clinical trials in the coming years. An example is the studies by Hellstrom and colleagues, in which a cloned gene for one of the major human melanoma tumor-associated antigens (p97) was introduced into the genome of a vaccinia virus. The virus then expressed both immunogenic viral antigens, plus the weaker immunogenic human melanoma antigens on the surface. This reagent will be tested in human studies in the near future. A novel approach is transfection of human *TIL* with genes for producing cytokines, such as tumor-necrosis factor (TNF). The ability to transfect cytokine genes into human *TIL* suggests adaptive cellular therapy with genetically transfected cells capable of producing high concentrations of tumor-necrosing factor or other lymphokines at the tumor site. This would deliver high concentrations of cytokine to the tumor site while sparing the vascular compartment of the otherwise deleterious effects of high-dose, systemic cytokine. Gene transfection also may be used to augment the immunogenicity of tumor vaccines. Preclinical studies demonstrate enhanced cellular immunity when whole-cell vaccines are transfected with IL-2, IL-4, IL-7, and/or *GM-CSF*. Several phase I and phase II clinical trials of cytokine-transduced cellular vaccines for patients with advanced melanoma are under way.

Other approaches to gene therapy of cancer are antisense oncogene and tumor suppressor gene therapy, which attempt to correct genetic disorders of cancer by suppressing the abnormal expression of proliferative genes. Potent regulatory antisense DNA sequences can prevent the translation of molecules that down-regulate host immunity to tumor.

Management of Distant Metastases at Specific Sites

Lung, Pleura, and Mediastinum

Two of the most common initial sites of metastasis are the lungs and pleura. Although pulmonary metastases are generally asymptomatic, they may cause persistent cough, shortness of breath, and/or chest pain. An irritating, dry, and unproductive cough may progress to hemoptysis.

A standard chest x-ray is sufficiently sensitive and cost-effective for screening all cancer patients and frequently will reveal hilar and mediastinal adenopathy in those with pulmonary metastases. Although pulmonary tomograms or CT scans have too low a yield and too high a cost to be justified when the chest x-ray is normal, they are of value in evaluating suspicious chest lesions or in determining whether the metastatic disease seen on the chest x-ray is present elsewhere in the chest. Tomograms can detect lesions as small as 6 mm in diameter, and CT scans can identify lesions as small as 3 mm. Their increased sensitivity is offset by decreased specificity; the false-positive rate can be as high as 15 percent. The choice between the two tests often depends on available facilities, cost, and skills of the radiologist. Neither test is indicated unless the presence of pulmonary metastases would alter the treatment plan or unless a better definition of lesions is required for entry into a research protocol.

Bronchoscopy with biopsy may be considered when the etiology of a pulmonary lesion is in doubt (e.g., metastatic disease, fungal disease, benign tumor, or bronchogenic carcinoma), especially when symptoms suggest bronchial involvement (e.g., a productive cough or a centrally placed or cavitory lesion). A scalene lymph node biopsy is indicated for palpable nodes. Mediastinoscopy is indicated if the chest x-ray, tomogram, or CT scan reveals abnormal mediastinal nodes that are accessible through the instrument. Thoracentesis or pleural biopsies may be helpful when evaluating effusions. Fine-needle biopsy of a pulmonary lesion under CT scan guidance may be useful in selected instances to establish the histologic diagnosis. Video-assisted thoracoscopy is increasingly used both diagnostically and therapeutically in the staging and treatment of lung cancer. This technique permits visualization of the entire visceral, parietal, and mediastinal pleural surfaces and excisional or incisional biopsy for establishing diagnosis. If the diagnosis remains in doubt, an exploratory thoracotomy may be necessary, especially for a solitary lesion, because some patients will have potentially curable primary lung cancer.

The treatment approach is determined by the location and number of thoracic metastases and by the patient's overall status. Nearly all patients with disseminated cancer develop metastases in the chest prior to death. Some neoplasms, such as melanoma, metastasize preferentially to the lungs. Surgical resection may be indicated even when there is more than one pulmonary metastasis. In most surgical series, the median survival is 17 months, with a 5-year survival rate of 20 to 25 percent. Some patients live more than 10 years. Resection of a solitary pulmonary metastasis provides a higher rate of 5-year survival than resection of primary bronchogenic carcinoma of the lung. Criteria for resection include absence of metastases at other sites, control of the primary tumor, potential for complete resection, and a long tumor doubling time. CT scans should be obtained preoperatively because the number of lesions demonstrated by CT scanning is often greater than that shown by chest x-ray. Lung parenchyma should be conserved during resection. Most metastases occur just below the pleura, and a wedge of tissue removed by segmental resection suffices. Stapling, electrocautery, and laser surgery can be useful. Lobectomy and pneumonectomy usually are not indicated.

Patients who are ineligible for surgery, such as those with multiple slow-growing tumors, might be monitored but receive no treatment while they are asymptomatic. If the pulmonary metastases progress rapidly, chemotherapy can be considered, especially if multiple visceral metastases exist at other sites or if the patient has disease symptoms. A pleural effusion associated with lung cancer does not rule out resection; malignant pleural disease must be documented. If patients are symptomatic, they can be treated by thoracentesis, tube thoracostomy, or thoracoscopy with chemical pleurodesis. Closed chest tube drainage and sclerosis often are necessary for effective control of recurrent symptomatic effusions. Talc diluted in normal saline solution is the agent of choice for chemical pleurodesis. Talc can also be delivered via video-assisted thoracoscopy. Fever is a common side effect, and chest pain, dyspnea, and pulmonary infiltrates sometimes occur. Pleural effusions are generally associated with a short survival time.

Tumor Doubling Time

The growth rate of a tumor can be expressed by the time the tumor doubles in volume. The tumor doubling time (TDT) is an accurate and reproducible measure of biologic aggressiveness that can be used to determine the indications for surgical resection. TDT represents the balance between the intrinsic proliferative rate of the tumor cell and the patient's immune defense mechanisms.

TDT measurement is especially useful in treating patients with pulmonary metastases because neoplasms tend to be peripherally located and discretely identified on chest radiographs. It is quite easy to obtain accurate serial chest x-rays that can be used to measure the changing diameters of the lesion. The greater and lesser diameters are averaged and then plotted against time on semilogarithmic paper. The slope of the line drawn between any two points represents the rate of tumor growth. The horizontal distance between any two doubling points represents the TDT in days.

TDT may vary from 8 to 600 days, but most tumors double in 20 to 100 days. Patients with a short TDT have aggressive, fast-growing metastatic lesions; patients with a long TDT might have nonaggressive lesions that would be responsive to surgery. TDT is an important prognostic tool for selecting surgical candidates. TDT also can be used to monitor the effects of chemotherapeutic agents and compare different therapeutic regimens. Patients with pulmonary metastases can be divided into three survival groups according to TDT. Those patients with TDT less than 20 days are not recommended for surgery; it is likely to be ineffective and will not result in long-term survival. Patients with a TDT of 20 to 40 days are not ineligible for surgery, particularly if a slowing of TDT is observed after preoperative chemotherapy; their long-term survival rates are not much improved by surgery alone. Patients with a TDT of 40 days or more can have long-term survival after resection of the pulmonary lesion. Sarcoma patients with a TDT of more than 40 days were found to have significant palliation from pulmonary resection and remained free of disease for as long as 5 years; patients with a TDT of less than 20 days did not significantly benefit from resection of metastatic lesions.

Liver, Biliary Tract, and Spleen

Hepatic metastases can occur in many patients with metastatic disease, especially those with gastrointestinal malignancies and breast cancer. There are no reliable and accurate tests for early detection of liver metastasis, and no common symptoms and physical signs. The patient might experience decreased appetite with loss of weight followed within weeks by general lassitude and debility. The loss of appetite can precede a clinically palpable liver by a month or more. Conversely, the patient may have an easily palpable liver and feel perfectly well. As the liver disease progresses, nausea, vomiting, jaundice, night sweats, and fever can develop.

A history and physical examination and serum liver chemistries with appropriate tumor markers are the most cost-effective screening tests. Elevated levels of lactic dehydrogenase or alkaline phosphatase in the presence of normal or only slightly elevated levels of serum glutamic- oxaloacetic transaminase or bilirubin suggests liver metastasis. An elevated lactic dehydrogenase level is a clinically useful and relatively specific indicator for metastatic melanoma.

Suspected liver metastasis should be confirmed by ultrasonography, dynamic CT scan, or CT portography. Radionuclide liver scanning and hepatic arteriography are less frequently used. The choice depends on the availability and cost, the interpretive skills of the radiologist, and the generation of equipment used, which is especially important in CT scanners and ultrasound units. Abdominal CT scans are more accurate and reliable than ultrasonography and radionuclide liver scans for evaluation of liver masses. *PET* scans also are increasingly useful in detecting metastatic disease. Hepatic metastases are not detected by radiologic tests until they are more than 1 cm in diameter.

Angiography is used only when the differential diagnosis cannot be established by noninvasive techniques, when the information gained would affect the treatment decision, or when hepatic resection is contemplated. Biopsy usually is not necessary to confirm the diagnosis of liver metastasis. In the few instances in which biopsy confirmation is essential to treatment decisions, a needle biopsy can be performed percutaneously with CT or ultrasound guidance, or by laparoscopy, or during laparotomy.

Some patients with isolated liver metastases from colorectal cancers can benefit from surgical resection. Those patients with a solitary metastasis or metastases located in one lobe are often successfully treated with resection, and approximately 25 percent will survive for 5 years. Most liver metastases are not amenable to surgical excision. Systemic chemotherapy or hepatic arterial chemotherapy is the most common intervention for patients with nonresectable hepatic metastasis, and response rates vary. Cryosurgery might offer effective palliative treatment for patients with nonresectable primary or metastatic hepatic malignancies; in certain cases, extended survival has been reported with the potential for cure. Other treatments include hepatic artery embolization, chemoembolization, radiation therapy, and alcohol injection.

Brain and Spinal Cord

Many cancers, particularly breast cancer, lung cancer, and melanoma, metastasize to the brain, a common cause of death. Headache and mental deficits are the most common symptoms of brain metastasis. Headache resulting from brain metastasis characteristically begins as a mild morning headache. As the condition progresses and the intracranial pressure increases, the headache will persist longer into the day and become more severe. It is usually generalized, but it may be slightly worse in the frontal or occipital region and is sometimes associated with visual changes. The most common physical sign of brain metastasis is a focal neurologic deficit; seizures are common. The presence of papilledema is a helpful sign, but its absence is not useful diagnostically.

The best tests for diagnosing intracerebral metastasis are MRI and CT with contrast enhancement. MRI, a technique that depends on the intrinsic paramagnetic properties of biologic tissue, is generally the preferred test to detect and stage brain and spinal metastases. MRI can detect tumors that cannot be detected by CT scans. MRI has an advantage particularly for lesions at the base of the skull and in the posterior fossa, because only a weak signal is generated from the adjacent bone. MRI scans appear to have a higher tissue sensitivity, including a better ability to distinguish hemorrhage from tumor, than CT scans.

The accuracy and sensitivity of these scans make it unnecessary, in most cases, to perform a radionuclide brain scan or electroencephalogram unless there are some equivocal findings. A carotid arteriogram may be indicated to rule out vascular abnormalities. A lumbar puncture and cerebrospinal fluid analysis to diagnose meningeal involvement occasionally is necessary (after a CT scan) for a patient who has a cranial nerve palsy, bladder dysfunction, or nonlocalizing or bilateral neurologic signs and symptoms.

The mainstay of initial treatment is corticosteroids, the most effective of which is dexamethasone (up to 100 mg/day). Dexamethasone reduces edema around the tumor and temporarily helps to relieve symptoms in the majority of patients. The steroid dose should be tapered over 2 to 4 weeks as tolerated and the therapy stopped after definitive treatment unless the patient's symptoms intensify during steroid withdrawal. Steroids often do not help patients with rapid neurologic deterioration because this condition usually reflects intracerebral hemorrhage around the metastasis. Chemotherapy is not usually effective for brain metastasis.

Surgical excision followed by cranial irradiation is the treatment of choice for a solitary, surgically accessible metastasis. Tumor excision by means of a craniotomy is relatively safe; it alleviates symptoms in most patients and prevents further neurologic damage in patients with demonstrable metastases. The treatment may be considered in some patients who have disease at other sites plus symptomatic brain metastases because their estimated life span can exceed 3 months, and their neurologic status usually improves.

Patients treated with open brain surgery and fractionated radiotherapy have a better outcome than those treated with radiation alone, but many patients do not have surgically accessible cerebral metastases. In these cases, stereotactic radiosurgery using the "gamma knife" may offer the best chance of prolonged survival.

Bone

Bone metastases are common in patients with advanced breast or prostate cancer but infrequent in patients with gastrointestinal cancers. They are medullary in location and destructive in nature. The pain from bony metastases is typically nocturnal at first, becoming persistent, progressive, and localized, and it can become quite severe.

Bone metastases are frequently diagnosed in symptomatic patients, but occasionally they are seen incidentally on radiographs (e.g., rib metastases on routine chest x-ray) or a bone scan prompted by an elevated serum alkaline phosphatase level in the absence of liver metastasis. They are generally osteolytic in appearance on radiography and provoke little if any bone formation, but some patients with prostate cancer have osteoblastic bone metastases. Axial metastases account for up to 80 percent of bony lesions and are most common in the spine and rib. When bony lesions involve the vertebral body, there are often compression fractures that may lead to neurologic symptoms, such as radicular back pain, paresthesia or paresis of the legs, and urinary retention. Only about 10 percent of lytic lesions occur in weight-bearing bones, but these could result in pathologic fractures.

The radionuclide bone scan is the initial test for evaluating suspected bone metastases. Its sensitivity is reportedly 50 to 80 percent greater than radiographs alone, but bone scan abnormalities are nonspecific and must be correlated with radiographic study (x-ray or CT scan) and patient history (fractures, trauma, arthritis, etc.) to distinguish between benign and malignant causes. A bone biopsy might be necessary to establish the diagnosis before instituting treatment.

The treatment of bone metastases depends on the degree of symptoms, the location and magnitude of the lesions, and the patient's life expectancy. The goals of therapy are to relieve pain and maximize ambulation. Patients without symptoms should be monitored to assess the progression of their lesions but should receive no major treatment unless they become symptomatic.

Symptomatic metastases frequently involve non-weight-bearing bones, particularly the spine and ribs. In these cases, irradiation of the lesions usually provides relief. The radiation fields should be restricted to those lesions responsible for the symptoms. Symptomatic bone lesions only occasionally respond to systemic chemotherapy, but bone metastases from breast cancer sometimes respond well to hormonal therapy.

Symptomatic metastases in weight-bearing bones (e.g., the femur) require special consideration. If the lesion is large, and if there is evidence of cortical destruction, prophylactic stabilization and irradiation are sometimes used when the patient's life expectancy is at least 2 months. Stabilization includes operative metallic bone fixation (e.g., with intramedullary rods), joint replacement, repair with methyl methacrylate, or external braces or a cast. Radiotherapy is generally given postoperatively. Alternatively, the lesion might be treated with radiation alone, but the patient must be closely monitored for evidence of pathologic fracture. Unless the surgical risk is high or the patient's expected life span is short, pathologic fracture of a weight-bearing bone should be stabilized, maximizing the patient's quality of life and decreasing hospital or nursing home costs. Patients with fractures of the vertebrae that have compressed the spinal cord require prompt treatment to avert paralysis. The treatment may require decompressive laminectomy and postoperative irradiation, or irradiation alone, depending on the extent of the disease and the patient's overall medical condition.

Skin, Subcutaneous Tissues, and Distant Lymph Nodes

These are the most common sites of distant metastases and are often the first sign of hematogenous spread. Skin and subcutaneous metastases generally are 0.5 to 2.0 cm in diameter and are readily detectable by physical examination. Distant lymph node metastases can occur in any area. The more superficial nodal metastases are easily diagnosed by physical examination. Metastases within the thorax usually can be detected on chest x-ray, with CT scans or tomograms used as confirmatory tests, but abdominal nodal metastases are generally detected by CT or ultrasound scans. These lesions usually are treated, especially when symptomatic and isolated, by surgical excision (if superficially located) or radiation therapy. Other treatments include intralesional immunotherapy with *BCG*, regional chemotherapy (isolated perfusion of the extremities), or systemic chemotherapy or hormone therapy, especially when there are multiple lesions or simultaneous visceral metastases.

Gastrointestinal Tract

Some cancers, particularly melanoma, can metastasize to the gastrointestinal tract, often to multiple sites. Early gastrointestinal involvement usually causes persistent but nonspecific complaints, such as epigastric distress, nausea, anorexia, or weight loss. The most common clinical manifestations are the result of chronic bleeding (anemia, anorexia, and weight loss), obstruction of the small bowel (abdominal pain, nausea, and vomiting), and acute bleeding (hematemesis or melena). For example, a patient with melanoma metastatic to the gastrointestinal tract typically presents with a symptom complex of gastrointestinal complaints, guaiac- positive stool, and anemia.

Gastrointestinal metastases are difficult to detect by radiologic studies, the routine use of which is not indicated for screening. Follow-up clinical examination should include a guaiac test of a stool specimen. Although subject to limited specificity, a positive result is an indication for further investigational studies using barium enema, colonoscopy, esophagogastroduodenoscopy (EGD), or CT scans of the abdomen and pelvis. Newer studies, such as *PET* scans and radiolabeled monoclonal antibody scans, might be helpful in identifying the general location of a metastasis. Persistent anemia without an identified lesion may indicate further studies, such as small bowel enteroclysis, radionuclide scans, or angiography, with possible embolization to control persistent bleeding from nonoperable lesions.

Repeated blood transfusions might be indicated for persistent anemia in patients who have nonresectable visceral metastases or for whom a thorough workup failed to reveal a source of bleeding. Chemotherapy can be considered for patients with multiple gastrointestinal lesions, but surgical excision should be considered for *isolated* gastrointestinal metastases if the patient's condition is good. Surgery is recommended for most patients who have acute complications of obstruction, massive bleeding, or perforation because the alternative is to allow the patient to die. The final decision depends on the patient's overall clinical condition, but symptoms can be successfully alleviated in most cases, and survival after surgical excision averages 4 to 8 months.

PSYCHOLOGIC MANAGEMENT AND REHABILITATION

The physician can ease the cancer patient's fear of the disease by free and open communication. Psychologic support and education are necessary for the patient to deal with any disability that can result from therapy. Examples include training in the care of a stoma following curative surgery for colonic and rectal cancer and referral to lay groups associated with the American Cancer Society for counseling the anxious patient with an altered body image resulting from mastectomy.

It is impossible to predict the exact course of any malignant tumor. Patients with a poor prognosis are occasionally cured by aggressive therapy, and spontaneous regressions are sometimes observed in patients with metastases. In contrast, some patients with apparently localized disease can die of disseminated cancer in a few months. Uncertainty about the future is one of the most difficult adjustments that cancer patients and their families face. It is reassuring to emphasize that the chances for cure improve each month after successful treatment of the primary neoplasm, particularly for tumors such as squamous cell carcinoma of the lung or oropharynx. Other, more slowly growing neoplasms, such as carcinoma of the breast and malignant melanoma, can recur after disease-free intervals of 10 to 20 years, though the chances of recurrence also decrease with time. Recognition that cancer is a chronic disease is an important aspect of management. Long-term, consistent follow-up provides opportunities for reassurance and usually can ensure detection of recurrence at an early stage.

Some patients suspect the worst but do not want to hear the truth from their physician. However, a lie is never appropriate, even if requested by the family. Untruths often create barriers between patients and their families that can lead to psychologic isolation of patients, who are unable to discuss their fears and anxieties with those they need most. Gentle and optimistic truth is generally the best approach, even when primary cancer therapy has failed and the patient is judged incurable. Realistic and consistent support is actually more important to the patient and family at this stage of the disease than earlier. There is increasing evidence that patients tolerate the process of dying much better when sustained by the physician's continuing concern and active support.

Some incurable patients are unable to accept the realities of the situation. In this case, it is essential that a responsible family member be informed. The duration of the incurable patient's life is so uncertain that predictions should be avoided. If, as frequently happens, the relatives insist on some estimate, a combined minimum-maximum prognosis, such as from 6 months to 2 years, will help the family accept this uncertainty.

The basic aim in caring for the patient with advanced cancer is to prolong useful life, but not useless suffering. The patient should be permitted to die with dignity when active therapy can no longer be of benefit.

SURGERY IN THE FUTURE

Increasing evidence suggests that surgery should be the last, rather than the first, therapeutic intervention. Surgery undertaken after chemotherapy and radiation therapy can remove cancer cells that are resistant to these modalities. Chemotherapy and radiation therapy before surgery can shrink the tumor mass to be excised and improve the possibility of organ preservation. There have been promising results from preliminary trials using these concepts in bone and soft tissue sarcomas, locally advanced breast cancer, and other neoplasms.

Surgery may be considered a form of immunotherapy. Any therapeutic maneuver that lowers tumor burden can reverse tumor-associated immunosuppression, altering the immune balance in favor of the patient. Tumor-associated immunosuppression is caused by antigens shed from a growing neoplasm into the blood and by humoral factors produced by or in response to the neoplasm. Cancer surgery effectively removes the cancer cell mass that produces the immunodepression and allows the patient's immune responses to recover. Once the tumor mass has been removed, the patient's immune system can deal with any clinically silent micrometastases. Surgical resection of apparently localized tumors can favorably affect the host-tumor relationship and may even cure the patient with subclinical distant metastases. By reducing the number of tumor cells, it also increases the curative potential of systemic therapies.

Early Detection

In many neoplasms, prognosis depends on the status of the lymph node basin draining the primary tumor. The extent and timing of lymph node dissection is controversial. Sentinel lymphadenectomy, a promising technique for early detection of nodal disease, is under investigation in multicenter trials. Detection of the sentinel node (i.e., the first lymph node draining a primary tumor) was introduced for melanoma and is being applied to breast carcinoma and other neoplasms. Initially the technique relied on injection of a vital blue dye at the tumor site and visual tracking of this dye along the lymphatics to the nodal basin. Sentinel node mapping is now facilitated by adding a radiolabeled isotope to the dye and monitoring its path by a handheld gamma probe.

Radioimmunoguided surgery (RIGS) using murine monoclonal antibody (MAb) enables surgeons to localize previously undetected malignant lesions and disseminated disease intraoperatively. It is especially effective in localizing primary and secondary colorectal, gastric, and ovarian carcinomas. For RIGS, MAb is conjugated to ¹²⁵I, which has a half-life of about 60 days. Radiolabeled MAb is administered intravenously approximately 2 weeks before surgery. To avoid radioactive uptake by the thyroid gland, a supersaturated solution of potassium iodide is administered 2 days before the MAb and continued for 3 weeks. During surgery, the surgeon manipulates the gamma-detecting device, consisting of a detection crystal, a preamplifier, and a signal processor with a digital readout. This device produces audible and numerical displays as it encounters radiolabeled tumor cells. It allows the surgeon to define tumor margins, to seek out malignant lesions that might have escaped previous detection by CT scan or plain chest x-ray, and to examine thoroughly those sites that might contain tumor cells.

INTRODUCTION

Transplantation is the process of taking a graft—cells, tissues, or organs—from one individual—the donor—and placing it into another individual—the recipient, or host. If the graft is placed into its normal anatomic location, the procedure is called *orthotopic* transplantation (e.g., heart transplants, liver transplants). If the graft is placed in a different site, the procedure is called *heterotopic* transplantation (e.g., kidney transplants, pancreas transplants). The genetic relationship between donor and recipient is described by the following terms: *syngeneic* refers to transplantation between individuals of a genetically identical strain, or between identical twins. In this situation, the genetic makeup of donor and recipient are identical, and rejection does not occur. Transplantation between genetically different members of the same species is referred to as *allogeneic* transplantation, such as transplantation of tissues or organs between two different strains of experimental animals (e.g., rat strain ACI to Lewis). In human beings, all transplants except those between identical twins are allotransplants. Transplants between members of different species (e.g., pig to man) are referred to as *xenogeneic* transplants. If a graft (e.g., skin) is transplanted from one site to a different site within the same individual, it is referred to as an *autotransplant*.

Although attempts at transplantation date back to ancient times, the impetus for modern transplantation was World War II and the Battle of Britain. Royal Air Force pilots often were severely burned when their planes crashed. The mortality rate associated with burns corresponds to the size of the area of skin that has been injured, and the survival rate can be improved if burned skin is replaced. For this reason, British doctors turned to skin transplantation from other human donors as a mode of therapy. However, attempts to replace damaged skin with skin from unrelated donors were uniformly unsuccessful. Over a matter of several days, the transplanted skin would undergo necrosis and fall off. This problem led many investigators, including Nobel Prize winner Sir Peter Medawar, to study skin transplantation in animal models. His work, performed in collaboration with Gibson, formed the basis of modern transplantation biology. Medawar could establish that the failure of a skin graft to “take” was the result of a process later termed *immunological rejection*, which was mediated by the recipient's white blood cells. Later studies by Gowens revealed that lymphocytes play a major role in transplant rejection.

In the late 1940s Medawar became aware of an observation made by Dr. Ray Owen from the University of Wisconsin. Owen had observed that nonidentical cattle twins who shared a placenta in utero were chimeric for red blood cells carrying the genetic makeup of the nonidentical twin for the rest of their lives. When skin grafts were exchanged between these two nonidentical twins, they did not undergo rejection. Medawar concluded from these experiments that antigen delivered to the immature individual during intrauterine development or shortly after birth would result in long- term immunological tolerance. Billingham, Brent, and Medawar tested this hypothesis by injecting blood cells from mouse strain A into neonatal animals of mouse strain B. Later, when mouse strain B animals received skin grafts from mouse strain A, the grafter were accepted indefinitely, without the need for immunosuppressive therapy. The concept of inducing stable tolerance to prospective recipients of organ transplants is still the main focus of transplantation research today, almost 50 years after Medawar's initial discovery.

It became obvious during the early 1950s that kidney transplants in human beings undergo rapid and violent rejection as early as a few days after transplantation, and it is not surprising that the first successful kidney transplants were performed between identical twins. This early series of live-donor kidney transplants was performed in Boston by Murray, Hume, and Merrill. Primitive attempts to prolong kidney transplant survival between nonidentical individuals included radiation therapy and the use of 6-mercaptopurine. Later, with the addition of corticosteroids, improved survival was achieved. In the early 1960s Woodruff described the immunosuppressive effect of antilymphocyte serum. This antiserum was induced by the injection of donor strain lymphoid tissue into other species (rabbit, goat, horse). Thus an antiserum was generated that destroyed or functionally incapacitated the recipient's lymphocytes.

Once clinicians were confident that adequate immunosuppression was available, organ replacement for end-stage organ failure entered its early investigational phase. In 1963 the first liver transplant was performed by Starzl in Denver, and although this series remained largely unsuccessful, many of the technical principles that still guide liver transplantation were established. A few years later, Sir Roy Calne in Cambridge initiated the second-largest liver transplantation program in the world. Today more than 200 programs worldwide perform liver transplantation.

The first pancreas transplant was performed in 1966 in Minneapolis by Kelly, Lillehei, and Merkel. For many years, pancreas transplantation remained an unsuccessful mode of therapy for the treatment of end-stage diabetes, but in the early 1980s, with the refinement of surgical techniques and the introduction of new immunosuppressants such as cyclosporin A, the results in pancreas transplantation improved. The 1-year survival rate for simultaneous pancreas-kidney transplants in the United States is approaching 80 percent. One year after the first pancreas transplant, the first heart transplant was performed by Christiaan Barnard in Cape Town, South Africa. The first recipient survived only for a short time, but the second recipient survived for almost 2 years, and this success stimulated a worldwide surge in heart transplants. Many of these transplants, however, were performed in centers inadequately prepared, and results remained poor for several years. It is to the credit of the systematic scientific work by the Stanford group and its leader, Dr. Norman Shumway, that the foundation was laid for the current success achieved in heart transplantation.

Rejection of the transplant remained a major obstacle until the late 1970s, when a new drug, cyclosporin A, discovered by Jean Borel, revolutionized transplantation. After the introduction of cyclosporine, graft survival rose 15 to 30 percent. Shortly thereafter, the first monoclonal antibody to become commercially available for clinical use, OKT3, was tested for its effect in treating acute transplant rejection. Clinical trials led by Cosimi, from Massachusetts General Hospital, showed that this antibody was highly effective in reversing acute rejection in renal transplants, a finding that was later confirmed for heart, pancreas, and liver transplants.

The decade from 1985 to 1995 was characterized by the introduction of many new immunosuppressive agents. The original description of tacrolimus (FK506, Prograf) by Ochiai in Japan was followed by extensive clinical trials demonstrating that this agent was as potent as cyclosporine and in some instances demonstrated superiority in reducing the incidence of rejection. A new antimetabolite, mycophenolate mofetil (CellCept) was first tested at the University of Wisconsin, and other large-scale clinical trials demonstrated that this drug, in combination with cyclosporine, further reduces the incidence of rejection episodes.

Other new agents in clinical trials include rapamycin (sirolimus), mizoribine, and leflunomide. It is unclear whether these drugs will exhibit a benefit beyond the drugs that are used in current clinical practice. Monoclonal antibodies for the treatment of acute rejection or for use in induction therapy are being tested.

More than 40 years of clinical experience in organ transplantation has proved that the side effects of prolonged immunosuppressive therapy greatly contribute to morbidity and mortality after transplantation. The ultimate goal, as set out by Medawar, Brent, and Billingham, remains the induction of long-term stable immunological tolerance without prolonged immunosuppressive therapy. In recent years animal models have been established that allow scientists to test new strategies to accomplish this goal. These strategies will soon be tested in human subjects.

TRANSPLANT IMMUNOLOGY AND IMMUNOSUPPRESSION

Allan D. Kirk and Hans W. Sollinger

No field of medicine has been so intimately related to scientific advances as transplantation. Since the landmark technical developments of Alexis Carrel in 1902 that allowed vascular anastomoses to be routinely performed, it has been clear that transplantation of tissues between genetically nonidentical individuals fails. This failure has been broadly termed *rejection*, and its study has fueled most of the major discoveries in immunology. Components of the immune system are widely recognized not only for their importance in graft rejection but also for their roles in shock, tumor growth, autoimmune disease, and the systemic response to trauma. An understanding of immunology is critical to a thorough understanding of the biology of modern surgery.

Terminology

An *epitope* is the molecular unit of specific immune recognition. It is generally a carbohydrate or peptide moiety with a defined stereochemical configuration. The word *antigen* is used to describe an epitope containing molecules that can be bound by one of two types of lymphocyte receptors: the *T-cell receptor* (*TCR*) of T cells, or the *antibody* (or *immunoglobulin*) of B cells. Antigens may contain several epitopes.

Organs transplanted between genetically nonidentical individuals of the same species are termed *allografts* (the word *homograft* was used in earlier literature). The degree to which an allograft shares regulatory molecules of the immune system with the recipient is referred to as the *histocompatibility* of the graft. This is a description of the similarity of a cluster of genes on chromosome 6 known as the *major histocompatibility complex* (*MHC*, known as *human leukocyte antigen* [*HLA*] in human beings). The structure of the MHC has been described in detail. Two different classes of MHC gene products are produced, *class I* and *class II*. The importance of MHC gene products stems from their *polymorphism*. Unlike most genes, which are identical within a given species, polymorphic gene products differ in detail while conforming to the same basic structure. Since MHC is polymorphic, it can serve as an antigen to another individual. Antigens derived from different MHC molecules within the same species are called *alloantigens*. Allografts that are matched to their recipient at HLA are referred to as HLA-identical allografts, and those matched at half of the HLA loci are termed *haploidentical*. HLA-identical allografts differ genetically and are distinguishable from *isografts*. Isografts are organs transplanted between identical twins and are immunologically inconsequential. *Xenografts* are organs transplanted from one species to another (they were formerly described as heterografts).

Historical Background

The phenomenon of nontechnical loss of transplanted tissues was recognized by many investigators in the early 1900s, beginning with Carrel and Guthrie. Carrel was awarded the Nobel Prize for his initial contributions. The routine technical success of vascularized allografts was closely followed by Murphy's observation that lymphocytes were critical to the process. In the 1940s Peter Medawar's classic studies of skin-grafted rabbits demonstrated that rejection was a genetically controlled, donor-specific event mediated by lymphocytes and monocytes and governed by multiple transplant-related antigens. He showed that immunity could be invoked by prior exposure to donor tissues other than the transplanted tissue, that the immunity was remembered by the host immune system, and that active cell division was required for host response amplification. Building on the observations of Owen, Medawar and his colleagues also demonstrated that transplant immunity was acquired during ontogeny rather than being an innate property of the host, and

that the barrier to transplantation was not absolute. Like Carrel's, Medawar's advance was recognized by the Nobel Committee. Mitchison further demonstrated the importance of lymphocytes in the rejection process by transferring transplant immunity with leukocyte transfusion. In a period of 10 years, the problem was defined, the effector identified, and the solution envisioned. These investigations heralded the beginning of modern transplant immunology and have served as the basis for all subsequent work.

The next two decades were marked by extraordinary progress in the understanding of the genetic basis of immune recognition. Landmark investigations on the immunogenetics of the MHC began with Gorer and Snell's description of the H-2 system in mice, a genetic locus that segregated with transplant tumor survival. This erythrocyte-based system was soon shown by Amos to exist on leukocytes and to elicit an antibody response toward the antigens encoded by H-2. This antibody response became critical to establishing the correlate of H-2 in human beings. Dausset used this finding, together with his observation that antibodies could also be generated by antigen exposure via transfusion or pregnancy, to establish the first serologically based typing system for human transplant antigens, the Mac antigens. This system used serum from multiparous females to lyse cells based on differences in the cell surface antigens of lymphocytes. These differences were subsequently shown to be based on polymorphisms of the class I (HLA-B) molecules. This system was followed quickly by the 4a4b system of van Rood and the LA system of Payne. Snell and Dausset shared a Nobel Prize for their observations, perpetuating the pattern of fundamental discoveries in transplant immunobiology.

Class II MHC polymorphism also was defined in this period. Bach demonstrated that lymphocytes would proliferate in response to contact with lymphocytes of a different genetic background. This phenomenon, known as the *mixed lymphocyte culture (MLC)*, was found to be based on differences in class II MHC molecules and was defined as HLA-D.

These findings set the stage for a series of workshops from 1964 to 1970 organized to integrate the growing number of systems into a single, unified system. Stimulated by the increasingly rapid pace in defining HLA polymorphism, methods for rapid serologic definition of HLA were developed and broadly applied, primarily Terasaki's lymphocytotoxicity assay and refinements of Bach's MLC. This resulted in the current definition of HLA as six loci on chromosome 6, encoding two related cell surface molecules: class I (HLA-A, B, and C) and class II (HLA-DR, DP, and DQ).

In the 1970s advances in molecular biologic techniques allowed the genetic basis of HLA polymorphism to be established, leading to Bjorkman and Brown's discovery of the three-dimensional structure of HLA antigens. These methods allowed the fundamental aspects of antigen recognition to be defined. Particularly important were the Nobel Prize-winning contributions of Tonegawa that showed that antigen receptors were generated by complex rearrangements of the somatic genes in T and B cells. These studies have allowed further examination of the fundamental nature of neonatal tolerance first described by Medawar.

The characterization of HLA catalyzed numerous fundamental investigations in immunology in the 1980s. The function and structure of the T-cell receptor, the importance of adhesion molecules and costimulatory signaling in T-cell activation, and the elucidation of the soluble mediators of cell activation, cytokines, were products of this period. They have led to a reasonably comprehensive picture of the mechanism of allograft rejection and the physiologic functions of lymphocytes.

The close link between the basic scientific community and pioneer transplant clinicians has been underscored by the rapid application of new discoveries to the problem of rejection. Clinical observations have aided greatly in understanding the importance of basic observations. After the genetic basis for transplant rejection was established, Murray applied the concept by successfully transplanting a kidney between identical twins. The importance of lymphocyte division also was quickly recognized and exploited. Elion and Hitchings developed a 6-mercaptopurine analogue, azathioprine, which inhibited lymphocyte nucleic acid metabolism. It was applied first, experimentally, by Calne and Murray, and then, clinically, by Murray to allow the first successful allografts in human subjects. Elion and Hitchings were honored by the Nobel Committee in 1988 and Murray in 1990.

The most significant advance in immunosuppression was the discovery of cyclosporine by Borel in 1976. This selective inhibitor of T-cell activation was quickly recognized by White and Calne and applied to renal transplantation. The release of this drug in 1983 made clinical transplantation routinely successful not only for kidneys but for other organs as well. The success of cyclosporine has benefited T-cell biology too, because it stimulated much of the investigation necessary for understanding cytokine function and overall transmembrane receptor signaling.

Today's armamentarium to combat rejection is large and varied. It is now rare for an allograft to be lost to acute rejection. Future advances must focus on the chronic diseases of a growing transplant population. Ideally, the concept of specific immunological tolerance first described 50 years ago will soon be understood and will allow for transplantation without immunosuppression.

Overview of Immunity

Immunity in vertebrates has evolved into two distinct, but complementary, branches to combat disease: innate and acquired immunity. These two types of immunity differ in the degree of specificity with which their receptors or proteins bind to pathologic agents. Innate systems use germ line-encoded proteins that are limited in specificity but are broadly reactive against common components of pathogenic organisms, e.g., lipopolysaccharides on gram-negative organisms or other glycoconjugates. Acquired immunity is based on antigen receptors formed by germline gene rearrangement, which leads to highly specific binding interactions, primarily the activity of B and T cells. These rearrangements occur during ontogeny to ensure that the receptors released into the periphery are adapted to the MHC molecules of each individual. MHC polymorphism leads to a receptor repertoire that is unique to each individual. Its evolution has ensured that the population is adapted to deal with an extraordinary array of pathogens and has minimized the possibility of an all-encompassing plague.

The hallmark of acquired immunity is *specific* recognition and elimination of nonself. Highly specialized mechanisms for distinguishing pathogenic organisms and transformed cells from normal tissues have evolved to facilitate this goal. The pathogen is recognized as a specific entity, not just as nonself, and a record of that encounter is retained for more rapid response to future encounters, a phenomenon known as immunological memory. Antigens are peptides, or carbohydrates, containing epitopes, and they are the portion of a pathogenic cell or foreign body that is recognized by the acquired immune system. Antigen recognition is mediated by lymphocytes, T cells, and B cells, each of which is endowed with receptors for detection of specific antigens. T cells protect the cells of the body against alterations by mutation or viral infection (cellular immunity) and bind peptide antigens that have been processed by the body's cells. B cells provide protection against extracellular infectious organisms and foreign material (humoral immunity) and recognize antigens in their native unprocessed state. Both B and T cells rearrange the germ line configuration of their genome during ontogeny to form as many as 10^{11} clones of cells, each dedicated to the recognition of one specific antigen. An individual's ability to recognize a given antigen is determined before birth.

T cells use a specific receptor, the T-cell receptor (TCR), to recognize processed peptide antigens bound to MHC molecules. Self cells "contaminated" with peptide antigens are identified for elimination. This binding event is strengthened by *adhesion molecules* that improve the binding affinity and communicate information about the nature of the binding to the T cell. Parenchymal cells express class I MHC molecules. These class I molecules display peptides from within, e.g., peptides from normal cellular processes or from viral replication, which are bound by T cells expressing an adhesion molecule with special affinity to class I, the CD8 molecule. Hematopoietic cells also express class II MHC molecules. These molecules display peptides that have been phagocytized from surrounding extracellular spaces and bind to T cells complemented by an adhesion molecule with affinity for class II-CD4. Under physiologic conditions, CD4+ T cells are first alerted of an invasion of the body by *antigen-presenting cells (APCs)* and activate CD8+ T cells to search the body for cells that have been infected by this invader. Many other adhesion molecules control the movement of immune cells through the body, monitor their trafficking to specific areas of inflammation, and nonspecifically strengthen the TCR:MHC binding interaction.

B cells bind soluble antigens and secrete soluble forms of their receptor, known as *antibodies*, to bind these foreign molecules. Material that is bound by an antibody is opsonized (flagged) for destruction by cells of the innate arm of immunity—phagocytic cells lacking the ability to distinguish self from nonself—primarily macrophages, monocytes, and *polymorphonuclear leukocytes (PMNs)*. This also improves the efficiency by which APCs engulf and present pathogens to T cells. Antibody-bound surfaces activate a destructive enzymatic cascade known as the *complement* system. This leads to destruction of the membrane to which the complement is bound and further opsonization for APC uptake. Specific immunity is complemented by innate defense mechanisms that, once activated, destroy in a more indiscriminate manner.

The entire immune process is facilitated by a means of amplifying the response of one cell to one antigen. *Cytokines* (known as interleukins [IL]) (see Table [10-1](#)) are polypeptides that are released by many cell types and activate or suppress adjacent immune cells. Other soluble chemicals released during an immune response increase blood flow to the area and improve the exposure of the area to lymphocytes and the innate immune system. The prototypical cytokine of T-cell activation is IL-2.

While each component of the immune system has a defined role in the defense against disease, the immune response to an allograft is multifaceted and complex. This is reflective of its serendipitous nature. There has been no selective pressure to evolve a means of counteracting engrafted tissue. The immune response to an allograft is the result of incompatibility between the recipient's receptor repertoire and the donor's MHC polymorphisms. Effector mechanisms that have evolved to counteract viral, fungal, and bacterial infection, as well as those in place to prevent malignancy and autoimmunity, all come into play after transplantation. The innate and acquired arms of the immune system are involved in rejection, and the process of counteracting rejection limits the defense against other pathogenic entities.

Rejection, like physiologic immunity, can be divided into humoral and cellular mechanisms. Humoral rejection of a graft can be the result of antibodies existing in circulation prior to exposure, or antibodies acquired following exposure. This type of rejection involves the binding of antibody specific to the donor tissue MHC discrepancies, and subsequent activation of the complement cascade and cell lysis. Cellular rejection is the result of T-cell incompatibility between the donor and recipient. T cells recognize the MHC molecules of the donor themselves (either intact or processed and presented by APCs) as antigens, and identify the cells as contaminated and worthy of elimination. These two categories of rejection are not mutually exclusive.

Genetic and Structural Characteristics of Transplant Antigens

The antigens primarily responsible for human allograft rejection are those encoded by the HLA region of chromosome 6 (Fig. [10-1](#)). The polymorphic proteins encoded by this locus that directly affect transplant rejection are class I molecules (HLA-A, B, and C) and class II molecules (HLA-DR, DP, and DQ). Class I genes with limited polymorphism (E, F, G, H, and J) are not currently typed. Other genes encoded by HLA are the tumor necrosis factors a and b, components of the complement cascade (class III molecules), the heat-shock protein HSP 70, and genes necessary for class I and class II presentation of peptides to the body's T cells (peptide transporter proteins TAP 1 and TAP 2, and proteasome proteases LMP 2 and LMP 7). While other polymorphic genes, referred to as *minor histocompatibility antigens*, exist in the genome, these antigens are more important in bone marrow transplantation than in solid organ transplantation. Even HLA-identical individuals are subject to rejection on the basis of these minor differences. The blood group antigens of the ABO system also must be considered polymorphic transplant antigens, and their biology is critical to humoral rejection.

Each class I molecule is encoded by a single polymorphic gene that is combined with the nonpolymorphic protein b₂-microglobulin (b₂M, from chromosome 15) for expression. The polymorphism of each class I molecule is extreme, with 30 to 50 alleles per locus. Class II molecules are made up of two chains, a and b, and individuals differ not only in the alleles represented at each locus but also in the number of loci present in the HLA class II region. The polymorphism of class II is increased by combinations of a and b chains and a hybrid assembly of chains from one class II locus to another. As the HLA sequence varies, the ability of various peptides to bind to the molecule and be presented for T-cell recognition changes. This extreme diversity is thought to improve the likelihood that a given pathogenic peptide will fit into the binding site of these antigen-presenting molecules, preventing a

single viral agent from evading detection by T cells of an entire population. The importance of class I and class II structure is underscored by the relationship of HLA allotypes to many viral and autoimmune diseases.

While the structure of HLA is becoming increasingly complex, the clinical importance of the region is easily understood by simple Mendelian genetics. Recombination within the locus is uncommon, occurring in approximately 1 percent of molecules, and therefore the HLA type of the offspring is predictable. The unit of inheritance is the haplotype, which consists of one chromosome 6, and one copy of each class I and class II locus (HLA-A, B, C, DR, DP, and DQ). The genetics of HLA are particularly important in understanding clinical living-related donor (LRD) transplantation. Each child inherits one haplotype from each parent; the probability of a sibling's being HLA-identical is 25 percent. Haploidentical siblings occur 50 percent of the time and completely nonidentical siblings 25 percent of the time. Parents are haploidentical with their children. The degree of HLA match also can improve if the parents are homozygous for a given allele, giving the same allele to all children. If the parents share the same allele, the likelihood of that allele's being inherited improves to 50 percent. The inheritance of HLA also is affected by linkage disequilibrium, or a propensity of certain class I and class II genes to be located on the same chromosome.

The three-dimensional structure of class I molecules (HLA-A, B, and C) was first elucidated in 1987 and is shown in Fig. 10-2. Class I is expressed as a single MHC-encoded, transmembrane alpha chain, in combination with β_2 M. The alpha chain has 3 domains, alpha 1, 2, and 3. The critical structural feature of class I molecules is the presence of a groove formed by two α helices mounted on a β -pleated sheet in the alpha 1 and alpha 2 domains. Within this groove, a nine-amino acid peptide, formed from fragments of proteins being synthesized in the cell's endoplasmic reticulum, is mounted for presentation to the body's T cells. Almost all of the significant sequence polymorphism of class I is located in the region of the peptide binding groove and in areas that directly contact T cells. It is this variation in sequence at the HLA:TCR interface that is the essence of alloreactivity. Class I molecules are found on all nucleated cells except neurons.

The three-dimensional structure of class II molecules (HLA-DR, DP, and DQ) was inferred by sequence homology to class I and was eventually proved by x-ray crystallography. The structural features of class II molecules are strikingly similar to those of class I molecules (see Fig. 10-2). In particular, the groove and platform for peptide binding are present and are held away from the cell surface by two subunits. Class I is a single chain of three domains that relies on a non-MHC-encoded subunit for expression (β_2 M); class II is formed by two MHC-encoded chains, alpha and beta, each with two domains. The peptide binding site for class II is formed by the alpha 1 and beta 1 domains. This site is filled with a peptide derived from endocytosed proteins (as opposed to proteins formed by the cell, as is the case for the groove of class I). These peptide fragments are the result of proteolytic degradation of captured extracellular material and are substantially larger (up to 23 amino acids long) than the peptide found in class I. Like class I, the sequence polymorphism of class II is located at this TCR interface region. Class II molecules are found primarily on cells of the innate immune system, particularly phagocytes, such as dendritic cells, macrophages, and monocytes, but can be up-regulated to appear on other parenchymal cells by cytokines released during an immune response or injury.

Another important sequence-related difference between class I and class II molecules is located on the supporting subunits (alpha 3 domain for class I and beta 2 domain for class II). A loop extends outward and serves as a binding site for accessory molecules associated with the T-cell receptor. The TCR accessory molecule CD8 selectively binds the loop of class I while the accessory molecule CD4 binds the loop of class II. In this way T cells geared toward the initial recognition of intruders and subsequent amplification of the immune response (CD4+ helper T cells) are targeted to bind the cells with the ability to capture and present these antigens. Similarly, T cells that survey the body's parenchyma for signs of entrenched intracellular pathogens and destroy infected cells (CD8+ cytotoxic T cells) are outfitted to perform this duty.

Biology of Transplant Antigens

The physiologic role of MHC molecules is twofold: to provide a mechanism for T-cell inspection of parenchymal cells, and to provide an interface between innate immune cells (APCs) and T cells. For the structural reasons detailed above, class I molecules serve the first role and class II molecules serve the second. Organ transplantation is not a physiologic process but rather an artificial situation. T-cell responses to either class of MHC molecule can generate a rejection episode.

The assembly of class I is dependent on association of the alpha chain with β_2 M and occupation of the peptide groove with a native peptide. Incomplete molecules are not expressed. All peptides made by a cell are candidates for presentation, although sequence alterations in this region favor certain sequences over others. Human class I presentation occurs on all nucleated cells in contact with blood, allowing the acquired immune system to inspect and approve of ongoing protein synthesis. T cells develop on the basis of their ability to bind without activation to self MHC molecules presenting self peptides. Alterations in the peptide content, for example, by introduction of viral peptide synthesis, cause activation. In the case of transplantation, this alteration is possible not only with the peptide but also with the presenting molecule itself. T cells interpret any binding event not established as appropriate during their development as worthy of presenting cell destruction. Class I molecules are bound only by T cells expressing CD8, and CD8+ T cells have enhanced cytotoxic capabilities for infected cell destruction.

Class II molecule assembly requires association of an alpha chain and a beta chain in combination with a temporary protein called the *invariant chain*. This third protein covers the peptide binding groove until the class II molecule is out of the endoplasmic reticulum and is sequestered in a forming endosome. Proteins that are engulfed by a phagocytic cell are degraded at the same time as the invariant chain is removed, allowing peptides of external sources to be associated with, and presented by, class II. In this way the acquired immune system can inspect and approve of proteins that are in free circulation. The T cells that bind class II molecules are CD4+ and have enhanced abilities for activation of CD8+ T cells and antibody-producing B cells. When an inappropriate peptide is detected, CD4+ T cells release cytokines to recruit CD8+ cells into the area to inspect nearby cells for intracytoplasmic presence of the offending peptide. B cells also are stimulated to release antibody to bind the offending peptide and aid in its clearance by the innate immune system. The cytokines released by CD4+ cells, particularly interferon- γ , also induce expression of class II molecules on local cells and increase expression of class I molecules locally. This increases the chances that infected cells will be detected. In the case of transplanted organs, as with class I, an abnormal peptide or the foreign class II molecule itself can lead to T-cell activation. Ischemic injury at the time of transplantation accentuates the potential for T-cell activation by foreign MHC by causing up-regulation of both class I and class II molecules.

While matching donors and recipients with regard to HLA type has been shown to improve outcome after kidney, heart, and pancreas transplantation, no such correlation exists in liver transplantation. Matching may reduce overall survival. The reasons for this lie in the dualistic nature of HLA in the pathophysiology of liver disease. T-cell-mediated rejection of the liver is mechanistically the same as with other organs; therefore, rejection is reduced with improved HLA compatibility. The physiologic role of HLA is the presentation of viral peptides to T cells to initiate destruction of virally infected cells. HLA compatibility potentiates the inflammation during viral reinfection after transplantation for viral hepatitis and increases the chances for clinical recurrence of the original disease. Similarly, T-cell-mediated autoimmune diseases, e.g., primary biliary cirrhosis, are etiologically based on T-cell recognition of HLA-presented peptides. Recurrence of autoimmune diseases may be potentiated as well. Further knowledge regarding specific disease states worsened by certain HLA matches may be useful for selective typing in the future.

Clinical Definition of Transplant Antigens

There is no doubt that matching the recipient and the donor as closely as possible with regard to their MHC genes reduces the risk of acute rejection. However, given the time constraints, pretransplant matching is feasible only in cadaveric renal transplantation and living-related allografts. Other organs are MHC-typed retrospectively. As immunosuppression has improved, the relative importance of MHC matching, even for renal allotransplantation, has decreased. When determining the destination of an organ, significant emphasis is placed on the recipient's physical condition and time on the waiting list. The degree of match, however, should be considered when allocating renal allografts and when evaluating organ dysfunction after allotransplantation.

Historically, MHC polymorphism has been defined with the use of two biologic assays: the lymphocytotoxicity assay and the MLC. Both assays define MHC epitopes but do not comprehensively define the entire antigen or the exact genetic disparity involved. Techniques now exist for precise genotyping that distinguishes the nucleotide sequence of an individual's MHC.

The lymphocytotoxicity assay is performed by taking serum from donors with anti-MHC antibodies of known specificity, and mixing it with lymphocytes from the individual in question. Rabbit complement is added with a vital dye, such as trypan blue, which is not taken up by cells with intact cell membranes. If the antibody binds to MHC, it activates the complement, leads to cell membrane disruption, and stains the cell with the dye. Microscopic examination of the cells can determine if the MHC antigen exists on the cells. This assay has been extremely valuable, but it is limited by the nature of the reagents. Antibodies bind to epitopes. The presence of one epitope does not preclude the presence of other epitopes that may differ from the desired MHC type. Many antibodies *cross-react* with MHC antigens other than the one with which they were raised. The pattern of these cross-reactivities is reasonably well established, and the use of a large panel of antibodies allows reasonable definition of the genetic locus in question.

The MLC is performed by incubating recipient T cells with irradiated donor T cells in the presence of ^{3} H-thymidine. If the cells differ at the class II MHC locus, the recipient cells proliferate and incorporate the radionuclide into the new cells. This incorporation can be detected and quantified. While class II polymorphism is detected by this assay, it takes several days to complete one assay (unlike the lymphocytotoxicity assay, which takes 4 to 6 h). The use of MLC as a prospective typing assay is limited to living-related donors. The antigen receptor is again the biologic reagent of this assay, and the genetic basis for the reaction can only be inferred from a series of reactions.

The sequencing of the class I and class II HLA loci has allowed several genetics-based techniques to be used for histocompatibility testing. These include restriction fragment length polymorphism (RFLP), oligonucleotide hybridization, and polymorphism-specific amplification using the polymerase chain reaction and sequence specific primers (PCR-SSP). Of these methods, the PCR-SSP technique is most commonly employed for class II typing. Serologic techniques are the predominant method for class I typing because of the complexity of class I sequence polymorphism. Sequence polymorphisms that do not alter the TCR:MHC interface are unlikely to affect allograft survival; the enhanced precision of molecular typing may provide more information than is clinically relevant.

Genetic and Structural Characteristics of Transplant Antigen Receptors

Receptors

Two cell types have evolved with the ability to specifically bind to antigen: T cells and B cells. Their receptors are similar in genetic development but differ in the types of antigens bound. T-cell antigen receptors bind peptide antigens that have been processed by cells and combined with MHC molecules, and B-cell antigen receptors, also known as antibodies, bind antigens in their native conformation free in the extracellular fluid. T-cell receptors are fixed; B-cell receptors can be secreted and act at locations remote from the cell.

T-Cell Receptor

The formation of the TCR is fundamental to the understanding of alloreactivity and self nonreactivity. T cells are formed in the fetal liver and bone marrow and migrate to the thymus during the first trimester of fetal development. At this stage, they have no TCR or accessory molecules. Upon entering the thymus, T cells undergo a remarkable rearrangement of the DNA that encodes the TCR (Fig. 10-3). This series of genetic deletions and splicing events is driven by two recombination activating genes, RAG-1 and RAG-2. Four distinct loci (α and δ on chromosome 14, and β and γ on chromosome 7), each made up of a highly polymorphic variable (V), junctional (J), and/or diversity (D) region and a well-conserved constant (C) region, are involved. The recombination event randomly joins C, V, D, and J regions together to form a functional α , β , γ , or δ chain. The γ and δ loci recombine first,

and if recombination is successful, a gd TCR is formed. If this event is not successful, then the α and β regions recombine to form an ab TCR. Approximately 95 percent of cells progress to express an ab TCR. The order of genetic rearrangement recapitulates the evolution of the TCR, as T cells expressing the gd TCR have more primitive functions, including recognition of heat-shock proteins, activity similar to natural killer (NK) cells, and MHC recognition.

Regardless of the genes used, individual cells recombine to express a single TCR with a single specificity. The rearrangements occur randomly in all T cells, resulting in a population of T cells capable of binding 10⁶ different specificities—essentially all combinations of MHC and peptide. These developing T cells also express CD4 and CD8, increasing the binding repertoire of the population to include either class I or class II MHC molecules. If this population were released unmodified, they would quickly bind to all self cells, activate, and destroy the individual.

To avoid the release of self-reactive T cells, developing cells undergo a process after recombination known as *thymic selection*. Cells initially interact with the MHC-expressing cortical thymic epithelium. If binding does not occur to self MHC, the cells are useless to the individual because they would be unable to bind and function in the periphery. All nonbinding cells undergo *apoptosis*, or programmed self-destruction, a process called *positive selection*. Cells surviving positive selection then move to the thymic medulla and lose either CD4 or CD8. If binding to self MHC in the medulla occurs with an unacceptably high affinity and apoptosis results, this is called *negative selection*. The precise nature of this affinity threshold most likely involves interaction with hematopoietic cells that reside in the thymus and simulate APCs. The only cells released into the periphery are those that can bind self MHC without activation. Any foreign peptide encountered alters the affinity that has been preordained in the thymus, resulting in T-cell activation. MHC molecules that were not part of the T cell's thymic education will bind the TCR with unacceptable affinity and lead to activation. This phenomenon defines alloreactivity.

In addition to thymic selection, mechanisms exist for peripheral modification of the T-cell repertoire. Much of this is in place for removal of T cells after an immune response and down-regulation of activated clones. A molecule known as Fas (CD98) is expressed on activated T cells. Under appropriate conditions, binding of this antigen to its ligand leads to apoptosis. This method is dependent on TCR binding and the activation state of the T cell. The Fas ligand, in addition to its role in down-regulation, can serve as a molecular barrier to T-cell invasion of certain immunologically privileged sites, e.g., testes. Complementing this deletional method to TCR repertoire control are nondeletional mechanisms that selectively anergize (make unreactive) specific T-cell clones. One prominent receptor group mediating this function is the CD28:B7 pair. TCR binding leads to activation only if the costimulatory molecule B7 is bound to its ligand CD28, generally found on APCs. In the absence of binding, the cell is turned off until exogenous IL-2 is added. TCR binding that occurs to self in the absence of appropriate antigen presentation or active inflammation fails to lead to self reactivity.

The manipulation of the TCR repertoire by central (thymic) and peripheral mechanisms is responsible for the phenomenon described by Medawar as *tolerance*. Its understanding will yield the methods required for specific allograft acceptance.

The end result of TCR formation is a heterodimeric transmembrane receptor with a site for binding to peptide: MHC combination. The receptor is combined with an accessory-binding molecule (CD4 or CD8) and a transmembrane-signaling complex known as CD3.

Antibody

Antibody, also called immunoglobulin (Ig), is formed in B cells much the way the TCR is in T cells, although maturation occurs in the bone marrow, not in the thymus, and continues in the periphery. Five different heavy-chain loci (μ , γ , α , ϵ , δ) on chromosome 14 and two light-chain loci (κ on chromosome 2 and λ on chromosome 2), each with V, D, J, and C regions, are brought together randomly by the RAG-1 and RAG-2 apparatus to form a functional antigen receptor. Antibodies have a basic structure of four chains, two of which are identical heavy chains, and two of which are identical light chains. The heavy-chain usage defines the Ig type as being either IgM, IgG, IgA, IgE, or IgD. This structure forms two identical antigen binding sites brought together on a common region known as the Fc portion of the antibody (Fig. 10-4). The Fc portion is bound by Fc receptors on phagocytic cells of the innate immune system, facilitating phagocytosis, followed by destruction of the antigen and processing of antigenic peptides. The Fc portion of IgM, and some classes of IgG, also serve to activate complement. A mechanism for regulating B-cell tolerance exists, although our understanding of it is less complete than that for T-cell tolerance.

Unlike the TCR, the Ig loci undergo continued alteration after B-cell stimulation to improve the affinity and functionality of the secreted antibody. In an alteration known as isotype switching, Ig genes change their initial heavy-chain gene usage from the IgM type (used for initial and baseline responses against common carbohydrate antigens), to one of four types, each providing heightened specialization for a given purpose. IgG becomes the most significant soluble mediator of opsonization and is the dominant antibody resulting from allostimulation. IgA is formed for mucosal immune responses, IgE for mast-cell mediated immunity, and IgD as a primary cell-bound antibody form. Once a clone of cells is activated, the D and J regions of the utilized gene undergo random additions through the action of terminal deoxynucleotide transferase (TdT), to slightly altering the gene coding for the antigen binding site. This process, called affinity maturation, results in clones that have altered antigen affinity. Those with increased antigen affinity are retained for a more vigorous response in the event that this antigen is reencountered. Individuals with prior exposure to an alloantigen are more likely to have clones of B cells that have mutated to form a gene complex expressing an IgG with extremely high affinity. To avoid a vigorous humoral rejection of the graft, screening for these antibodies must be done before transplantation.

Biology of Transplant Antigen Recognition and Destruction

T-Cell Activation

T cells can respond to transplant antigens directly, through TCR binding to foreign MHC molecules expressed on transplanted tissues, or indirectly, by encountering APCs that have phagocytosed fragmented allograft tissues and processed the antigens for expression on self MHC. Regardless of the source of the activating MHC, the ensuing activation of the cell proceeds in the same way as it does for physiologic T-cell function. This process has been exploited at almost every critical step to prevent acute rejection, and its understanding is key to the rational use of immunopharmacologic agents.

Initial T-cell binding to an APC or endothelial cell is nonspecific and mediated by adhesion molecules. These molecules, including ICAM-1, VCAM-1, LFA-1, and other integrin family molecules are all up-regulated upon APC activation. This increases the likelihood that a T cell with pertinent specificity will bind and become activated. Once nonspecific adhesion has formed, MHC recognition can occur.

Because the number of potential antigens is high and self antigens are likely to vary minimally from foreign antigens, the nature of the TCR binding event has evolved such that a single interaction with an MHC molecule is not sufficient to cause activation. A T cell must register a signal from approximately 8,000 TCR ligand interactions with the same antigen before a threshold of activation is reached. Resting T cells have low TCR density, which usually is accomplished by sequential binding and internalization over several hours. Transient encounters are not sufficient.

The TCR transmits its signal to the cell by initiating the activity of intracytoplasmic protein tyrosine kinases (PTKs). These PTKs include p56^{lck} (on CD4 or CD8), p59^{Fyn}, and ZAP70, the latter two of which are associated with the TCR-associated transmembrane protein complex called CD3 (Fig. 10-5). Repetitive binding signals eventually activate phosphokinase- γ (PLC- γ 1), which in turn hydrolyses the membrane lipid phosphatidyl inositol biphosphate (PIP₂), releasing inositol triphosphate (IP₃) and diacylglycerol (DAG). IP₃ binds to the endoplasmic reticulum, causing a release of calcium that induces calmodulin to bind to and activate calcineurin. Calcineurin dephosphorylates the critical cytokine transcription factor NF- κ B, prompting it to initiate transcription of IL-2. IL-2 is then released and binds to the T cell in an autocrine loop, potentiating DAG activation of protein kinase C (PKC). PKC is important in activating many gene regulatory steps critical for cell division.

In addition to TCR engagement, a second confirmatory signal is required for T-cell activation. This is most likely the role of the T-cell surface molecule CD28. It binds to molecules on APCs known as B7 molecules (B7-1 or CD80 and B7-2 or CD86). Binding of CD28 directly potentiates the TCR-initiated tyrosine phosphorylation, allowing more efficient signal transduction and lowering the number of binding events required for T-cell activation from 8,000 to about 1,500. B7 expression appears to distinguish MHC-expressing cells with potent APC function (so-called “professional” APCs, such as dendritic cells and macrophages) from cells with poor ability to present antigen. A second receptor, CTLA-4, acts to negatively regulate CD28, while the surface molecule gp39 binds to CD40 on B cells and macrophages to up-regulate B7 and potentiate costimulation. Costimulation can control whether a TCR signal results in activation or quiescence. This control plays a role in self-tolerance.

Activation also is dependent on the presence of a “danger” signal. By requiring an indication that the binding event is occurring in a location undergoing injury, spontaneous T-cell activation is prevented. This signal may be given by dendritic cells activated by phagocytosis of injured or opsonized material and likely is closely tied to the CD28/CTLA-4 costimulation pathway.

T-Cell Amplification

Once activation occurs, cytokines, particularly IL-2 and interferon- γ (IFN- γ), create a potent milieu, recruiting other T cells into the response and potentiating clonal expansion. Cytokines, particularly IFN- γ , also induce the nonlymphoid tissues to express class II molecules and to up-regulate expression of class I molecules. B-cell activation also is mediated through cytokine secretion. Cytokines are responsible for many of the systemic symptoms of fever and malaise associated with severe graft rejection.

T cells, once activated, develop into one of two phenotypes based on cytokine expression. T cells mediating cytotoxic responses, such as delayed-type hypersensitivity (DTH), express IL-2, IL-12, IL-15, and IFN- γ and have been called Th1 cells. T cells supporting the development of humoral or eosinophilic responses express IL-4, IL-5, IL-10, and IL-13 and have been called Th2 cells. This dichotomy is supported by the fact that many Th1 cytokines have a common receptor chain called γ that is not used by Th2-type cytokines. While extensive study has shown that differential cytokine expression alters the character of the effector response on a population scale, the predominance of a given cytokine is based on skewed expression along a continuum rather than absolute expansion of a single cell type. This is particularly true in the presence of immunosuppressive agents. Although evolved physiologic responses to pathogens have been shown to align themselves into discrete cytokine profiles, this division is less valid during transplant rejection. Immunosuppression produces artificial patterns of gene expression, resulting in nonphysiologic patterns of cytokine secretion. Responses also vary on the basis of the organ targeted for rejection. Kidneys are infiltrated by T cells in the context of a Th1-type milieu plus IL-10, but livers have a significant eosinophil infiltration and a large amount of IL-5. The patterns of inflammation seen during allograft rejection result from cytokine-mediated amplification but vary considerably according to other factors.

In the late phases of rejection, the inflammatory response recruits cells with nonspecific cytotoxic activity to the organ. T cells expressing the gd TCR and other T lineage cells, such as lymphokine-activated killer cells, are activated to destroy surrounding tissue in an MHC-unrestricted fashion. IL-8, released by activated macrophages and T cells, also recruits PMNs to the scene to remove necrotic tissue.

T-Cell-Mediated Cytotoxicity

T cells assume one of two roles: that of an amplifier or that of a cytotoxic effector. The amplification role generally is performed by CD4⁺ cells, because these cells are most suited for communication with class II-expressing APCs. Cytotoxicity is best mediated by CD8⁺ cells, since they bind to the MHC of all nucleated cells. In the artificial situation presented by organ transplantation, both CD4⁺ and CD8⁺ cells can mediate cytotoxicity. This occurs by a Ca²⁺-dependent secretory mechanism or a Ca²⁺-independent binding mechanism. The Ca²⁺ flux that occurs with activation also causes the exocytosis of cytolytic granules. These granules contain a lytic protein called *perforin* and serine proteases called

granzymes. Perforin polymerization in the presence of extracellular Ca^{2+} forms defects in the target cell's membrane, allowing granzyme activity to lyse the cell. In the absence of Ca^{2+} , T cells can induce apoptosis of a target cell. Apoptosis is a programmed death that involves fragmentation of the nuclear contents. It occurs when a surface Fas is cross-linked by its ligand. Cytotoxic T cells up-regulate Fas ligand upon activation.

After activation, non-MHC-restricted, T-cell-mediated cytotoxicity occurs. This allows the utilization of T cells activated in the area of inflammation without a TCR specific to the antigen to take part in protective, or in the case of transplant rejection, detrimental immunity. The mechanisms of direct T-cell-mediated destruction of microorganisms or non-MHC-expressing tissue remain poorly defined. T cells expressing the gd TCR are prominent effectors of non-MHC-restricted cytotoxicity. This type of activity is induced by high concentrations of IL-2, which may be relevant in the local milieu of a rejecting allograft. This type of killing may be involved in rejections precipitated by infections or trauma to the transplanted organ and is certainly elicited during vigorous MHC-directed rejection.

B-Cell Activation and Clonal Expansion

B cells recognize antigen in its native form without the requirement for processing and presentation on MHC molecules. Surface antibody cross-linking by antigen leads to B-cell proliferation and differentiation into a plasma cell. Like the T cell, the threshold for B-cell activation is high. This can be lowered by a factor of 100 by costimulation signals received by the transmembrane complex CD19/CD21. B cells also can internalize antigens bound to surface antibody and process them for presentation to T cells. They can receive signals from T cells via CD40 mediated binding to the T cell's gp39. This signal up-regulates expression of B7 molecules on B cells and facilitates antigen presentation and T-cell costimulation. As such, B cells can bind antigen in circulation and initiate a T-cell response to deal with antigen incorporated into tissues of the body. Plasma cells (activated B cells) are distinguished histologically by their hypertrophied Golgi apparatus. They secrete large amounts of monoclonal antibody (antibody with a single specificity). During the activation process, the specificity of the antibody is altered by affinity maturation, as detailed previously.

In addition to being secreted after exposure to an antigen, antibody can be present as part of a natural repertoire in circulation for initial response to common pathogens. Antigen exposure generally leads to B-cell affinity maturation and isotype switching, and produces high-affinity IgG antibodies. Naturally occurring antibodies are IgM antibodies with low affinity and are generally thought to respond to a broad array of carbohydrate epitopes found on many common bacterial pathogens. Natural antibody is responsible for ABO antigen responses and discordant xenograft rejection.

Antibody-Mediated Cytotoxicity

Antibody facilitates the destruction and removal of antigenic cells. Once bound to an antigen, antibody serves as an anchoring site for the complement component C1q. In a pathway known as the *classical complement activation cascade*, two antibody Fc portions bind and initiate C1q-mediated activation of C3, the central activating enzyme of the complement cascade. This leads to formation of the membrane attack complex (MAC) of polymerized C5, C6, C7, C8, and C9, resulting in disruption of the target's cell membrane and lysis. In addition, several by-products of C3 cleavage serve as chemoattractant agents for phagocytic cells and as opsonins potentiating antigen phagocytosis. Antibody also can serve as an opsonin directly. Most phagocytic cells have receptors for the Fc portion of IgG and actively engulf antibody-coated targets in a process known as *antibody-dependent cellular cytotoxicity* (ADCC).

Antibody binding to the endothelium, and the subsequent activation of complement, also alters the activation status of the endothelial cell. This leads to cellular retraction and exposure of the underlying matrix, which in turn potentiates platelet activation and aggregation. Endothelial activation also alters its usually anticoagulant environment in favor of a procoagulant one. Heparin sulfate is shed, as is thrombomodulin. This prevents thrombomodulin-mediated activation of protein C and the interaction of activated protein C with protein S. The result is microvascular thrombosis, a hallmark of the two antibody-mediated graft rejections: hyperacute rejection and acute vascular rejection.

Clinical Rejection Syndromes

Rejection has been classified as hyperacute, acute, or chronic on the basis of the general pathophysiology and effector arm of the immune system involved. Of these, only acute rejection can be successfully reversed. Though hyperacute rejection is untreatable, it is mostly a preventable phenomenon. Chronic rejection remains a difficult problem.

Hyperacute Rejection

Hyperacute rejection (HAR) is caused by presensitization of the recipient to an antigen expressed by the donor. It develops in the first minutes to hours following graft reperfusion. Antibodies in circulation prior to transplantation, the result of prior exposure to donor-type alloantigens or ABO blood group antigens, bind to the donor tissue. This initiates complement-mediated lysis and induces a procoagulant state, resulting in immediate graft thrombosis. Exposure usually is in the form of prior transplant, transfusion, or pregnancy. While there is no treatment for hyperacute rejection, a thorough understanding of its cause has resulted in preoperative screening tests, namely the lymphocytotoxic crossmatch and ABO typing. These two tests identify donor-to-recipient combinations in which HAR could be avoided. The crossmatch is performed by mixing cells (nonactivated T cells that express class I, but not class II, MHC antigens on their surface) from the donor with serum from the recipient in the presence of complement. Lysis indicates the presence of antibodies directed against the donor. Many variations of this test exist, each detecting many antibody types against a variety of donor antigens. However, only detection of IgG antibodies directed against class I MHC molecules represents a positive test and a contraindication to transplantation. Preoperative verification of proper ABO matching and a negative crossmatch effectively prevents hyperacute rejection in 99.5 percent of transplants.

A delayed variant of HAR known as *vascular rejection* also is mediated by humoral factors. Vascular rejection occurs when offending alloantibodies exist in circulation at levels undetectable by the crossmatch assay, even though presensitization has taken place. Reexposure leads to restimulation of the memory B cells responsible for the donor-specific antibodies. The result is initial graft function, followed by deterioration on or about postoperative day 3. Enhanced immunosuppression with steroids, combined with nonspecific antibody depletion with plasmapheresis, occasionally is successful in attenuating vascular rejection. Vascular rejection also can occur through de novo antibody synthesis spurred on by T-cell-dependent B-cell activation.

Acute Rejection

Acute rejection is caused primarily by T cells and evolves over a period of days to weeks. It can occur at any time after the first 5 postoperative days, but is most common in the first 6 months, and is the inevitable result of an allotransplant unless immunosuppression directed against the T cell is used. To initiate acute rejection, T cells bind antigen via their TCR either directly or after phagocytosis of donor tissue and re-presentation of MHC peptides by self APC. This leads to cell activation as described previously. The result is a massive infiltration of the graft of T cells, with destruction of the organ (Fig. [10-6](#)).

Kidneys can be preserved long enough to allow organ allocation to the recipient to be the most closely matched to the MHC of the donor. Other organs cannot be matched in this way. The incidence of acute rejection declines with decreasing MHC disparity, but any mismatch puts the patient at risk for T-cell-mediated graft destruction and mandates T-cell-specific immunosuppression. Like HAR resulting from humoral presensitization, presensitization at the T-cell level results in an accelerated form of cellular rejection mediated by memory T cells.

Treatment leads to successful restoration of graft function in 90 to 95 percent of cases, and failure to treat results almost uniformly in graft loss. Prompt recognition of acute rejection is imperative. Most acute rejection episodes for patients on modern immunosuppression therapy are asymptomatic until the secondary effects of organ dysfunction occur. By this time the rejection is well-entrenched and difficult to reverse. For this reason, monitoring for acute rejection must be intense, particularly during the first year after transplantation. Unexplained graft dysfunction should prompt biopsy and evaluation for the lymphocytic infiltration and graft parenchymal necrosis characteristic of acute rejection. Liver acute rejection is characterized by eosinophil infiltration in addition to lymphocytic infiltration.

Chronic Rejection

Unlike acute and hyperacute rejection, chronic rejection (CR) is poorly understood. Its onset is insidious, occurring over a period of months to years, and because the pathophysiology is not well defined, it is untreatable. Heightened immunosuppression is not effective in reversing or retarding the progression of chronic rejection. Its distinction from acute rejection by biopsy is important. Acute rejection can be superimposed on CR, with treatment for the acute rejection leading to partial return of graft function. Histologically, CR tends to exhibit anomalies; regardless of the organ involved, it is characterized by parenchymal replacement by fibrous tissue with a relatively sparse lymphocytic infiltrate. Those organs with epithelium show a dropout of the epithelial cells and endothelial destruction. Chronic rejection is related to the recognition of MHC by the recipient's immune system, but nonimmunologic factors probably have a role in its progression. The time course, histology, and refractory nature of CR suggest that direct cell-mediated tissue destruction is not a primary mechanism. Cumulative effects of mild subclinical immune recognition by several limbs of the immune system, and the resulting exposure to soluble factors, including fibrogenic cytokines, eventually takes its toll on the fragile epithelium and endothelium. Chronic rejection requires retransplantation.

Immunosuppression

Without some attenuation of the immune system, all allografts eventually would be destroyed. The redundancy and plasticity of the innate and acquired immune systems has prevented any single manipulation from specifically preventing graft destruction. As allograft recognition is mediated by an immune system formed for the detection and elimination of pathogenic microbes or, to some extent, malignantly transformed cells, manipulations altering this system do so at the expense of a vital defense network. No immunosuppressive intervention is allograft-specific, nor do all maneuvers preventing allograft loss put the recipient at increased risk for infection or malignancy. Rational, selective use of several immunosuppressive agents acting through different synergistic mechanisms is required to successfully prevent rejection without completely removing the body's defenses.

For all organs, the events occurring at the time of transplantation are the most critical in establishing the state of immune unresponsiveness necessary for long-term graft survival. For this reason, immunosuppression is extremely intense in the early postoperative period and subsequently tapers. This initial conditioning of the recipient's immune system is known as *induction* immunosuppression. It usually involves deletion of the T-cell response completely and cannot be maintained indefinitely without lethal consequences. Medications used to prevent acute rejection for the life of the patient are called *maintenance* immunosuppressants. These agents are well tolerated if dosed appropriately. All have side effects that increase the risk of infection and malignancy. Immunosuppressants used to reverse an acute rejection episode are called *rescue* agents. They are the same as the agents used for induction therapy.

Corticosteroids

Corticosteroids, in particular the glucocorticoid effect of steroid preparations, remain a central tool in the prevention and treatment of allograft rejection. Used alone, they are ineffective in preventing allograft rejection, but in combination with the other agents described below they significantly improve graft survival. Higher doses of steroids also are used as a rescue agent to treat acute cellular rejection. Although steroids have a desirable immunosuppressive effect, they can contribute significantly to the morbidity of transplantation.

Despite the use for decades of steroids as an antiinflammatory agent, the mechanism of the immunosuppressive effect of glucocorticosteroids has not been completely elucidated. Glucocorticosteroids bind to an intracellular receptor after nonspecific uptake into the cytoplasm. The receptor-ligand complex then enters the nucleus, where it acts as a

DNA-binding protein and increases the transcription of several genes, the most important of which is probably the gene for IkBa. This protein binds to and prevents the function of NF-κB, a key activator of proinflammatory cytokines. In doing so, steroids prevent the primary mechanism by which lymphocytes amplify their responsiveness. The resulting effects are predictably diverse. Steroids block transcription of IL-1 and TNF-α. They also block IFN-γ production, PMN migration, and lysosomal enzyme release by PMNs. Phospholipase A₂, and consequently the entire arachidonic acid cascade, is inhibited. The up-regulation of MHC also is muted by steroids. By blocking the response of leukocytes to chemotactins, and by inhibiting vasodilators, such as histamine and prostacyclin, steroids exert a profound effect to dampen the inflammatory response and ultimately to blunt T-cell proliferation. They do not have a significant influence on antibody production.

Hydrocortisone (cortisol) is the major endogenous glucocorticoid. Numerous synthetic steroids have greater antiinflammatory potency and less mineralocorticoid effect than cortisol. In addition, the plasma half-life of each preparation varies. The most commonly used form of steroid is prednisone or its intravenous substitute, methylprednisolone.

The adverse effects of steroid therapy are numerous. Patients receiving maintenance steroids have a suppressed hypothalamic-pituitary-adrenal axis. When undergoing the stress of severe illness or injury, these patients need coverage with a steroid preparation in the amount equal to their endogenous adrenal capacity. This should not exceed 50 mg hydrocortisone every 8 h. The acute complications include impairment of glucose tolerance, delayed wound healing, salt and fluid retention that may exacerbate hypertension, and CNS effects, such as insomnia, depression, nervousness, and euphoria. These events usually can be ameliorated by tapering the steroid dose. Chronic side effects of corticosteroids include Cushing's syndrome (central obesity, acne, striae, hirsutism, altered facies), cataracts, muscle wasting, and growth retardation in prepubertal children. Patients show increased propensity toward peptic ulceration. Osteoporosis results from the combined effects of the inhibition of bone matrix formation and of intestinal absorption of calcium. The current trend in transplantation is to minimize the dose of steroids used (limiting the side effects) by adding two to four other immunosuppressive agents. There also are subsets of patients who may not require maintenance steroids, such as those with HLA-identical donors. In addition, a patient's rejection history should be considered; patients who have survived a year without a rejection episode can be considered for withdrawal from steroids.

Antiproliferative Agents

Azathioprine

The antimetabolite azathioprine was the first immunosuppressive pharmaceutical agent used in organ transplantation, and it remains a part of many maintenance immunosuppressive protocols. Azathioprine undergoes hepatic conversion first to 6-mercaptopurine (6-MP), and then to 6-thio-inosine monophosphate (6-tIMP). These derivatives inhibit DNA synthesis by alkylating DNA precursors and inducing chromosomal breaks through interference with DNA repair mechanisms. They also inhibit the enzymatic conversion of *inosine monophosphate (IMP)* to adenosine monophosphate (AMP) and *guanosine monophosphate (GMP)*. The primary effect is to deplete the cell of adenosine. The effects of azathioprine are relatively nonspecific; it acts not only on proliferating lymphocytes and PMNs but on all rapidly dividing cells.

Azathioprine effectively inhibits rejection when given as a maintenance agent but, unlike steroids, has no value as a rescue or induction agent. It is generally given in a dose of 1 to 3 mg/kg/day. Its primary toxicity is directed at the bone marrow, gut mucosa, and liver. The dose is decreased as the total white blood cell count falls, or it is stopped when leukopenia develops (usually less than 3,000/mL). In the presence of infection, azathioprine generally is withheld so as not to impair the physiologic response of the immune system. Because azathioprine is a hepatotoxin, its use is limited during liver dysfunction, and it is rarely used in liver transplantation. Mycophenolate mofetil is gaining popularity as a more specific purine antimetabolite.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) (RS-61443) is a potent immunosuppressive agent approved for use in adults. It is a morpholinoethyl ester of mycophenolic acid (MPA), an established noncompetitive, reversible inhibitor of IMP dehydrogenase. This modification improves the bioavailability of MPA.

Physiologic purine metabolism requires that GMP be synthesized for subsequent synthesis of guanosine triphosphate (GTP) and deoxyguanosine monophosphate (dGTP). GTP is required for RNA synthesis and dGTP for DNA synthesis. GMP is formed from IMP by IMP dehydrogenase, and therefore MMF prevents a critical step in RNA and DNA synthesis. Of major importance is the presence of a "salvage pathway" for GMP production in most cells *except* lymphocytes (hypoxanthine-guanine phosphoribosyl transferase–catalyzed GMP production directly from guanosine). MMF exploits a critical difference between lymphocytes and other body tissues, including PMNs, to produce relatively selective immunosuppressive effects. MMF blocks the proliferative response of both T and B lymphocytes, inhibits antibody formation, and prevents the generation of cytotoxic T cells. MMF also strongly suppresses in vitro B-cell memory responses.

MMF does not cause nephrotoxicity or hepatotoxicity at immunosuppressive doses, and its marrow-suppressive potential is less than that of azathioprine. Mild gastrointestinal irritation, in the form of diarrhea and nausea, has been reported. Because of its low toxicity in human beings and its antiproliferative effect on T and B cells, MMF was evaluated in a multicenter clinical trial of renal allotransplantation, comparing it in combination with prednisone and cyclosporine to azathioprine, prednisone, and cyclosporine. The results showed that MMF decreased the rate of biopsy-proved rejection or treatment failure from 48 to 31 percent and decreased the need for antilymphocyte agents in rescue therapy from 20 percent to a range of 5 to 10 percent, depending on the dose of MMF used. MMF has replaced azathioprine in patients with high risk of rejection. MMF also is effective as a rescue agent. In a comparison of high-dose methylprednisolone to MMF for the treatment of biopsy-proved rejection, MMF was shown to reduce the incidence of graft loss by 45 percent and the risk of recurrent rejection by 50 percent. MMF may interact with tacrolimus, potentiating the effect and possibly the side effects of this drug.

Calcineurin Inhibitors

Cyclosporine

In 1976 Borel demonstrated the T-cell–specific immunosuppressive properties of cyclosporin A, a cyclic endecapeptide isolated from the fungus *Tolypocladium inflatum* Gams. In 1983 cyclosporine was approved for use in the United States. Its use resulted in dramatic improvements in the results of all organ transplants, but particularly in hepatic and cardiac transplantation. It has remained a mainstay immunosuppressant in most maintenance regimens.

Cyclosporine's mechanism of action is mediated primarily through its ability to bind to cytoplasmic protein cyclophilin. Cyclophilin is a *cis-trans* peptidyl- prolyl isomerase critical for the proper folding of proteins (also known as a rotamase or an immunophilin). This function of cyclophilin is not critical to the immunosuppressive effects of cyclosporine but may be related to the toxic side effects of the drug. The cyclosporine-cyclophilin complex binds with high affinity to the calcineurin-calmodulin complex and blocks its role in the calcium-dependent phosphorylation and activation of the transcription- regulating factor NF-AT. This prevents the transcription of the IL-2 gene and other genes critical for T-cell activation. The role of cyclophilin in cellular cytotoxicity is probably interrupted. Cyclosporine reversibly inhibits T- lymphocyte–mediated immune responses, but it does not prevent antigen recognition by T cells, and its effects can be overcome with exogenous (or in the case of an ongoing rejection episode, ambient) IL-2. For this reason, once IL-2 is present in the graft cytokine milieu, cyclosporine is ineffective. Cyclosporine therefore works solely as a maintenance agent and is ineffective as a rescue agent.

Cyclosporine is a cyclic polypeptide, insoluble in aqueous solutions but soluble in lipids and organic solvents. A microemulsion formulation is now available that has improved cyclosporine's lipophilic nature. It usually is given orally but can be administered intravenously by slow infusion. While the gastrointestinal absorption of cyclosporine depends on bile flow (a significant concern in liver transplantation), the absorption of its microemulsion form is not. Cyclosporine is metabolized by the hepatic cytochrome P-450 enzymes, and blood levels are therefore increased by inhibitors of cytochrome P-450 (ketoconazole, erythromycin, calcium channel blockers) and decreased by cytochrome P-450 inducers (rifampin, phenobarbital, phenytoin). Liver failure slows the clearance of cyclosporine, because 90 percent of its metabolites are cleared in the bile. Renal failure does not alter cyclosporine clearance significantly, because only 6 percent of the dose given appears in urine.

Cyclosporine causes dose-related nephrotoxicity, because it has a vasoconstrictor effect on proximal renal arterioles. Cyclosporine tends to increase vascular resistance in the kidney and may delay the resolution of acute tubular necrosis or hepatorenal insufficiency. An additional renal effect is an idiosyncratic reaction producing hemolytic uremic syndrome. Hyperkalemia also may result from its effects on the proximal and distal renal tubules. Long-term use causes a 30 percent reduction in renal function, which usually can be reversed by discontinuing the drug. Hypertension also is a common adverse effect but usually can be effectively treated. Cyclosporine frequently causes neurologic side effects consisting of tremors, paresthesias, headache, depression, confusion, somnolence, and, rarely, seizures. Hypertrichosis of the face, arms, and back is seen in about 50 percent of patients. Gingival hyperplasia also may occur. Hepatotoxicity with elevation of bilirubin and serum aminotransferases may occur, as well as elevation of skeletal alkaline phosphatase. Renal toxicity usually is noticeable before hepatotoxicity occurs.

Tacrolimus

Tacrolimus (FK506) is a macrolide produced by *Streptomyces tsukubaensis* that was discovered in 1984 in Japan during a search for new immunosuppressive agents. Kino and coworkers first demonstrated its in vitro immunosuppressive properties in 1987. Tacrolimus, like cyclosporine, blocks the effects of NF-AT, prevents cytokine transcription, and arrests T- cell activation. The intracellular target is an immunophilin protein distinct from cyclophilin, known as FK-binding protein (FK-BP), the effect of tacrolimus is thus additive to that of cyclosporine, and the use of tacrolimus with cyclosporine produces prohibitive toxicity. Tacrolimus is 100 times more potent in blocking IL-2 and IFN-γ production than cyclosporine. Like cyclosporine, the effects of tacrolimus are relatively T-cell–specific, but in addition to its role as a maintenance agent, tacrolimus has shown promise as a rescue agent. The side effect profile of tacrolimus is similar to that of cyclosporine with regard to renal and hepatic toxicity. Neurotoxicity, in the form of tremors and mental status changes, is somewhat more pronounced, as is its diabetogenic effect. Cosmetic side effects are reduced substantially. Tacrolimus is extremely effective for liver transplantation and is the drug of choice. Enthusiasm for its use in children, particularly infants, has been tempered by a high rate of posttransplant lymphoproliferative disorder (PTLD), approaching 40 percent in some series. This may reflect early dosing inexperience.

Antilymphocyte Preparations

Antilymphocyte Globulin

Antilymphocyte globulin (ALG) is a polyclonal serum produced by inoculating heterologous species with human lymphocytes, collecting the plasma, and purifying the IgG fraction. Thymocytes rather than lymphocytes are sometimes used, and this is designated as *anti-thymocyte globulin (ATG)*. The most commonly inoculated species is the horse, and ATGAM is the most widely used preparation. Sera from rabbits and goats also are available. ATGAM targets the central mediator of acute rejection, the T cell, by coating multiple epitopes on this cell type and promoting their clearance through complement-mediated lysis, opsonin-induced phagocytosis, and internalization of key surface receptors. Because ATGAM is polyclonal (composed of antibodies with many specificities), antibodies to both T and B cells, and probably to other cells, are present. Only a small fraction of the serum is estimated to be biologically active against T lymphocytes. One prominent side effect is severe thrombocytopenia, which may result from cross-reactivity with platelets and therefore may limit the use of the drug.

The usual dose of ATGAM is 10 to 20 mg/kg/day, given intravenously, and the dose may be adjusted according to toxicity. The usual duration of therapy is 10 to 14 days, but this may vary. ATGAM should be given through a central line to avoid phlebosclerosis and delivered through a filter to prevent administration of insoluble aggregates that may develop during storage. Infusion should be relatively slow (over 4 to 6 h) to limit the intensity of any adverse reactions. Any history of allergy to horse or horse products should be elicited from the patient before ATGAM is used. Intradermal skin testing is available, but anaphylaxis is rare.

ATGAM is most commonly used as part of a multidrug induction immunosuppression protocol in renal transplantation with cyclosporine, azathioprine or mycophenolate mofetil, and prednisone. Limiting the dosage of each drug, and thus limiting the side effects, is the rationale for multidrug therapy. ATGAM often is used sequentially with cyclosporine or tacrolimus in the early postoperative period after renal transplantation to avoid the nephrotoxicity of these drugs early in the transplant course.

Most of the side effects of ATGAM are from its heterologous origin and heterogenous composition, but major side effects are rare, and the drug is well tolerated by most transplant recipients. The most common symptoms are the result of transient cytokine release after antibody binding. Chills and fevers occur in up to 20 percent of patients. These symptoms usually are transient and can be ameliorated by pretreatment with steroids, antihistamines, and antipyretics. The symptoms generally diminish in intensity as the treatment progresses. A skin rash characterized by large, raised, erythematous wheals on the trunk, neck, and proximal extremities may develop in up to 15 percent of patients. Treatment does not need to be discontinued because of these symptoms, which usually can be treated effectively with an antihistamine. Thrombocytopenia and leukopenia do require an alteration in treatment. Thrombocytopenia occurs to some degree in most patients, and leukopenia occurs less frequently. Hemolysis also may occur. When using ATGAM it is imperative that daily white blood cell and platelet counts be performed. Decreasing the dose or temporarily discontinuing therapy usually is accompanied by rapid recovery. If thrombocytopenia is the problem and therapy must be continued, pooled platelet transfusions prior to administration may be used. Because antilymphocyte preparations profoundly inhibit T lymphocytes, they also suppress cell-mediated immunity. The use of ALG has been associated with an increase in the reactivation and development of primary *cytomegalovirus (CMV)* infections. In addition to CMV infections, herpes simplex virus (HSV), Epstein-Barr virus (EBV), and varicella infections may occur more frequently after therapy with antilymphocyte preparations.

OKT3

Monoclonal antibodies have very specific targets. The technology for the creation of effective amounts of monoclonal antibodies stems from the hybridoma work in the late 1970s by Kohler and Milstein. The only commercially available preparation of monoclonal antibodies for use in organ transplantation is the murine monoclonal antibody to the signal transduction subunit on human T cells (CD3), known as Orthoclone OKT3. OKT3 is the product of a hybridoma formed from a myeloma cell and a primed murine lymphocyte capable of producing this antibody; the cell lines are cultured in mouse ascites and the final product is purified.

There are several ways in which OKT3 is thought to have its effect. The CD3 determinant is a cluster of transmembrane proteins found on the surface of all mature T lymphocytes. Because OKT3 binds to the CD3 determinant, it prevents signal transduction of the T-cell receptor antigen binding event and arrests amplification of a rejection episode. After the administration of OKT3, there is a rapid decrease in the number of circulating T lymphocytes. This is partially a result of opsonization and clearance by the reticuloendothelial system of the OKT3-lymphocyte complex. Several days after administration, there is a return of T cells expressing the accessory binding molecules CD4 and CD8, but lacking the T-cell receptor. Another way in which OKT3 exerts its effect is by down- regulation of the T-cell receptor complex, producing a “blind” T cell incapable of binding to antigen. In addition to interfering with the generation of cytotoxic T cells and the modulation of cell surface proteins, OKT3 blocks the cytotoxic activity of already activated T cells through inappropriate activation and degranulation. This is perhaps its most important function, but it leads to substantial side effects.

T-cell–derived cytokines have evolved as activators of adjacent cells. Their release is strongly polarized to the side of the cell actively engaged in cell- to-cell contact. The most potent T-cell activator, IL-2, exerts most of its effect in an autocrine loop. Pan-activation of the body’s T cells leads to transient activation and systemic cytokine release. This is similar to, but greater in magnitude than, the effect of the superantigen staphylococcal exotoxin, the etiologic agent of toxic shock syndrome. Administration of OKT3 leads to a profound, systemic cytokine release syndrome that can result in hypotension, pulmonary edema, and, rarely, fatal cardiac myodepression. In approximately 2 percent of patients, the inflammatory response manifests itself as aseptic meningeal inflammation. Administration of high-dose methylprednisolone prior to OKT3 administration is required to blunt this adverse response, but rarely is the response averted altogether. The syndrome abates with subsequent dosage as the target cells available for degranulation are consumed or exhausted.

The usual adult dose of OKT3 is 5 mg/day for 10 to 14 days. Unlike ATGAM, which must be given slowly and into a central line, OKT3 is given as a bolus injection over 1 min and may be given through a peripheral line. Pretreatment with methylprednisolone before administration of OKT3 as well as the use of antihistamines and antipyretics will help to limit the adverse reactions. Measurement of serum levels of OKT3 is possible but not done routinely. More commonly, the percentage of CD3-positive cells is determined by flow cytometry. The presence of less than 10 percent CD3- positive cells usually is associated with therapeutic efficacy; more than 10 percent CD3-positive cells usually indicates the presence of anti-OKT3 antibodies, which may limit the therapeutic effect. These antibodies may be directed against structural regions of the antibody (constant or variable regions) or the actual binding site (idiotypic) of the OKT3 antibody; they usually arise after a prolonged course of OKT3 or after the cessation of therapy. Levels of these antibodies can be measured. There is evidence that the use of azathioprine and other immunosuppressive agents during treatment with OKT3 may reduce the formation of anti-OKT3 antibodies. Occasionally, increasing the dose of OKT3 can overcome the effect of these antibodies.

OKT3 was first used as a rescue agent to treat acute renal allograft rejection. It is vastly superior to conventional steroid therapy in reversing rejection and improving allograft survival, but its side effects and the limiting nature of the antimurine antibody response have served to limit its use to the treatment of steroid-resistant rejection. The use of OKT3 in induction immunosuppressive protocols for kidney transplants is common. There are compelling data supporting the use of OKT3 in immunological high-risk patients, such as those requiring renal retransplants, to improve graft survival. OKT3 is used extensively in heart transplantation and may be used to reverse steroid-resistant rejection in liver transplant recipients.

OKT3, like other antilymphocyte preparations, causes a high reactivation rate of cytomegalovirus. Epstein-Barr virus infection leading to lymphoproliferative disorders also has been reported with the use of OKT3. Pediatric patients treated with OKT3 are at a higher risk of becoming infected with the varicella virus. It is not uncommon to see a rise in serum creatinine after the first several doses of OKT3 when treating acute renal allograft rejection. This may be a result of lysis of T lymphocytes within the renal tubules. The creatinine usually rises for 2 to 3 days and falls as treatment progresses.

New Immunosuppressive Agents

Rapamycin

Rapamycin is a macrolide antibiotic derived from *Streptomyces hygroscopicus*. This agent was described initially as an antifungal agent and was subsequently found to have immunosuppressive properties. Structurally, rapamycin is similar to tacrolimus, and the two have been shown to antagonize each other's biologic activity. Both interact with the cytoplasmic protein FK-BP, but rapamycin does not affect calcineurin activity, because its binding sterically hinders engagement with this molecule. As a result, rapamycin does not inhibit the expression of NF-AT or of IL-2, but it impairs signal transduction by the IL-2 receptor (IL-2R) through interaction of the rapamycin/FK-BP complex with the cytoplasmic protein RAFT-1, a critical kinase in IL-2R–associated activation. In doing so, the p70 S6 kinase cascade is arrested and T cells are prevented from entering the S phase of cell replication. This has the advantage of interrupting the T-cell activation pathway even if IL-2 is present from an exogenous source or ongoing rejection. Other receptors also are affected, including those for IL-4, IL-6, and platelet-derived growth factor (PDGF). Another benefit may lie in rapamycin's ability to antagonize B-cell lymphomas, and potentially it may be used to prevent the development of posttransplant lymphoproliferative disease.

At very low doses rapamycin dramatically prolongs mouse heart and skin allograft survival, as well as rat cardiac allograft survival. It is significantly more potent than cyclosporine. In vitro studies also have demonstrated marked synergy among rapamycin, cyclosporine, and steroids, allowing a dramatic reduction in dosages while inhibiting lymphocyte proliferation. These findings are important, because the toxicity of these agents should be reduced with combined therapy. Nephrotoxicity has not been observed, but hypertriglyceridemia may be a significant side effect.

Deoxyspergualin

The antitumor antibiotic spergualin was isolated from *Bacillus laterosporus* in 1981. Deoxyspergualin (DSG) has the strongest antiproliferative properties, and it is an immunosuppressant. The mechanism of DSG is not completely understood, but there is evidence that it is immunosuppressive via a predominantly antimonocyte-antimacrophage effect. It does prevent the nuclear translocation of NF-kB, perhaps through its association with the heat-shock proteins HSP 70 and HSP 90. This interaction inhibits the release of IκB, possibly mimicking a critical part of the steroid mechanism of action. The close relationship with HSPs, combined with evidence that the inhibitory effect of DSG on cytotoxic T cells can be abolished by the MHC–up-regulating cytokine IFN-γ, suggests that the primary effect of DSG is to inhibit antigen presentation or the costimulatory function of APCs.

DSG is effective in prolonging allograft survival in animal models of renal, pancreas, liver, and heart transplantation. Studies in renal transplantation suggest that it will be effective in this setting. Although severe gastrointestinal disturbances in canines have been noted, these may be species-specific. A trial of DSG in renal transplant recipients with rejection reported only mild gastrointestinal disturbances. Headache, fatigue, perioral numbness, and decreased white blood cell and platelet counts and hematocrit level also were noted. None of these was severe enough to justify discontinuing therapy. The overall response rate was 79 percent in 34 cases of rejection. Additional study is required to elucidate the mechanism of action of DSG and its place in the immunosuppressive armamentarium.

Brequinar

Brequinar sodium (BQR) is an immunosuppressive agent that selectively inhibits T- and B-cell proliferation. It functions by inhibiting the enzyme dihydroorotate dehydrogenase, thus interfering with pyrimidine synthesis. BQR, like mycophenolate mofetil, inhibits lymphocyte DNA synthesis and interrupts the rejection process at the level of clonal expansion. Prolongation of heart, kidney, and liver allograft survival was shown in several experimental models, and the effects of BQR are synergistic with cyclosporine. Primary side effects are related to leukopenia.

Anti-IL-2 Strategies

One approach to achieving more specific immunosuppression is to target antigens expressed only on activated lymphocytes. The interleukin-2 receptor (IL-2R) is one such antigen. While a low-affinity version of the IL- 2R is constitutively expressed on T cells, the high-affinity form required for clonal expansion is dependent on the up-regulation of a 55-kD subunit known as Tac. Experience with anti-Tac monoclonal antibodies has been encouraging. Induction with anti-Tac has prevented and reduced the frequency of early rejection episodes when used in combination with cyclosporine. Because anti-Tac and cyclosporine are synergistic, lower doses of cyclosporine could be used, thereby decreasing nephrotoxicity. A rat IgG2a monoclonal antibody, 33B3.1, also demonstrated excellent results in preventing posttransplant rejection, even without cyclosporine. Once rejection occurred, however, 33B3.1 was effective in reversing only 60 percent of rejection episodes. Experience has been reported with BT563, also of murine origin. In a double-blind placebo-controlled study using BT563 as an induction agent with cyclosporine and prednisone, freedom from rejection at 3 months was observed in 89 percent of the treated group, compared to 72 percent of the control group. While these results are comparable to other induction strategies with ATGAM or OKT3, the side effect profile was more favorable. This approach combines the specificity of monoclonal therapy with the targeting of a nonactivating ligand, avoiding the profound cytokine release syndrome seen with OKT3, and the promiscuous cell lysis seen with ATGAM. Longer follow-up is required to fully evaluate the efficacy of these agents.

Costimulation Blockade

The prevention of rejection has been based on a strategy of pharmacologic suppression of T-cell activation or T-cell ablation. Although this approach is effective, it is not specific for

the allogeneic response; rather it pan- suppresses all T-cell immunity. A more comprehensive understanding of T- cell biology may allow specific control of immunity by exploitation of the requirements for dual T-cell stimulation. Once the TCR is engaged, the T cell can follow one of two paths: activation, through CD28 binding to B7, or anergy, in the absence of CD28 binding. Interruption of the CD28 pathway of costimulation may selectively anergize only those cells undergoing binding to the allograft, leaving nonreactive cells unaffected. Increasing amounts of literature document a tolerogenic effect of specific biologic blockade of the CD28 or CD40 pathway. In rodents, simultaneous blockade of CD28 and CD40 at the time of transplantation can allow for indefinite survival of cardiac and skin allografts without the need for any subsequent immunosuppression. Agents under evaluation include antibodies directed against B7-1 and B7-2, CD28, CD40, gp39, and a fusion protein, CTLA4-Ig, which links the receptor CTLA4 to the Fc portion of IgG.

Xenotransplantation

The success of transplantation has led to its widespread application, but the indications for organ replacement have expanded far beyond the available donor supply. Most people who could benefit from a transplanted organ are unable to receive one, and those who do receive one usually have a significant waiting time and undergo a deterioration before operation. Many investigators are examining the feasibility of xenotransplantation to improve the availability of organs. There are two types of xenografts, discordant and concordant. The immunology of these two types of xenografts differs markedly.

Concordant Xenografts

For human beings, concordant grafts are derived from closely related species, such as Old World monkeys and apes. The critical element defining an animal as concordant is the assembly of carbohydrate antigens on the cell surface. In particular, the enzyme galactosyl transferase is absent in these animals, preventing the synthesis of the N-linked disaccharide galactose α(1-3)-galactose [GAL α(1-3)GAL]. Rather, they express typical blood group antigens of the ABH system. The antibodies present in circulation of potential human recipients can be predicted by ABH typing, avoiding the problem of hyperacute rejection (HAR) that occurs for allografts. With HAR removed as a threat, the typical mechanisms of graft rejection are left, including acute cellular rejection, acute vascular rejection, and, presumably, chronic rejection.

Most of the critical molecular elements responsible for antigen presentation and T-cell–mediated rejection are evolutionarily conserved in mammals. Xenogeneic MHC polymorphism is restricted to the antigen-binding region, with the areas responsible for accessory molecule binding intact. Costimulatory and adhesion molecules required for adequate T-cell interaction with a target cell function well across the species barrier. For these reasons, cellular rejection and T-cell–dependent humoral rejection proceed similarly to an allograft completely mismatched at the HLA locus.

Experimental models of concordant xenograft rejection, and occasional ventures into the clinical arena, have demonstrated that concordant xenotransplantation is feasible with available immunosuppressive pharmaceutical agents. Prevention of concordant xenograft rejection would require induction with a T-cell–specific biologic agent and chronic cellular suppression, including calcineurin inhibition, an antiproliferative agent such as mycophenolate mofetil, and steroids. Results matching those seen for poorly matched allografts could be expected, including the complications from the immunosuppression required for engraftment. With the possible exception of neonatal cardiac transplantation, the use of endangered, intelligent species with little ability to be bred or genetically altered, could not meet the need for readily available, size-matched organs. Widespread application of concordant xenografts would quickly deplete the supply of nonhuman primates, particularly when a loss rate extrapolated from poorly matched allografts is taken into consideration. There also is significant concern that zoonotic transfer of disease, in particular, retroviral illness, would put the patient and the public at undue risk. It is anticipated that xenotransplantation will primarily involve discordant species.

Discordant Xenografts

Discordant grafts are derived from distantly related species, such as New World monkeys and nonprimates. When transplanted into human beings, these organs rapidly undergo hyperacute rejection. The primary cause of the rejection varies from species to species but generally involves preformed IgM antibodies directed against atypical carbohydrate residues, such as GAL α(1-3)GAL, acting in concert with complement. These antibodies might serve a protective role against cross-reactive bacteria. Vigorous T-cell–mediated rejection also can occur because human T cells can be bound and activated by discordant MHC. Induced antibody responses similar to a vigorous vascular rejection are seen. In addition to the typical patterns of cellular rejection, there also is a substantial detrimental effect of natural killer cells and other innate cellular elements.

Because of the spectrum of effectors involved in discordant rejection, intervention at all levels of innate and acquired immunity will be required for successful engraftment. A multimodal approach will be required. Significant advances have been made, particularly in the pig, toward establishing a xenogeneic source of donor organs. Several groups have transgenically altered pigs to express human complement regulator proteins, such as CD59, decay-accelerating factor, and membrane cofactor protein. Other investigators have altered the balance of carbohydrate processing to favor production of typical H-antigen synthesis over GAL α(1-3)GAL. Added to conventional immunosuppression, these interventions as well as several inhibitors of complement, including anti-C5 monoclonal antibodies, cobra venom factor, and soluble complement receptor type 1, have been successful in abrogating HAR and extending survival in primates from minutes to weeks. While clinical application remains several years away, the flexibility afforded by genetic engineering will allow for custom organs to be available as necessary.

VASCULAR AND NERVE GRAFTS

Hans W. Sollinger

Vascular grafts usually are used as autografts. Their predominant use is for replacement of damaged or atherosclerotic arteries. Vein grafts are the optimal conduit for coronary artery bypass grafting. The saphenous vein is harvested from one or both legs of the individual undergoing coronary revascularization. Careful handling of the vein grafts, avoiding mechanical trauma and overdistention during flushing, is mandatory. Vein grafts may undergo similar changes to the patient's own coronary arteries as time passes. Vein grafts also are used for reconstruction of the arterial supply of the lower extremities. Femoral popliteal, or even distal bypass grafting, can be achieved with the use of appropriate vein grafts. In patients with injuries to the arterial systems, vein grafts can be used as patch grafts to cover a defect of limited size. In selected cases, vein grafts may be used for the creation of long-term dialysis access, but because of repeated sticks by large bore dialysis needles, aneurysms develop frequently, limiting the life span of these conduits.

Autografting of arteries is used occasionally for arterial replacement of a diseased renal artery. The hypogastric artery is the best size-matched artery. Allogeneic grafting of arteries is rare in normal individuals because it requires systemic immunosuppressive therapy. Sometimes allogeneic arterial substitutes can be used for the repair of renal transplant stenosis. The authors have replaced the diseased or stenotic renal artery on several occasions with segments of common or external iliac artery from a cadaveric donor source. There has been no incidence of rejection, aneurysm, or restenosis. Allogeneic arterial conduits are the ideal replacement material for transplant renal artery stenosis.

Nerve autotransplants are used to bridge defects after traumatic injury to important motor nerves. Allografts in the form of liophilized nerve grafts have been attempted, but are less successful. The transplanted nerve serves as a route along which the patient's own nerve can regenerate. Attempts have been made to transplant vascularized nerve grafts utilizing microsurgical techniques.

PANCREAS

Jon S. Odorico and Hans W. Sollinger

The discovery of insulin in 1921 was hailed as the cure of diabetes. By preventing death from diabetic coma and controlling overt symptoms, insulin rapidly led to increased life expectancy among diabetics and altered the natural history of diabetes. But as diabetic patients lived longer, complications developed in other vital organs. Diabetes is now the leading cause of renal failure in the United States and commonly contributes to blindness, debilitating neuropathies, and accelerated atherosclerosis. Numerous studies, particularly the Diabetes Control and Complications Trial (DCCT), have demonstrated the beneficial effect of intensive glucose control on arresting the development and progression of end organ complications. Experimental animal studies have shown that kidney transplants from normal to diabetic animals develop histologic findings characteristic of diabetes, but kidney transplants from diabetic to normal animals showed disappearance or stabilization of these lesions. These observations suggest that it might be possible to prevent or ameliorate systemic complications of diabetes by achieving more precise glucose control.

Alternative methods of insulin replacement therapy are under investigation. These include insulin pumps, bioartificial pancreases (vascularized, implantable devices seeded with pancreatic islets and protected from the patients' immune system by a semipermeable membrane), and pancreatic islet allotransplantation. None of these modalities has been successful enough to warrant more widespread application. It is understood that Type I diabetes is an autoimmune disease, and attempts have been made to *prevent* the development of diabetes by modulating the host's immunity with cyclosporine. In a Canadian trial, cyclosporine given to newly diagnosed diabetics with residual insulin secretion was moderately successful in preventing diabetes. This approach is limited by the inability to reliably identify patients in the prediabetic state. The most successful approach to restoring normal long-term glucose homeostasis in Type I diabetes is whole-organ pancreas transplantation.

Historical Background

The first successful clinical pancreas transplants were performed by Kelly and Lillehei at the University of Minnesota in 1966. Their procedure employed transplantation of a segmental graft to the iliac fossa with ligation of the pancreatic duct. This technique resulted in a significant incidence of graft pancreatitis, and it became apparent that a method for handling the exocrine secretions of the graft was necessary. In 1973 Gliedman and associates suggested using the urinary tract for exocrine pancreatic drainage. They reported anastomosing the pancreatic duct to the ureter. Groth in Stockholm pursued the development of enteric drainage techniques, employing a Roux-en-Y anastomosis with temporary exteriorization of pancreatic juice via a small catheter.

In 1982 investigators at the University of Wisconsin developed the concept of direct drainage of exocrine secretions into the urinary bladder. This technique evolved from a direct duct-to-mucosa anastomosis to a duodenal button and eventually to a duodenal segment. Using a whole pancreaticoduodenal allograft with anastomosis of the duodenal segment to the bladder is the safest and most popular method of handling exocrine secretions, with over 90 percent of all pancreas transplants worldwide performed in this fashion. However, there has been a resurgence in the United States in using enteric drainage techniques.

Indications

Proper patient selection is crucial to the success of pancreas transplantation. Type I insulin-dependent diabetics younger than 45 years of age are potential candidates (Table [10-2](#)). Death in diabetics is often secondary to myocardial infarction and stroke; therefore, patients with significant coronary artery disease are excluded. Patients older than 25 years should undergo thallium stress testing, and if reversible ischemia is identified, coronary angiography is performed. Diabetics with major amputations secondary to severe peripheral vascular disease or severe visual impairment are not appropriate candidates, because they are unlikely to derive improvement in function at the end organ level. For major organ transplant necessitating long-term immunosuppression, contraindications include untreated malignancy, active infection, and HIV seropositivity.

Pancreas transplantation is performed in three different sets of circumstances: *pancreas transplantation alone (PTA)* in the nonuremic diabetic with minimal or no evidence of diabetic nephropathy; *pancreas transplantation after successful kidney allografting (PAK)* , and *pancreas transplantation performed simultaneously with a kidney transplant (SPK)* in

the uremic patient.

Approximately 90 percent of pancreas transplants performed in the United States are SPK transplants. SPK transplantation is the procedure of choice in the diabetic uremic patient with only mild and potentially reversible secondary complications of diabetes. One exception to this is the young diabetic patient for whom a suitable living-related renal transplant is available. A living-related renal transplant offers excellent long-term results with less immunosuppression than is required for SPK transplantation. After a successful renal allograft, the patient may be offered a PAK graft. PAK transplants should be offered to young diabetics with two or more end-organ complications of diabetes, who have undergone prior living-related or cadaveric renal transplantation, and who are currently stable, with excellent renal function. Two or more diabetic complications in diabetics with normal native renal function would be an indication for a PTA transplant. Other indications for PAK or PTA grafting in nonuremic diabetics include evidence of early histologic changes of diabetic nephropathy in their native or transplanted kidneys, and evidence of glucose hyperlability with frequent episodes of hypoglycemia without overt symptoms. Patients with marginal renal transplant or native kidney function should be strongly considered for SPK transplants because the high doses of cyclosporine or tacrolimus (FK506) used postoperatively after PAK and PTA transplants can precipitate renal failure.

Operative Procedure

The most widely used duct management technique for pancreas transplantation is bladder drainage, in which a duodenal segment is anastomosed side-to-side to the dome of the bladder (Fig. 10-7). Bladder-drained pancreas grafts reported to the *International Pancreas Transplant Registry (IPTR)* had significantly better long-term graft survival rates than grafts whose ducts were managed by enteric drainage, but there has been a renewed interest in draining the exocrine secretions enterically. Advantages of bladder drainage include the ability to use urinary amylase determinations as a screening test for rejection, avoidance of an enteric anastomosis and spillage of bowel contents, and reduced potential for peripancreatic infections. Advantages of the enteric drainage technique include avoidance of the postoperative urologic complications that occur in up to 30 percent of patients, avoidance of chronic dehydration and the need for bicarbonate replacement, and early removal of the Foley catheter. A retrospective comparison of pancreas transplants with bladder versus enteric drainage noted equal efficacy, graft survival rates, and morbidity rates.

The pancreatic graft harvested en bloc with the liver is first separated and prepared in cold saline solution at 4°C. Vascular reconstruction of the pancreatic blood supply is performed at this time with a donor iliac artery “Y” graft (Fig. 10-8). The duodenum segment is shortened to approximately 10 to 12 cm, taking care to avoid injury to the head of the pancreas and the ampulla of Vater. Peripancreatic fat is trimmed and neurovascular tissue in the region of the celiac axis is ligated carefully. The spleen is then removed by ligating the splenic artery and vein in the splenic hilum. If necessary, the common bile duct can be opened and cannulated to confirm patency of the ampulla of Vater. Arterial reconstruction is carried out by end-to-end anastomosis of the donor iliac artery “Y” graft to the splenic artery and the superior mesenteric artery. Careful handling of the pancreas is crucial, because rough handling leads to posttransplant pancreatitis.

The recipient operation begins with a midline transabdominal incision. Intraabdominal placement of the graft is associated with a lower incidence of lymphoceles and peripancreatic fluid collection than retroperitoneal placement. The right colon, small bowel, and sigmoid colon are reflected medially and superiorly, allowing access to the iliac vessels. The ureters are mobilized bilaterally, and the common, external, and internal iliac arteries and veins are extensively mobilized. The pancreas usually is placed into the right iliac fossa, and the kidney, if transplanted simultaneously, is implanted on the left side. The venous anastomosis is performed first. A tension-free venous anastomosis is essential to minimize the risk of vascular thrombosis. This can be achieved by anastomosing the portal vein of the pancreas graft to the distal inferior vena cava or to a completely mobilized iliac vein, obviating the need for an interposition graft.

The arterial anastomosis is then performed between the reconstructed donor iliac artery “Y” graft and the common iliac artery. There is no need for administration of systemic heparin or low-molecular-weight dextran during the anastomoses, which may be associated with a higher risk of postoperative bleeding complications.

After completion of the vascular anastomoses, the clamps are released slowly to minimize a precipitous rise in pressure within the graft. Delayed graft reperfusion minimizes edema and blood loss and allows an opportunity to ligate bleeding pancreatic vessels. Shortly after release of the vascular clamps, the pancreas begins to secrete pancreatic juice into the closed duodenal segment. The duodenal segment should not be allowed to distend, because increased pressure may promote reflux into the pancreatic duct, resulting in pancreatitis. If bladder drainage is chosen, a pancreatic duodenocystostomy is performed in a side-to-side anastomosis to the dome of the bladder with two layers of running absorbable sutures (see Fig. 10-7). If enteric drainage is performed, the duodenal segment is sutured to the ileum in a side-to-side anastomosis with two layers of interrupted silk sutures (Fig. 10-9).

During the procedure, generous intravenous doses of mannitol and albumin are administered to limit reperfusion injury and tissue edema. The abdominal cavity is irrigated copiously with antibiotic solution, including amphotericin B, miconazole, and cephalothin, to minimize the risk of peripancreatic infection, abscesses, and mycotic aneurysms. The use of drains is not recommended. The patient is routinely euglycemic in less than 12 h postoperatively, without the need for postoperative insulin therapy.

Postoperative Management

Rejection occurs with greater frequency after pancreas and simultaneous pancreas-kidney transplantation than after isolated renal transplantation. This difference requires management that balances aggressive immunosuppression against the risks of infection. A quadruple drug regimen, including ATGAM or OKT3, mycophenolate mofetil, cyclosporine, or tacrolimus and steroids, has been the backbone of immunosuppressive therapy. Antibody therapy generally is administered intraoperatively and for 10 to 14 days postoperatively. Analysis of the *United Network for Organ Sharing (UNOS)* registry data failed to demonstrate an improvement in graft survival at one year for SPK recipients whose immunosuppression was induced with antibody therapy versus no anti-T-cell agents, but use of anti-T-cell therapy is standard at most institutions.

Acute rejection is the rule rather than the exception after pancreas transplantation, occurring in 70 to 80 percent of patients, and primarily occurring in the first year after transplantation. Patients treated for rejection are treated with high-dose steroids for two days; if there is no response, the patient is then treated with OKT3 or antithymocyte globulin (ATGAM). With early treatment, 90 percent of rejection episodes are reversed, although rejection remains the primary cause of graft loss.

Difficulty in achieving early diagnosis of rejection is the principal barrier to successful long-term function. Serial histologic studies of pancreas rejection have shown that lymphocytic infiltrates initially involve the exocrine portion of the gland and that islet cell tissue becomes involved later. As a result, a decrease in exocrine secretions occurs early and can be detected by a decrease in urinary amylase. A consistent drop in urinary amylase levels of more than 25 percent strongly suggests the possibility of rejection. Evaluation of pancreas biopsies obtained because of hypoamylasuria in pancreas transplant recipients revealed that only 55 percent of patients exhibiting hypoamylasuria had biopsy evidence of rejection. Although a stable urinary amylase level essentially rules out rejection, a decreasing urinary amylase measurement is not a reliable indicator of rejection. Because most physicians prefer to treat patients for rejection on the basis of histologic evidence, tissue diagnosis of rejection is considered the gold standard. Commonly used biopsy techniques include transcystoscopic pancreatic and duodenal needle biopsies, and percutaneous pancreatic biopsies performed with ultrasound guidance.

In SPK patients, rejection of the pancreas graft alone is unusual, occurring in less than 15 percent of all rejection episodes. Pancreas rejection more commonly occurs with kidney rejection. Because of this, diagnosis of rejection after SPK transplantation relies almost entirely on serum creatinine, β_2 -microglobulin and renal biopsy. In the setting of PAK or PTA transplantation, however, isolated pancreas rejection does occur. There is no ideal screening test for rejection of the pancreas allograft, as the creatinine level is for kidney rejection. Numerous serum and urinary markers of pancreas graft rejection have been evaluated experimentally, including serum immunoreactive anodal trypsinogen level, pancreas-specific protein level, serum amylase and lipase levels, urinary cytology, pancreatic juice cytology, and neopterin level. Their clinical usefulness remains to be definitively demonstrated. Certain findings, such as decreased endogenous insulin levels and hyperglycemia, occur late enough to preclude their use in monitoring for allograft rejection. The clinical signs of rejection, such as fever, graft tenderness, and malaise, are not specific enough to indicate a diagnosis of rejection, but these findings do alert the physician to initiate proper diagnostic studies. When graft rejection is diagnosed, treatment is influenced by previous rejection therapy, response to initial therapy, and the severity of rejection.

Complications

Despite improvements in technique, preservation, and patient selection, surgical complications are not uncommon and threaten the survival of the graft and the patient. Proper management of complications is critical to a successful outcome. The development of a urologic complication (Table 10-3) is the most frequent cause for readmission to the hospital after SPK transplantation performed with bladder drainage.

Postoperative gross hematuria usually is mild and self-limited, clearing within three days of surgery. If bleeding is not stopped with Foley catheter irrigation, cystoscopy is performed with fulguration of the bleeding point, which usually is located along the duodenocystostomy suture line. Hematuria occurring later in the postoperative course may be a result of a suture granuloma, urinary tract infection, or ulceration of the duodenal segment. If hematuria persists despite appropriate therapy, conversion to enteric drainage is indicated. Enteric drainage generally is not required for early postoperative hematuria, but it is required in approximately 33 percent of patients presenting with late or chronic hematuria.

A postoperative urinary leak can occur from three potential sources: the ureteral implantation site, the duodenocystostomy anastomosis, and the duodenal segment. With the extravesical modified Liche technique and the use of an intraureteral stent during surgery, leaks from the ureteral implantation site are rare. Early urinary leaks are almost always technical and usually are located at the bladder-duodenum suture line, but urinary leaks more than 4 weeks after operation occur at the lateral duodenal staple lines or as the result of an ulcer within the duodenal segment. Patients with urinary leaks present with sudden-onset lower abdominal pain, fever, leukocytosis, and increased serum amylase and creatinine levels. A significantly elevated serum amylase level (over 400 U/L) and the development of pancreatic ascites discernible on CT scan are highly suggestive of a urinary leak. The diagnosis is confirmed by a voiding cystourethrogram (VCUG). Whether a conventional Gastrografin VCUG or a ^{99m}Tc -DTPA VCUG is more sensitive or specific is being studied. For small, early contained leaks, treatment consists of Foley catheter bladder decompression for 2 to 3 weeks. Large leaks or leaks that recur after conservative therapy require exploration and repair of the anastomosis or enteric conversion. If duodenal ulceration is found, excision of the ulcer usually is performed in conjunction with the enteric conversion. Late leaks almost always necessitate enteric conversion.

Urinary tract infections are the most common infectious complication after pancreas transplantation, and are significantly more common after bladder-drained SPK transplantation than after renal transplantation alone. Pancreas transplant recipients may be more predisposed to urinary tract infections than renal transplant recipients because of the additive effect of several contributing factors, including alkalinization of the urine secondary to bicarbonate and exocrine secretions, presence of a diabetic neurogenic bladder with incomplete emptying, mucosal injury at the bladder anastomosis, and prolonged catheter drainage. A cause for therapy-resistant or recurrent infection should be sought with diagnostic cystoscopy. Most are caused by a foreign body (e.g., suture granuloma, bladder stone), which can be treated with cystoscopic removal. Conversion to enteric drainage occasionally is indicated for recalcitrant urinary tract infections.

Persistent urethritis can result in urethral stricture or disruption. Urethritis is most likely caused by the digestive action of pancreatic enzymes on the urothelium. Urethritis usually manifests as perineal pain and discomfort during urination, and it occurs almost exclusively in males. Treatment with Foley catheter drainage for several weeks is recommended. If perforation occurs, it usually is in the membranous portion of the urethra and presents with perineal and scrotal swelling in addition to pain, and occasionally in association with acute bladder outlet obstruction. To avoid complications of urethral stricture and disruption, early enteric conversion is recommended if urethritis fails to respond to a short course of

conservative treatment, but these complications are unusual, occurring in only 5 percent of SPK transplant recipients.

Early postoperative hyperamylasemia, thought to be from preservation injury, is not uncommon, is asymptomatic, and improves rapidly. Persistent or marked elevations indicate possible technical errors, including duct ligation or leak. An infrequent but potentially fatal complication occasionally associated with graft pancreatitis is the rapid development of acute respiratory distress syndrome (ARDS) after pancreas transplantation. Pancreases from obese donors are particularly prone to preservation- induced pancreatitis. If ARDS and sepsis develop, strong consideration should be given to immediate removal of the pancreas transplant. Late graft pancreatitis (sometimes referred to as reflux pancreatitis) is defined by the following elements: (1) sudden-onset lower abdominal pain, (2) elevation of serum amylase level, (3) absence of a leak, (4) evidence on CT scan of gland edema and retroperitoneal inflammation and peripancreatic inflammation, without evidence of abscess or fluid collections, and (5) resolution of symptoms within 24 h of Foley catheter drainage. Treatment with Foley catheter drainage for several days usually is successful.

A metabolic acidosis is present postoperatively in approximately 80 percent of patients after pancreas transplantation with bladder drainage, and usually is a result of excessive urinary loss of bicarbonate-containing exocrine fluids. Oral replacement should be initiated to maintain a serum bicarbonate level of at least 22 to 25 mg/dL. Urinary bicarbonate loss is accompanied by an obligate loss of fluid; therefore, low serum levels are associated with dehydration. This problem usually stabilizes and diminishes over time and only infrequently requires conversion from bladder to enteric drainage.

Peripancreatic fluid collections visualized by ultrasonography and CT scans are common and should be drained if there is a suspicion of infection. The incidence of intraabdominal sepsis after bladder-drained pancreas transplants may be less than in transplants performed with enteric drainage. Postoperative graft thrombosis is unusual after SPK transplantation in the uremic recipient, occurring in less than 1 percent of patients. The incidence of this complication after PAK and PTA transplantation in the nonuremic patient may be somewhat higher. Mycotic pseudoaneurysms of the vascular anastomoses occur on rare occasions and can be devastating.

Exocrine secretions of the pancreas transplant must be converted from bladder drainage to enteric drainage in 10 to 25 percent of pancreas transplant recipients. Common indications for enteric conversion are persistent hematuria and urinary leaks from the duodenal segment. The technique of enteric conversion involves taking down the duodenocystostomy, repairing the bladder with a two-layer closure, and performing a simple two-layer side-to-side duodenoileostomy at the terminal ileum (Fig. 10-10). It is helpful to distend the bladder intraoperatively to assist in identifying the duodenocystostomy suture line. If an ulcer of the duodenal segment is the cause, it should be excised in conjunction with enteric conversion.

Results

Between 1987 and 1995, over 4,500 cadaver donor pancreas transplants were performed in the United States and reported to the IPTR. The 1-year patient survival rate is more than 90 percent, and the 1-year pancreas graft survival rate (as measured by insulin independence) is more than 75 percent. The addition of a pancreas to a kidney transplant does not adversely affect patient or kidney graft survival rates in uremic diabetic patients. Eighty-seven percent of pancreas transplants are performed simultaneously with a kidney transplant in the United States. PAK and PTA transplants account for 7 percent and 5 percent of the reported transplants, respectively. The two most significant factors affecting graft survival are the circumstances in which the pancreas transplant occurs and the duct management technique used. When compared with PAK and PTA, SPK is associated with the highest graft survival rate and the lowest technical failure rate. The 1-year pancreas graft function rates for SPK, PTA, and PAK are 78, 55, and 56 percent, respectively. PAK, PTA, and SPK transplants have equally good pancreatic graft survival (better than 75 percent 1-year graft survival). The IPTR reported that bladder-drained pancreas grafts had a better 1-year graft survival rate than grafts whose ducts were managed by enteric drainage or duct occlusion. By 5 years posttransplant, however, this difference was lost and equivalent graft function could be predicted for both techniques. Another factor identified in the UNOS database that correlated with a worse outcome was retransplantation, which was associated with a risk of graft loss 1.5 times higher. Neither HLA mismatching, nor longer preservation times (up to 30 h), nor recipient age had a significant negative impact on graft survival in the UNOS analysis.

A review of 356 patients who received SPK transplants from 1989 to 1997 revealed that immediate insulin independence was achieved in 99.6 percent of patients. There was one primary nonfunctioning pancreatic graft, and the rate of pancreas graft vascular thrombosis was 0.8 percent. For the simultaneously transplanted kidney, postoperative hemodialysis was necessary in only 2.4 percent of patients. One-year pancreas graft and patient survival were 88 percent and 96.5 percent, respectively. Five-year actuarial survival rates in SPK recipients with bladder-drained grafts were 90 percent for patients, 82 percent for kidney grafts, and 80 percent for pancreas grafts (Fig. 10-11). Kidney graft survival in SPK recipients is comparable to that for isolated cadaveric renal transplant recipients. Long- term kidney function is not negatively affected by a simultaneous pancreas transplant. Because of the excellent results of mycophenolate mofetil in renal transplantation, the authors use it rather than azathioprine the immunosuppressive protocol for pancreas transplantation. Using mycophenolate mofetil–based immunosuppression with cyclosporine (Neoral) reduced the incidence of rejection in 1-year SPK recipients from 73 to 21 percent. OKT3 use for steroid-resistant rejection also fell significantly from 28 to 15 percent, and after 1 year no grafts were lost for immunologic reasons.

Effect of Pancreas Transplantation on Secondary Complications of Diabetes

The major benefit of a pancreas transplant over a kidney transplant alone is enhanced quality of life. Other advantages over kidney transplantation alone include reversal of neuropathies, prevention of diabetic nephropathy, and amelioration or stabilization of diabetic retinopathy. Studies evaluating the effects of pancreas transplantation on secondary complications have been prospective, comparative, nonrandomized trials of concurrent pancreas and kidney transplants versus kidney transplants alone in diabetic recipients, or pancreas-kidney recipients with a failed pancreas graft. These studies have consistently demonstrated improvement in pancreas recipients regarding most secondary complications and quality of life.

Diabetic nephropathy recurs almost universally in diabetic patients who receive an isolated kidney transplant, although recurrence of disease may not be evident for many years. A functioning pancreas graft prevents the recurrence of diabetic kidney disease in the renal transplant. Histologic studies of renal allografts in patients who have undergone SPK transplantation demonstrated no evidence of recurrent diabetic nephropathy for up to 4 years after transplantation. Serial posttransplant biopsies have shown that glomerulomesangial volumes in diabetic patients with kidney transplants alone were significantly greater than in patients with combined pancreas-kidney transplants.

After SPK transplantation, most patients have subjective improvement of neuropathic symptoms. Studies have demonstrated an improvement in patient symptoms of peripheral neuropathy and significant objective improvement in motor and sensory nerve conduction velocities up to 4 years after pancreas transplantation. The Diabetes Control and Complications Trial Research Group conducted a multicenter, randomized, single-blinded, controlled trial in diabetics to determine what effect intensive glycemic control had on the progression of neuropathy. They found that after 5 years, fewer patients receiving intensive insulin therapy than patients receiving usual care had clinical neuropathy confirmed by nerve conduction studies (10 percent versus 25 percent). The association of neuropathy with previous poor control and the improvement of conduction velocities observed after better glycemic control have persuaded most clinicians to strive for tight control. This is a compelling argument for achieving permanent long-term normoglycemia with pancreas transplantation. Subjective improvement in gastroparesis has been noted in several studies.

Improvement in visual impairment after pancreas transplantation has been suggested in one study. Regression of retinopathy was noted in 43 percent of SPK recipients, compared to only 23 percent of recipients of a kidney transplant alone. Furthermore, 27 percent of isolated kidney transplant recipients showed progression of disease, but vision deteriorated in only 7 percent of SPK recipients.

One of the most important advantages gained from pancreas transplantation is the improvement in overall quality of life. Several well- controlled studies have been carried out at centers in the United States and in Europe experienced at performing pancreas transplantation. Patients with functioning pancreas transplants were nearly unanimous in judging their overall health and quality of life as significantly improved by insulin independence. Isolated pancreas transplantation most likely will be offered with increasing frequency to diabetics with normal renal function to prevent or reverse end-organ complications and to prevent life-threatening hypoglycemic episodes.

INTESTINE

Anthony M. D'Alessandro

Attempts to transplant small intestine in human beings were made between 1960 and 1980. The initial excitement over this challenging mode of therapy for patients with short-bowel syndrome rapidly faded as technical, immunologic, and septic complications resulted in unacceptable morbidity and mortality rates.

During the same era, parenteral nutrition, which could deliver all necessary fluids and nutrients, became the standard treatment for patients with short-bowel syndrome. Total parenteral nutrition (TPN) has been shown to be an excellent treatment modality that has allowed many patients with intestinal failure to survive with a reasonable quality of life.

Most patients remain dependent on TPN indefinitely and develop complications, such as catheter-related sepsis, metabolic derangements, vascular access problems, and liver dysfunction. One year of TPN treatment in the United States is estimated to cost between \$50,000 and \$120,000. If intestinal transplantation could be performed with acceptable morbidity and mortality rates, it would offer a more physiologic and economic approach to the problem of short-bowel syndrome.

Potential Candidates

The majority of potential candidates for intestinal transplantation are patients with short-bowel syndrome. Different disease processes can lead to short-bowel syndrome, but adults and children generally develop this syndrome after extensive intestinal resections. Approximately two patients per million population will start TPN each year. One patient per million population per year develops irreversible intestinal failure and lifelong TPN dependency.

Before the development of TPN, the long-term prognosis for patients with short-bowel syndrome was poor. Studies have shown that 50 percent of TPN patients are children who have high mortality rates primarily associated with the complications of TPN-related cirrhosis and liver failure. The mortality rate in adults from liver failure with short-bowel syndrome is estimated to be 5 to 10 percent. The long-term prognosis of children with short-bowel syndrome also is considered to be worse than in adults. This is related to growth problems, vascular access difficulty, and problems with psychosocial development.

Common indications for intestinal transplantation in adults are: Crohn's disease, mesenteric thrombosis, and trauma. Necrotizing enterocolitis, intestinal pseudoobstruction, gastroschisis, volvulus, and intestinal atresia are indications in children. However, any disease process that leads to short-bowel syndrome and TPN dependence may be considered for intestinal transplantation.

Operative Procedures

There are three methods of intestinal transplantation, the choice depending on the disease and sequelae that occur in combination with the short-bowel syndrome. For patients without liver failure, isolated intestinal grafting is preferred; patients with liver failure receive a combined liver-intestine transplant. In a small number of patients, a multivisceral procedure is performed that includes grafting of the liver, stomach, pancreas, duodenum, and small intestine with or without the colon.

Establishing continuity between the transplanted intestine and the remaining native intestine with early feeding is important. Portal venous drainage of the transplanted intestine appears to offer physiologic advantages over systemic venous drainage. At the time of implantation, a proximal or distal transplanted intestinal stoma is placed for endoscopic monitoring and biopsies.

Donor Issues

There is a shortage of suitable intestinal grafts, especially in the case of combined liver-intestinal transplantation. Most clinicians consider an identical ABO blood type mandatory because of previously reported hemolytic reactions. However, there have been reports of ABO-compatible but not identical liver-intestinal transplants being performed without problems. Because many recipients are children, a limiting factor is the required size match between donor and recipient. The waiting time and deaths while on waiting lists are higher for potential liver-intestinal recipients.

Management and Pretreatment

The management of the multiorgan donor during which the intestine (with or without liver) is retrieved for transplantation is more complicated. Mechanical cleansing of the intestine is performed as well as antibiotic decontamination with erythromycin and neomycin. ALG/ATG or OKT3 has been used to pretreat the donor in order to prevent recipient graft-versus- host disease. Because of the high incidence of lymphoproliferative disorders in patients treated with antilymphocyte preparations, and because of better immunosuppression with tacrolimus (FK506), donor pretreatment is not used routinely.

Preservation

In most multiorgan donor procedures, the University of Wisconsin (UW) solution is used for preservation. Compared to other solid organs, the intestine appears to be more sensitive to ischemia and reperfusion injury. The UW solution has been shown to sustain good results for up to 16 h of cold ischemic time. The addition of oxygen-free radical scavengers to the preservation solution or at time of reperfusion may be beneficial, facilitating an early repair of small-bowel mucosa and improving immediate function of the gut. Core cooling and immersion of the small bowel in the hypothermic preservation solution are believed to be the most important preservation measures, but one study suggests that luminal flushout with preservation solution may be helpful. It is unclear how well the current solutions preserve this organ. Until the appropriate studies are performed, it is recommended that the intestine be transplanted within 12 h of retrieval.

Immunology

The two major immunological problems after intestinal transplantation have been graft-versus-host disease (GVHD) and host-versus-graft disease (rejection). To prevent GVHD, sufficient immunosuppressive therapy must be administered. Graft pretreatment has been effective in experimental models. Studies have demonstrated the beneficial effects of irradiation, T- cell subset depletion, and mesenteric lymphadenectomy. A pretreatment method that has been applied is the administration of ALG/ATG or OKT3 to the donor prior to organ removal. Ablation of donor cells may be detrimental, since these cells may be required for the development of microchimerism and tolerance. After intestinal transplantation, a substantial migration of lymphoid cells has occurred in both directions, from graft to host and vice versa. T lymphocytes are essential in graft-versus-host reaction. Reducing the number of lymphocytes by using shorter segments, irradiation, or poly/monoclonal antibodies affects the severity of GVHD and possibly reduces its incidence. The introduction of cyclosporine has reduced, but not totally abolished, the incidence of GVHD. Reports on the use of tacrolimus for intestinal transplantation suggest that this drug is more effective against GVHD. Clinically, there has been a low incidence of GVHD even without donor pretreatment.

The prevention of rejection after intestinal transplantation is more difficult. Treatment with prednisone and azathioprine is insufficient to prevent or overcome rejection in intestinal transplantation. The addition of cyclosporine demonstrated improved results only in experimental models. The introduction of tacrolimus significantly improved the outcome after intestinal transplantation. Other new and more specific immunosuppressive agents that are currently being tested in combination with prednisone and cyclosporine or tacrolimus are mycophenolate mofetil (CellCept), rapamycin, and deoxyspergualin.

Most clinicians do not use ATG or OKT3 induction therapy. Oral tacrolimus usually is begun soon after surgery (0.15 mg/kg twice daily) and increased to achieve levels between 10 and 15 ng/mL. Intravenous tacrolimus may be given (0.02 to 0.07 mg/kg/day) if oral absorption is inadequate. Because of increased nephrotoxicity with intravenous tacrolimus, prostaglandin E (0.2 to 0.6 mg/kg/h) should be given to decrease renal dysfunction. Methylprednisolone usually is given in a 6-day taper, the initial dose being 250 mg in infants, 500 mg in children, and 1 g in adults. Azathioprine, cyclophosphamide, and mycophenolate mofetil have been added in an attempt to decrease rejection episodes and prolong graft survival.

Diagnosis of Rejection

The earlier rejection is detected, the more effective might treatment be in reversing the rejection process and minimizing damage to the grafted organ. Rejection is detected primarily by clinical symptoms and graft histology. These symptoms include fever, abdominal pain, elevated white blood cell count, ileus, increased stomal output, gastrointestinal bleeding, and positive blood cultures. Intestinal biopsies may show evidence of cryptitis, shortening of villi, mononuclear infiltrate, or even mucosal sloughing. Histologic changes may confirm the diagnosis of rejection, but usually only after significant progression of the rejection process. Immunopathology may be a more sensitive method of detecting rejection, because it can characterize increased class II or IL-2 receptor expression as well as the phenotypes of cells infiltrating the transplanted intestine before histologic changes have occurred. These techniques are labor intensive and operator dependent. Loss of mucosal integrity is an early indicator of rejection, so measures of intestinal permeability may be of value and are simpler to perform. The isotope ^{99m}Tc-DTPA, which has a short half-life, has been used successfully to diagnose clinical intestinal transplant rejection. The isotope is given orally and the urinary excretion is measured 6 and 24 h after administration. A value greater than 5 percent indicates increased permeability and possibly an acute rejection episode.

Results

The International Intestinal Transplant Registry reported results on 178 intestinal transplants performed worldwide since 1985. The results of tacrolimus-based immunosuppression were superior to cyclosporine-based immunosuppression. The 1-year and 3-year actuarial graft survivals were 65 percent and 29 percent for isolated intestine, 64 percent and 38 percent for liver/intestine, and 51 percent and 37 percent for multivisceral transplants. Although the results have not reached the levels of kidney, pancreas, liver, and heart transplantation, they are comparable to the results achieved with lung transplantation.

LIVER

Stuart J. Knechtle and Munci Kalayoglu

Historical Background

Liver transplantation was first performed successfully in an experimental dog model by Welch in 1955. The first human liver transplants were performed by Starzl in 1963. The decades of the 1960s and 1970s included pioneering work by Starzl in Denver and Calne in England to develop the technique of liver transplantation. Survival rates generally were less than 50 percent at 1 year. In the 1980s, with the advent of cyclosporine-based immunosuppression and technical innovations, such as venovenous bypass and University of Wisconsin preservation solution, the results of liver transplantation improved markedly. The 1990s have been characterized by efforts to expand the donor liver pool using techniques such as living-related liver transplantation, split-liver transplantation, reduced-size liver transplantation, and the use of non-heart-beating donors. Increased knowledge of proper donor and recipient selection, surgical techniques, and immunosuppressive therapy have improved the results of human liver transplantation, with an overall 1-year patient survival rate of 79 percent in the United States.

Indications

Liver transplantation is indicated for the treatment of irreversible liver failure from acute or fulminant disease or, more commonly, chronic liver disease. Fulminant hepatic failure frequently has an unknown cause but may be secondary to viral hepatitis, Wilson's disease, hepatotoxins, or alcoholic hepatitis. Outcomes for liver transplantation in patients with fulminant hepatic failure have a worse prognosis than in patients with chronic liver disease, because the former are generally more unstable and have more comorbid conditions. Survival rates of 70 percent at 1 year are expected for patients transplanted for fulminant disease.

Table [10-4](#) lists the most common causes of liver disease in adults treated with liver transplantation. Posthepatic cirrhosis resulting from hepatitis B or C is associated with the risk of recurrence of viral hepatitis and cirrhosis in the transplanted liver. Strategies to prevent recurrence of hepatitis B have included administration of hepatitis B hyperimmune globulin, interferon, and lamivudine. Hepatitis C also has been associated with frequent recurrence of disease in the transplanted liver and is often unresponsive to interferon therapy. Liver transplantation for primary biliary cirrhosis is associated with a high success rate, but the primary disease may recur and is difficult to distinguish from chronic rejection. Primary sclerosing cholangitis should be treated with liver transplantation before cholangiocarcinoma develops.

Patients with alcoholic liver disease account for 75 percent of liver failure in the United States, comprising the largest group of patients who could potentially benefit from liver transplantation. The ethics of liver transplantation for alcoholic cirrhosis have been debated in view of the behavioral contribution to these patients' liver failure. In support of liver transplantation being applied to this group are the facts that these patients tend to have an excellent outcome (88 percent 1-year patient survival) and a remarkably low recidivism rate (< 10 percent). A period of abstinence and evidence of family and social support are required before the candidate can be eligible for transplantation. Comorbid features, such as alcoholic cardiomyopathy, must also be excluded.

Numerous metabolic defects, such as alpha 1-antitrypsin deficiency and amyloidosis, can be treated successfully with liver transplantation. Many inborn errors of metabolism, with their primary defect in the liver, also can be corrected by liver transplantation. Examples of these conditions are listed in Table [10-5](#) along with other common causes of end-stage liver failure in children.

Liver transplantation for cancer is controversial, and, in general, the results are poor compared to transplantation for benign disease. Five-year patient survival rates around 40 percent are reported, which is better than the outcome without transplantation. Hepatoma and cholangiocarcinoma are associated with poor long-term survival because of the spread of micrometastases outside the liver before liver transplantation. Immunosuppression usually favors the reemergence of underlying malignancies. Fibrolamellar hepatomas, hepatomas found incidentally after hepatectomy but unsuspected by pretransplant CT scan, and small (< 4 cm) hepatomas are associated with favorable outcomes. Low-grade tumors, such as islet cell tumors metastatic to the liver without evidence of extrahepatic disease, may be an exception to the observation that cancer recurs after transplantation. Upper abdominal exenteration with cluster transplantation of the liver, duodenum, and pancreas has not improved long-term survival of patients with upper abdominal malignancies, but may be considered for low-grade malignancies.

Preoperative Evaluation

The signs and symptoms of liver failure (Table [10-6](#)) should be evaluated in detail in patients being considered for liver transplantation. The decision regarding the timing of liver

transplantation depends on an appropriate synthesis of numerous factors, including the practical issues of length of waiting time and donor organ availability. The degree of urgency of liver transplantation dictates the patient's position on a liver transplant waiting list.

Hepatic encephalopathy is determined by clinical examination and is often paralleled by serum ammonium levels. Patients with stage IV coma must be managed aggressively to prevent cerebral edema or hemorrhage, common causes of death in patients with end-stage liver failure. Evaluation may include head CT or MRI scanning to monitor cerebral edema, and continuous intracranial pressure monitoring in an intensive care unit.

Coagulopathy associated with liver failure is associated with an elevated *international normalized ratio (INR)* unresponsive to vitamin K replacement. Thrombocytopenia is common and usually is caused by hypersplenism related to underlying portal hypertension. Patients with bleeding should be treated with administration of fresh frozen plasma and platelet transfusions.

Gastrointestinal bleeding related to underlying portal hypertension, if associated with Child's Class B or C liver failure and liver fibrosis or cirrhosis, constitutes an indication for liver transplantation. Variceal bleeding before transplantation should be controlled with a combination of medical, radiologic, and, if necessary, surgical therapy. Transjugular intrahepatic portosystemic shunts (TIPS) have emerged as an attractive temporizing measure to relieve variceal hemorrhage before liver transplantation. These patients usually have an improvement in their overall liver function and can be more easily managed before liver transplantation.

Ascites resulting from portal hypertension may be severe and require medical treatment with diuretics and paracentesis. TIPS also is an effective means to relieve ascites before liver transplantation. Severe ascites may be associated with umbilical and inguinal hernias, which can be repaired at the time of liver transplantation. Ascites may present as a pleural effusion from transudation of ascitic fluid across the diaphragm. This may require aggressive therapy with paracentesis or TIPS and can be expected to resolve completely after liver transplantation.

Hepatorenal failure, a fatal condition before the advent of liver transplantation, is reversible after liver transplantation. Other correctable causes of underlying kidney dysfunction must be excluded before hepatorenal failure is diagnosed. If hepatorenal failure has caused renal function to deteriorate acutely over a period of days or weeks, renal function can be expected to return to normal after liver transplantation. Patients with concomitant intrinsic renal disease not caused by hepatorenal failure should be considered for combined renal and hepatic transplantation. This is advisable only if all other organ systems have excellent function.

Biliary obstruction in patients with primary biliary cirrhosis is associated with fatigue and severe itching, which can be debilitating psychologically and physically. Severe itching and fatigue should prompt liver transplantation. Patients with primary sclerosing cholangitis who develop recurrent bouts of cholangitis requiring hospitalization should be considered for early liver transplantation to avoid the septic complications of cholangitis. The risk of cholangiocarcinoma developing in these patients should be evaluated with CT scan and *endoscopic retrograde cholangiopancreatography (ERCP)* with brushings for cytology.

Nutritional depletion also may be a reflection of advanced liver failure and must be considered in the timing of liver transplantation. Patients with primary sclerosing cholangitis (PSC) may have associated inflammatory bowel disease and should be evaluated with colonoscopy before transplantation.

Patients with liver failure are immunocompromised. Spontaneous bacterial peritonitis may present with evidence of generalized sepsis and peritonitis and can be treated with antibiotics. Other causes of peritonitis, such as a perforated viscus, must be excluded. Growth of multiple organisms from a paracentesis culture should prompt suspicion of a perforated viscus and requires surgical exploration. Patients with advanced cirrhosis often have a substantial loss of their nonparenchymal liver mass and reticuloendothelial system, rendering them highly susceptible to sepsis, particularly by translocation across the gut.

Patients with liver failure develop a hyperdynamic state, with elevated cardiac output and low systemic vascular resistance. In advanced disease, pulmonary hypertension may develop, associated with clubbing of the digits and right-sided heart failure. Severe pulmonary hypertension is a risk factor for cardiac-related intraoperative death and should be assessed preoperatively when suspected. Patients with left-sided heart failure and liver disease, in addition to being evaluated for atherosclerotic heart disease, should be evaluated for alcoholic cardiomyopathy, hemochromatosis, and amyloidosis.

Contraindications

Contraindications to liver transplantation are summarized in Table 10-7. Liver transplantation in patients with multisystem organ failure (three or more organ systems in failure) is associated with a high mortality rate. Sepsis outside the liver would contraindicate liver transplantation, although patients with a septic focus within the liver may appropriately be treated with liver transplantation (e.g., a liver abscess or cholangitis in a cirrhotic liver would not contraindicate transplantation). Noncompliance with immunosuppressive therapy and medical management is associated with a poor outcome and should exclude patients from consideration. Active alcohol or drug abuse are examples of noncompliance. Severe cardiac or pulmonary disease may be a contraindication to liver transplantation because of the associated high mortality rate. Disseminated cancer would be an absolute contraindication to liver transplantation. A patient with a history of malignancy being considered for liver transplantation must have no evidence of malignant disease at the time of liver transplant evaluation. At the authors' institution, patients with a known malignancy generally are observed for at least 2 years for no evidence of disease before being considered for liver transplantation.

Immunologic Considerations

Graft failure in liver transplantation usually is not because of immunologic rejection in compliant patients, but more frequently is because of primary nonfunction, recurrence of original disease (hepatitis or primary biliary cirrhosis), or biliary and vascular complications. The reason for the liver's relative protection from rejection compared to other organs is poorly understood. Rejection episodes are common during the first 3 months posttransplant (about 50 percent incidence) but usually are reversible with steroids or anti-T-cell agents.

ABO blood group compatibility between donor and recipient is required for liver transplantation, but this is not absolute. ABO-incompatible liver transplants have been performed successfully, but they are associated with a higher risk of graft failure. ABO-compatible but nonidentical liver transplants (e.g., blood type O donor to type A recipient) may be associated with a self-limited graft-versus-host reaction, leading to hemolysis of recipient red blood cells. If necessary, the anemia can be treated with transfusion of donor-type blood. The liver is known to be associated with a much lower risk of hyperacute rejection than other organs transplanted to sensitized recipients, although hyperacute rejection may occur. A T-cell crossmatch usually is not performed preoperatively for liver transplantation, and even a positive cytotoxic crossmatch is of marginal significance, because of the liver's resistance to hyperacute rejection. HLA matching, routine in kidney transplantation, is not a consideration in liver transplantation, because the shorter preservation times required make it a practical impossibility.

Donor Procedure, Procurement, and Preservation

The liver can be procured from a brain-dead donor as part of an en bloc procurement with the pancreas (Fig. 10-12) or as an isolated liver procurement. Care must be taken to preserve anomalous arteries, such as a right hepatic artery arising from the superior mesenteric artery or an accessory left hepatic artery arising from the left gastric artery. All hepatic arteries must be preserved and reconstructed as necessary in order to avoid infarction of the transplanted liver. Various procurement methods are acceptable, but the preferred technique is aortic and portal vein flushing with University of Wisconsin (UW) solution prior to hepatectomy, followed by ex vivo portal vein, celiac axis, and superior mesenteric artery flushing and cold storage on ice. Non-heart-beating donors have been used for liver procurement with good graft function, comparable to that of heart-beating donors. For non-heart-beating donors, an en bloc technique is used to remove the entire abdominal viscera during aortic perfusion. After excision of the abdominal organs, the portal vein, celiac axis, and superior mesenteric artery orifices are flushed with UW solution.

The donor liver may be biopsied and submitted for frozen-section analysis to exclude severe hydropic change or fatty infiltration. The presence of more than 40 percent macrovesicular fat replacing the hepatic parenchyma, severe microvesicular fat, or severe hydropic change have been found to be predictive of primary nonfunction of the liver after transplantation. Biopsy information is useful in excluding these livers from transplantation.

Although the UW solution is capable of preserving livers for up to 24 h using cold storage on ice, an increased incidence of biliary strictures and primary nonfunction can occur with long preservation times. Other factors influencing the length of time the liver can be safely preserved include age of the donor, stability of the donor, injury to the donor liver reflected by elevated liver enzymes, and degree of fatty infiltration of the donor liver.

Recipient Operative Procedure

Orthotopic liver transplantation begins with native hepatectomy (including removal of a segment of the intraabdominal inferior vena cava) followed by implantation of the donor liver (Fig. 10-13). Because this technique requires occlusion of the inferior vena cava and portal vein simultaneously during the entire anhepatic phase, this method was found to result in hemodynamic instability in a significant proportion of adult patients. Venovenous bypass was developed to return blood from the inferior vena caval and portal venous circuits to the superior vena cava during the anhepatic period (Fig. 10-14). Venovenous bypass may be used routinely or selectively in patients who manifest instability after a trial of clamping.

The so-called "piggyback" technique (Fig. 10-15) is a variation of the conventional orthotopic liver transplant technique, in that the native inferior vena cava (IVC) is left intact after the native liver is dissected from it. All hepatic vein branches to the IVC are ligated except the three principal hepatic veins, which are then used to anastomose the donor suprahepatic IVC. The advantages of this technique are that it eliminates one of the vascular anastomoses of the conventional technique, namely, the infrahepatic inferior vena cava, and that inferior vena caval blood flow can be restored after completion of the suprahepatic caval anastomosis of the donor liver. Consequently, venovenous bypass rarely is necessary when the "piggyback" technique is used.

A donor liver procured from an adult may be reduced in size as necessary for transplantation to a pediatric recipient. The largest portion of the liver that would fit into the recipient usually is selected. If necessary, the left lateral segment (segments II and III) can be resected from the donor liver, leaving the hepatic artery, portal vein, and inferior vena cava intact for transplantation into an infant (Fig. 10-16). An additional modification is the split-liver technique, which uses the entire liver for two recipients; the right and left lobes are used for different patients. After reconstruction of the hepatic artery with the donor iliac artery graft and reconstruction of the portal vein with the donor iliac vein graft, segments II and III are transplanted into a child. The donor vessels supplying the liver remain with the right lobe and the medial segment of the left lobe (Fig. 10-17), which are transplanted into an adult. Application of these surgical techniques to the left lateral segment of a live donor has resulted in successful living-related liver transplantation, typically from a parent to a child with liver failure. Segments II and III usually are procured for this purpose. This procedure can be performed with minimal risk to the donor and with results for the recipient similar to those achieved using cadaveric liver donors.

Heterotopic and auxiliary liver transplantation have been used for fulminant hepatic failure, but the most common procedure for fulminant liver failure remains orthotopic liver

transplantation. The advantage of heterotopic or auxiliary liver transplantation (the latter involving a native lobectomy with replacement by the corresponding lobe of the donor liver) is that, should the native liver recover, the patient can be weaned from immunosuppressive drugs, allowing the transplanted liver to atrophy or be removed surgically.

Reconstruction of the common bile duct in liver transplantation involves an end-to-end anastomosis of donor-to-recipient bile ducts. This has been performed over a T tube, although using an internal stent, or no stent at all, has become popular. If the recipient common bile duct is inadequate or unsuitable for any reason, a Roux-en-Y choledochojejunostomy is performed.

If the recipient portal vein is unsuitable for anastomosis to the donor liver, usually because of portal vein thrombosis, a donor iliac vein graft can be interposed between the superior mesenteric vein of the recipient and the donor portal vein. This is an acceptable technique, with results equivalent to an end-to-end anastomosis of the donor and recipient portal vein (Fig. 10-18).

The donor hepatic artery is reconstructed by anastomosing the donor celiac axis to the recipient hepatic artery. If the recipient hepatic artery is compromised (including intrinsic or extrinsic stenosis of the celiac axis), a donor iliac artery graft is placed on the aorta in the supraceliac or infrarenal position and used as a conduit to the donor celiac artery.

Postoperative Management

The immediate postoperative management of liver transplant patients includes the twin goals of optimizing the patient's physiology and optimizing conditions that favor good liver function. This includes avoidance of vasoconstrictive inotropic agents, such as epinephrine, norepinephrine, phenylephrine, or high-dose dopamine, because these agents reduce blood flow to the liver. Every effort is made to avoid sepsis and hypotension, because of their deleterious effect on an already stressed liver as well as their systemic effects. Prostaglandin E₁ infusions may be useful for increasing renal and hepatic perfusion in the immediate postoperative period. Diuretic agents are useful in the first 24 to 48 h postoperatively to help patients mobilize the fluids sequestered as a result of cirrhosis.

Maintenance immunosuppression in liver transplant recipients relies principally on cyclosporine or tacrolimus. Tapering doses of steroids also are used. Induction with ALG or OKT3 is optional but may be useful in patients recovering from hepatorenal failure, because it allows a delay in starting nephrotoxic agents such as cyclosporine or tacrolimus. Azathioprine or mycophenolate mofetil also have been used as maintenance agents.

Acute rejection episodes after liver transplantation are common, but graft loss from rejection is rare. An elevation in liver enzyme levels, particularly canalicular enzymes (gamma-glutamyl transferase [GGT], alkaline phosphatase, and bilirubin), that is not explained by bile duct obstruction or hepatic artery thrombosis should prompt percutaneous liver biopsy, because the diagnosis of rejection is best made histologically. Rejection typically responds to bolus steroid therapy, but steroid-resistant rejection can be treated with antilymphocyte globulin or OKT3. In addition, elevations in liver function tests may occur months or years posttransplant from recurrent disease (e.g., primary biliary cirrhosis or viral hepatitis), de novo hepatitis, or chronic rejection. Chronic rejection may present as pruning of the hepatic arterial tree or as late hepatic artery thrombosis.

Complications

Liver transplant recipients are at risk for the same postoperative complications as any other patient with a major intraabdominal procedure, but several complications are unique to liver transplantation (Table 10-8). Primary nonfunction of the liver is manifested by a high INR, low fibrinogen level, and high ammonia level in the first several days posttransplant. Aspartate transaminase (AST) and alanine transaminase (ALT) may be markedly elevated initially, but they typically fall even in the presence of primary nonfunction simply because the hepatocytes have already died. Patients develop hepatic encephalopathy progressing to coma, and hepatorenal failure. The liver does not make bile or makes a clear-colored bile. Primary nonfunction must be treated with urgent retransplantation, but livers that demonstrate initial poor function typically recover after a period of days.

Portal vein thrombosis is a rare complication of liver transplantation but requires immediate diagnosis and operative intervention. Manifestations may include a marked rise in the serum ammonia level or variceal bleeding as a result of acute portal hypertension. It generally can be diagnosed by Doppler ultrasonography, which shows loss of the portal venous signal. Portal vein thrombosis should prompt immediate return to the operating room for thrombectomy, restoration of portal flow, and evaluation of the cause of thrombosis.

Hepatic artery thrombosis has an incidence of approximately 5 percent in adult liver transplantation and a higher incidence in pediatric liver transplantation. Early hepatic artery thrombosis, occurring within the first month posttransplant, usually is a result of technical problems, whereas later hepatic artery thrombosis is probably related to immunologic injury of the hepatic arterial tree. Because the biliary tree is dependent on hepatic artery blood flow, hepatic artery thrombosis results in ischemic changes of the bile ducts, resulting grossly in sloughing of the biliary epithelium and leading to plugging and obstruction of the bile ducts. If uncorrected, this leads to biloma formation and eventually liver abscess and sepsis. The management of hepatic artery thrombosis includes retransplantation or observation, since some patients tolerate this complication without ill effects. Most patients, however, develop biliary sludging with strictures and biloma formation. Bilomas can be drained percutaneously, and strictures of the common bile duct can be treated with resection and Roux-en-Y drainage.

Bile leaks after liver transplantation must be corrected immediately, because they lead to peritonitis, sepsis, and graft loss. A common complication of T-tube removal in liver transplant recipients is a bile leak from the T-tube exit site, because steroid therapy often prevents formation of a fibrous tract along the T tube. Bile leaks can be managed with operative intervention or by ERCP with papillotomy and temporary stenting of the common bile duct.

Recurrence of original disease may be a problem after liver transplantation in particular groups of patients. This includes primary biliary cirrhosis, which is difficult to differentiate from chronic rejection. Hepatitis B and C are likely to recur after liver transplantation but will not necessarily lead to cirrhosis of the transplanted liver. If alcoholism recurs after liver transplantation, it is considered a contraindication to retransplantation. Hepatoma or cholangiocarcinoma recurring in a transplanted liver contraindicates retransplantation.

Posttransplant lymphoproliferative disorder (PTLD) may arise in liver transplant recipients as a side effect of overimmunosuppression. Particularly at risk are pediatric recipients, especially those treated with high-dose immunosuppression for recalcitrant rejection. The primary treatment of PTLD is reduction of immunosuppressive therapy.

Results

Patient and graft survival with liver transplantation varies with institutional experience as well as comorbid conditions in the recipients before transplantation. Patients in better medical condition at the time of liver transplantation have better outcomes, which has prompted earlier referral of patients with liver failure. Combined patient and graft survival rates for U.S. centers are shown in Fig. 10-19. Pediatric graft and patient survival rates are shown in Fig. 10-20. Certain indications, such as primary biliary cirrhosis in adults and biliary atresia in children, are associated with higher- than-average success rates. The longest-living liver transplant patient is 26 years posttransplant.

Future improvements in liver transplantation include identification of patients who are immunologically tolerant of their livers and do not require long-term immunosuppression. Strategies to develop and monitor tolerance will likely be applied to liver transplantation, particularly since the liver appears to be less susceptible to immunologic rejection than other organs. The means of providing artificial liver support for patients in liver failure are urgently needed as short-term bridges to liver transplantation and as temporary support for patients whose livers might recover. Efforts in this direction include the use of extracorporeal porcine liver perfusion using genetically modified pigs, and the development of cultured human hepatocyte systems. The use of hepatic xenografts has not met with long- term success but remains a challenge with increasing appeal as the discrepancy between donor supply and recipient demand increases.

THORACIC ORGANS

David D. Yuh and Bruce A. Reitz

Transplantation of the human heart and lungs occupies a prominent place in the pantheon of medicine's greatest achievements in the past century. The deliberate, painstaking development of what was once considered a mystical concept into the lifesaving operations performed today stretched the limits to which we would go to renew the lives of those suffering from end-stage cardiopulmonary disease. Over the past 60 years the pioneering efforts of Carrel, Demikhov, Shumway, and others questioned long-standing assumptions and theories upon which conventional, palliative therapeutics were based. Their efforts forced physicians to seriously consider cardiopulmonary transplantation as a potential curative procedure. The decades since the first successful human cardiac transplant, performed by Christiaan Barnard in 1967, have witnessed the development of lung, combined heart-lung, and pediatric transplantation, expanding the range of potential recipients who would benefit from cardiopulmonary replacement. Despite steady experimental and clinical progress, significant problems remain, particularly donor organ shortage, chronic graft rejection, opportunistic infection, and limited organ preservation techniques.

Heart Transplantation

Historical Background

Experimental cardiac transplantation was launched in 1905 at the University of Chicago, where Alexis Carrel and Charles Guthrie, in the process of developing new vascular surgical techniques, transplanted a puppy's heart into the neck of an adult dog. Although the graft displayed normal contractile function for only 2 hours, this experiment established the technical feasibility of heart transplantation. In the mid-1940s the Russian surgeon V. P. Demikhov described a series of innovative anatomic variants of intrathoracic heterotopic cardiac transplantation in the classic monograph *Experimental Transplantation of Vital Organs*. In 1953 Neptune and colleagues described the use of hypothermic circulatory arrest for the purposes of graft preservation and recipient protection by placing donor and recipient dogs in beverage coolers. Using early techniques of "refrigerated" graft preservation and cardiopulmonary bypass, Webb and colleagues reported 12 successful canine orthotopic cardiac transplants in 1959, with the recipients surviving for periods ranging from 30 to 450 min. In these experiments, donor–recipient anastomoses were constructed among the aorta, pulmonary artery, and each of the pulmonary veins, requiring graft ischemic times ranging from 2 to 4 h.

The first successful orthotopic cardiac transplants were performed by Shumway and Lower at Stanford University in 1960. In a landmark *Surgical Forum* presentation, Shumway and Lower described a simple technique of orthotopic heart transplantation in canines through anastomosis of the atrial cuffs, pulmonary artery, and aorta, obviating the need for individual pulmonary venous anastomoses and shortening the graft ischemic time to about 1 h. Coupled with recipient protection using cardiopulmonary bypass and surface cooling as well as graft preservation with profound topical hypothermia, this technique resulted in extended recipient survival times, ranging from 6 to 21 days in five of eight dogs, with full recovery and return to normal activity until death by homograft rejection. In later studies Shumway and colleagues described electrocardiographic voltage drops associated with acute cardiac allograft rejection in dogs, the reversal of such changes with the administration of azathioprine and methylprednisolone, and consequent prolongation of recipient survival. Subsequent experimentation laid the groundwork for clinical cardiac transplantation by defining transplant physiology and by developing new methods of graft monitoring and preservation.

On December 3, 1967, the first successful human heart transplant was performed at the Groote Schuur Hospital in South Africa. Christiaan Barnard and his colleagues transplanted the heart of a 24-year-old automobile accident victim suffering from severe brain injury into a 54- year-old diabetic man with severe coronary artery disease and repeated myocardial

infarctions. The recipient survived for 18 days before expiring from *Pseudomonas pneumonia*. Subsequent heart transplants performed by Kantrowitz, Shumway, and others generated worldwide enthusiasm for the procedure. The number of centers performing human cardiac transplants grew exponentially in the years that followed. Only one year after Barnard's much-heralded operation, over 100 cardiac transplants had been performed in 17 countries.

The celebration of mankind's triumph over end-stage heart disease was short-lived. Numerous postoperative complications stemming from acute rejection and infection led to a 15 percent 1-year survival rate, driving morbidity and mortality rates to nearly unacceptable levels. Significant advances in the diagnosis and management of acute cardiac allograft rejection were made when Caves designed a biotome for safely obtaining serial transvenous endomyocardial biopsies and Billingham developed a clinically relevant histologic scheme for grading rejection in these specimens. Immunosuppressant regimens were refined, including the use of rabbit antithymocyte globulin (RATG) in the treatment of acute rejection. From 1974 to 1981 Stanford's clinical cardiac transplant program, involving 140 patients, achieved 1-year and 5-year postoperative survival rates of 63 percent and 39 percent, respectively. Despite these vital advances, it was the use of cyclosporine in heart transplant recipients at Stanford in 1980 that launched the rebirth of cardiac transplantation as the 1-year and 5-year survival rates surged to over 80 percent and 60 percent, respectively. The total number of cardiac transplants performed worldwide grew to more than 30,200 in over 200 centers by 1995.

Preoperative Considerations for Cardiac Transplantation

Recipient Selection

Rigid adherence to recipient selection criteria is important in achieving the excellent results observed in cardiac transplantation. Advances in the medical management of recipients before and after transplantation have led to a relaxation of certain criteria, including upper age limits, concomitant disease, and level of disability. Although a broader spectrum of patients has benefited from this expansion of eligibility, the problem of donor organ shortage has been exacerbated. Varying patient management philosophies and growing concerns about outcome statistics contribute to the problem. The United Network for Organ Sharing (UNOS) heart transplant waiting list contains over 2,800 patients, with about 300 new patients added to the list each month. Donor organ availability permits only 150 to 160 cardiac transplants each month. The average length of time on the waiting list has increased to over 300 days for outpatients, contributing to the 15 to 20 percent mortality rate among patients on the waiting list. Recent efforts have been directed toward refining and standardizing recipient evaluation methods and selection criteria to channel heart grafts to those patients who are in most immediate need while maintaining good short-term and long-term outcomes. There are several published reviews and recommendations regarding patient selection criteria, from the American Heart Association (AHA, 1992), the American College of Cardiology (ACC, 1993), and the International Society of Heart and Lung Transplantation (ISHLT, 1993). The selection criteria discussed in this section have been adopted by the majority of transplant centers in the United States.

Indications

Generally accepted indications for cardiac transplant evaluation are listed in Table 10-9. Patients who suffer from severe cardiac disability despite maximal medical therapy but who are otherwise healthy are considered for cardiac transplantation. Most cardiac transplant recipients suffer from end-stage, inoperable coronary artery disease or idiopathic cardiomyopathy (Fig. 10-21) and often require multiple hospitalizations. Other diagnoses include defined cardiomyopathy (e.g., viral, postpartum, familial), congenital anomalies, and valvular disease. Disabling symptoms typically include those associated with congestive heart failure (e.g., dyspnea, orthopnea, generalized edema, weakness), although recurrent symptomatic ventricular arrhythmias and severe ischemic symptoms (i.e., unstable angina) are frequently observed. Cardiac transplant candidates generally fall into the New York Heart Association's (NYHA) functional classes III and IV.

Formerly, a left ventricular ejection fraction (LVEF) of less than 20 percent was relied upon as a key indicator of severe cardiac dysfunction requiring transplantation, but refinements in medical management, particularly aggressive vasodilator therapy, have rendered this parameter less representative of severe patient disability or predictive of imminent death.

The NYHA functional classification scheme is widely used in the assessment of transplant candidates, but studies have shown that a more accurate and objective measure of functional capacity is provided by peak oxygen consumption during metabolic stress testing. Peak oxygen consumption, a function of peak cardiac output and peripheral oxygen extraction, correlates well with functional class and is an independent predictor of outcome in heart failure patients. Prospective studies have shown that patients with severely reduced peak oxygen consumption (< 15 mL/kg/min, approximately 50 percent of normal) have a 1-year mortality rate exceeding 50 percent and derive tremendous benefit in survival and functional capacity from transplantation. Oxygen consumption treadmill exercise testing is performed routinely or on an individualized basis for transplant evaluation in the majority of transplant programs in the United States.

Contraindications

There are several well-established contraindications to cardiac transplantation, which are based on significant risks of recurrent cardiac dysfunction, severe symptomatic limitations, and limited rehabilitation or survival after transplantation (Table 10-10). Contraindications include advanced age, irreversible hepatic, renal, or pulmonary dysfunction, active or extrapulmonary infection, severe peripheral or cerebral vascular disease (e.g., diabetes mellitus), unresolved malignancy, severe pulmonary hypertension, psychiatric illness or a history of medical noncompliance, drug or alcohol abuse, current tobacco use, and cachexia or morbid obesity. Some of these conditions represent relative or temporary contraindications, and exceptions can be made on a selective basis.

The original upper age limit of 50 years for cardiac transplant recipients has been raised to 60 or 65 years because of several reports that short-term survival rates and improvements in quality of life for recipients older than 60 years of age are comparable to those of younger recipients. Few transplant centers would disqualify an otherwise favorable candidate solely on the basis of advanced age, but it is generally agreed that older transplant candidates should undergo a more rigorous evaluation. Bull and associates demonstrated that short-term and long-term survival after transplantation was significantly lower for patients who were older than 60 years of age at transplantation than for younger patients. Their studies also showed that older patients were more likely to die of late infectious complications or malignant disease after transplantation. The authors hypothesized that this may be from decreased immune responsiveness and T-cell function, leading to relative overimmunosuppression. Older transplant recipients also are at higher risk for developing steroid-induced diabetes and clinically significant osteoporosis.

Patients presenting with significant irreversible hepatic, renal, or pulmonary dysfunction should not be considered for transplantation because of the high perioperative risks associated with these conditions. Severe chronic obstructive pulmonary disease usually is defined as a forced expiratory volume in 1 second (FEV₁) of less than 1 L or 50 percent of the predicted normal value in the absence of pulmonary edema. In the case of hepatic and renal insufficiency, it is important for the evaluating clinician to determine whether the dysfunction is the result of severe chronic heart failure (i.e., venous congestion, hypoperfusion) or disease intrinsic to the affected organ system. When renal and hepatic function markedly improves or even normalizes with the optimization of cardiac output through the administration of fluids, diuretics, vasodilators, or inotropes, cardiac transplantation may be a therapeutic option. Some transplant centers perform renal or hepatic transplantation in selected patients with irreversible disease in conjunction with cardiac transplantation. Diabetes mellitus, a controversial contraindication to transplantation because of the potential for peripheral vascular and end-organ disease, susceptibility to infection, and exacerbation by steroids, does not appear to have adverse effects on outcome of cardiac transplantation in carefully selected cases.

Active infection and malignancy are absolute contraindications to transplantation in view of the lifelong immunosuppression required. Acute transient infections must be thoroughly cleared before transplantation; chronic infective agents, including chronic hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) preclude transplantation. Chronic conditions predisposing to serious infection, including symptomatic cholelithiasis, severe diverticulitis, active peptic ulcer disease, and cerebral/pulmonary embolization, should be evaluated and treated before transplantation. With the exception of fully resected squamous cell carcinoma of the skin, patients with previous malignancies should not be listed for cardiac transplantation less than 5 years after the malignancy has been considered cured. An exception to this rule is young patients suffering from doxorubicin cardiotoxicity.

Severe, fixed pulmonary hypertension has been confirmed recently as a significant independent risk factor for early mortality after orthotopic cardiac transplantation because of a heightened incidence of acute posttransplant right ventricular failure. Retrospective studies showed that early posttransplant mortality rates were significantly higher in cardiac transplant recipients with a preoperative pulmonary vascular resistance of 5 Wood units or more or a transpulmonary pressure gradient (mean pulmonary artery pressure minus mean pulmonary capillary wedge pressure) of 15 mmHg or more. In some cases pulmonary vascular resistance can be lowered to acceptable levels with the aggressive administration of supplemental oxygen, vasodilators, and inotropic agents. Patients with pulmonary hypertension refractory to these measures should not be considered for orthotopic cardiac transplantation. The use of proportionally large donor heart grafts with short ischemic times to overcome significant pulmonary hypertension in marginal recipients has not been an effective approach and is not recommended. Patients with severe, refractory pulmonary hypertension should be considered for combined heart-lung transplantation.

The psychosocial assessment of a potential recipient's emotional stability, compliance, and socioeconomic environment is vital, because substantial emotional, medical, and financial demands are placed upon the recipient and his or her family. Active substance abuse, including drugs, alcohol, and tobacco, is an absolute contraindication to transplantation; abstinence for no less than 6 months must be documented before transplantation is performed. Morbid obesity (> 150 percent of ideal body weight) is often considered an indication of noncompliance. Obesity increases the risks for posttransplant complications, including diabetes, fractures, and hypertension. Cachexia suggests inadequate nutrition, predisposes to infection, and should be treated with nutritional supplementation preoperatively.

Evaluation and Management of Patients Awaiting Cardiac Transplantation

Much of the health-care cost incurred by cardiac transplantation is generated by the preoperative evaluation and, in many cases, the hospitalization of patients awaiting transplantation. Consequently, much attention has been paid to refining transplant evaluation protocols and medical management strategies to reduce these costs while maximizing the therapeutic benefits of cardiac transplantation.

Candidate Evaluation and Listing

An outline of screening and diagnostic tests used in the formal evaluations of potential heart transplant candidates is presented in Table 10-11. Most of these tests are mandatory and are conducted on an outpatient basis. Some patients in severe heart failure require hospitalization (i.e., monitoring, intensive medical therapy, mechanical circulatory support) and in-hospital evaluation.

Patients suitable for cardiac transplantation are categorized and listed on the basis of clinical status, time on the waiting list, body size, and ABO blood group. Clinical status is composed of two broad status classifications developed by UNOS. The status I designation is applied to patients who (1) require an intensive-care-unit setting receiving parenteral inotropic drugs or mechanical device support (e.g., intraaortic balloon pump, ventricular assist device, ventilator) to maintain adequate circulatory or ventilatory function or (2) are less than 6 months old. Status II comprises all other waiting patients. Depending upon the patient's condition, selected tests are performed, particularly peak oxygen consumption and hemodynamic measurements, and are repeated about every 6 months. Most listed patients continue to deteriorate over time, but a significant number stabilize or even improve with medical therapy, prompting their inactivation on or removal from the list.

Medical Management

The management of listed patients has two primary goals: (1) to relieve debilitating symptoms stemming from end-stage congestive heart failure, and (2) to preserve organ function and optimize the patient's condition for transplantation. Clinically stable transplant candidates with end-stage heart failure usually are treated with a combination of digoxin, diuretics, vasodilators, and angiotensin-converting enzyme inhibitors on an outpatient basis. Oral anticoagulation therapy is used by many transplant programs to reduce the risk of pulmonary and systemic emboli, which may occur asymptotically in as many as 60 percent of patients with idiopathic cardiomyopathy. Anticoagulation therapy is used selectively in patients predisposed to bleeding complications, including those in right ventricular failure with hepatic congestion. The use of antiarrhythmic agents as prophylaxis for ventricular arrhythmias and sudden cardiac death is controversial in view of their proarrhythmic potential and negative inotropic effects, particularly in patients with depressed left ventricular function. Amiodarone has improved survival in patients with end-stage heart failure without increasing perioperative risk, leading to its use in cardiac transplantation candidates. Patients with recurrent sustained episodes of ventricular arrhythmias refractory to antiarrhythmic medications are considered for implantation of an automatic implantable cardioverter/defibrillator (AICD) or a pacemaker cardioverter defibrillator (PCD).

When conventional therapies prove inadequate, more aggressive measures in the form of parenteral vasodilators (e.g., nitroprusside, nitroglycerin) and inotropic agents (e.g., dopamine, dobutamine) are used. Amrinone, a phosphodiesterase inhibitor with inotropic and vasodilator properties, has been used successfully in patients with ischemic cardiomyopathy. Its use is tempered by side effects, however, particularly its potential to produce or worsen ventricular arrhythmias.

Mechanical Support

Heart failure and clinical deterioration refractory to parenteral support necessitates mechanical intervention in the form of intraaortic balloon pump (IABP) counterpulsation or ventricular assist system (VAS) placement. IABP counterpulsation improves coronary perfusion and reduces afterload and mitral regurgitation; however, its overextended use is associated with significant rates of vascular complications. IABP is most appropriately used to deliver moderate, short-term support to patients with acute circulatory failure and end-organ dysfunction or patients with ischemia-related arrhythmias awaiting transplantation.

VASs are implanted mechanical pumping devices designed to assume a significant portion of the systolic work load from the left ventricle (LVAS), right ventricle (RVAS), or both ventricles (BiVAS) and are intended for intermediate to long-term circulatory support for patients in severe ventricular failure. Mechanical support is considered when the cardiac index is less than 2.0 L/min per m² body surface area, the ventricular filling pressures are greater than 20 mmHg, the urinary output is less than 20 mL/h (adults), and the systemic vascular resistance is greater than 2,100 dynes sec/cm⁻⁵ despite maximal parenteral inotropic and vasodilator therapy. Since the initial use of an LVAS as a bridge to transplant, LVASs have yielded encouraging results in transplant candidates. The three most widely used ventricular assist systems include the Novacor LVAS, the Thoratec VAS, and the HeartMate IP LVAS. All three systems have been used successfully to reduce the mortality rates among end-stage cardiac patients awaiting transplantation. The Novacor VAS and Thoratec VAS, used since 1976 and 1984, respectively, have bridged 60 to 65 percent of implanted patients to successful transplantation with 1-year posttransplant survival rates in excess of 80 percent; these survival rates are comparable to those of the general cardiac transplant population. A 55 percent decrease in pretransplant mortality rate and a 23 percent increase in 1-year survival rate was reported among patients placed on HeartMate IP LVAS support as a bridge to transplant. Complications observed in LVAS- supported patients include bleeding (40 percent), infection (20 to 75 percent), and right ventricular failure (10 to 30 percent). Bleeding in these patients often has been attributed to coagulopathy secondary to chronic heart failure and is ameliorated with the use of aprotinin during implantation. It is difficult to determine the actual incidence of significant device-related infections, because many postbypass patients have transient fevers and positive cultures, but LVAS patients have a low incidence of fatal infections. There are no reliable predictive factors for the development of right ventricular failure after LVAS implantation. The high mortality rates associated with this complication (30 to 50 percent) have prompted investigators to identify preimplantation criteria to determine which patients would benefit from biventricular versus left ventricular devices. Parameters such as ventricular size, filling pressures, and ejection fractions in addition to standard hemodynamic measurements are not reliably predictive of postimplantation right ventricular decompensation. It is suggested that a transplant candidate's clinical status rather than right ventricular function defines the need for additional right ventricular support. Patients requiring BiVAS are more compromised, with higher incidences of mental impairment, pulmonary edema, elevated creatinine levels, and lower mixed venous oxygen saturations than patients requiring LVAS. Perioperative blood transfusion requirements for diffuse bleeding are higher in patients requiring BiVAS.

Donor Selection and Management

Criteria

First and foremost, donors must have sustained irreversible brain death, usually as a result of blunt or penetrating head trauma or intracranial hemorrhage. Despite the development of a relatively streamlined organ procurement system in the United States, there remains confusion about brain death and declaration of brain death, because of variations in legislative language, procedures, and standards from state to state. However, absolute and optional criteria for brain death were established by a presidential commission in 1981.

Suggested criteria for cardiac donors and guidelines for recipient matching developed by the American Heart Association in 1992 are listed in Table [10-12](#). Donor evaluation consists of a directed history and physical examination, chest roentgenogram, 12-lead electrocardiogram, arterial blood gas determinations, echocardiogram, serologic screening (e.g., HIV, hepatitis B surface antigen [HB sAg], hepatitis C antibodies, herpes simplex virus, cytomegalovirus, and *Toxoplasma*), and pancultures. Normal cardiac function and the absence of a significant cardiac history and significant coronary atherosclerosis must be established. A donor age of less than 50 years is preferred, although potential donors aged 55 years and older are considered at most centers with a more detailed evaluation, sometimes including coronary angiography, to rule out significant cardiac disease. A higher risk of late graft atherosclerosis is associated with hearts obtained from donors over 40 years of age, and higher rates of early death have been noted in pediatric recipients of such hearts.

Absolute contraindications for donation include severe coronary or structural disease, prolonged cardiac arrest, prior myocardial infarction, a carbon monoxide–hemoglobin level greater than 20 percent, arterial oxygen saturation less than 80 percent, metastatic malignancy (sometimes excluding primary brain and skin cancers), and positive HIV status. Relative contraindications include thoracic trauma, sepsis, prolonged severe hypotension (i.e., mean arterial pressure less than 60 mmHg for more than 6 h), noncritical coronary artery stenosis, HB sAg or hepatitis C antibodies, multiple resuscitations, severe left ventricular hypertrophy, and a prolonged high inotropic requirement (e.g., dopamine in excess of 20 mg/kg/min for 24 h). It is important to rule out reversible metabolic or physiologic causes of impaired cardiac function, rhythm disturbances, and electrocardiographic anomalies (e.g., brain herniation, hypothermia, hypokalemia).

Despite these guidelines, the donor organ shortage coupled with critical clinical situations has prompted several groups to use cardiac grafts from “high-risk” donors with satisfactory short-term results. These include grafts that are potentially compromised by advanced age, high-dose inotropic support, donor-to-recipient undersizing, potential infection, echocardiographic abnormalities, or prolonged ischemic transport time.

Management

The primary goal of managing the cardiac donor is the maintenance of hemodynamic stability. Patients suffering from acute brain injury often are hemodynamically unstable, as a result of neurogenic shock/pulmonary edema, excessive fluid losses, and bradycardia. Continuous arterial and central venous pressure monitoring, aggressive fluid resuscitation, vasopressors, and inotropes usually are required. Judicious fluid management prevents intraoperative hemodynamic instability and minimizes the need for inotropes and vasopressors, which are myocardial stressors. Intravascular fluids should be given to maintain the central venous pressure between 5 and 12 mmHg. Diabetes insipidus is common in organ donors and requires the use of intravenous vasopressin (0.8 to 1.0 U/h) to reduce excessive urine losses. To maintain adequate perfusion pressures, dopamine is the standard inotropic agent, but alpha agonists (e.g., phenylephrine) often are appropriate. Blood transfusions should be used sparingly to maintain the hemoglobin concentration around 10 g/dL to ensure adequate myocardial oxygen delivery. Hypothermia should be avoided, because it predisposes to ventricular arrhythmias and metabolic acidosis.

Donor–Recipient Matching

Donor–recipient matching parameters include ABO compatibility and body size. ABO compatibilities are strictly adhered to because isolated episodes of hyperacute rejection have been observed in cardiac transplants performed across this barrier. Chan and colleagues report that body weight does not correlate well with heart size in adults weighing 50 to 100 kg, suggesting that strict size limits are not warranted. Although fairly wide limits are acceptable, size matching and graft ischemic time is particularly important for recipients with an elevated pulmonary vascular resistance (greater than 6 to 8 Wood units). Grafts from donors whose weight is less than 80 percent of that of the recipient or those with ischemic times longer than 2 h are avoided for adult and pediatric recipients with pulmonary hypertension. There is no upper donor size limit in adults, given the typically enlarged recipient pericardial space resulting from chronic congestive cardiac enlargement.

Once an appropriate donor–recipient pairing is made, the recipient is screened for preformed antibodies against a standardized panel of random donors. A panel-reactive antibodies (PRA) level greater than 5 percent prompts a prospective specific crossmatch between the donor and the recipient. Several retrospective studies demonstrated that the degree of donor–recipient HLA mismatching influences rejection rates and survival after cardiac transplantation, but HLA matching is not feasible on a prospective basis in thoracic transplantation.

Operative Procedures

Procurement

After the chest is entered through a median sternotomy, a retractor is placed and the pericardium is opened and tethered, creating a pericardial well (Fig. [10-22](#)). The heart is inspected and palpated for contusions, perforations, thrills, and coronary atherosclerosis. If the heart is deemed satisfactory, its acceptance is immediately communicated to the recipient team. The aorta and pulmonary artery are dissected superiorly to the level of the arch and bifurcation, respectively, to ensure adequate length for implantation. The superior vena cava is mobilized superiorly to the origin of the azygous vein and encircled with two ligatures, taking care to preserve the sinoatrial node. An adequate length of the inferior vena cava is dissected free from its pericardial reflection and is surrounded with an umbilical tape. The aorta is encircled with an umbilical tape, and a 14-gauge cardioplegia perfusion cannula is inserted into its ascending segment. Intravenous heparin is administered at a dose of 300 U/kg and allowed to circulate for 3 to 5 min.

Removal of the heart begins with ligation and division of the superior vena cava. The inferior vena cava is clamped and partially divided just above the diaphragm, and the heart is allowed to beat several times, until it is empty. The ascending aorta is then clamped distal to the perfusion cannula at the level of the innominate artery, and a hyperkalemic cardioplegic solution at 2 to 4°C is rapidly infused into the aortic root at a pressure of 150 mmHg, arresting the heart in diastole. Concurrently, topical cold saline at 4°C is poured onto the heart and into the pericardial well. When the heart is fully arrested, cooled, and perfused with cardioplegic solution, it is elevated from the pericardial well, and each of the pulmonary veins is divided at its pericardial reflection. The pulmonary artery is divided at the level of the bifurcation, and the aorta is divided at the level of the innominate artery. The explanted heart is placed into two sterile plastic bags with a cold saline interface. This in turn is placed in an airtight container filled with ice-cold saline solution and transported in a standard ice-filled cooler.

Orthotopic Transplantation

After anesthesia is induced in the transplant recipient and arterial and venous lines are placed, the supine patient's chest and groin areas are prepared and draped. Central venous access via the left internal jugular vein usually is obtained, sparing the right side for future endomyocardial biopsies. After a median sternotomy is performed and the pericardium is opened and suspended, the patient undergoes routine cannulation of the aorta and both venae cavae (Fig. [10-23](#)). The arterial cannula is inserted in the most distal aspect of the ascending aorta, just below the innominate artery. The venous cannulae are placed laterally in the right atrium and positioned in the superior and inferior venae cavae; caval tapes

are applied. After institution of cardiopulmonary bypass with moderate hypothermia (28 to 30°C) and snugging of caval snares, the ascending aorta is cross-clamped, and 50 to 100 mL of cardioplegic solution is infused rapidly into the aortic root, causing diastolic arrest. The atria are transected at the level of their atrioventricular grooves, excluding the atrial appendages, leaving two recipient atrial cuffs. The aorta and the pulmonary artery are then separated and divided at the level of the semilunar valve commissures.

The donor heart is placed in a bowl of cold saline solution, and the left atrium is opened by connecting the pulmonary vein orifices, fashioning the donor atrial cuff. The aorta and the pulmonary artery are completely separated from each other. Under continuous application of cold saline solution into the pericardial well, implantation begins with the direct anastomosis of the donor and recipient left atrial cuffs with a continuous 3-0 Prolene suture. On completion of this anastomosis, a cold saline infusion line is placed into the left atrium through the atrial appendage for continuous endocardial cooling and evacuation of air from the left heart.

The donor right atrium then is opened with an incision extending from the inferior vena cava orifice superiorly in a curvilinear fashion along the lateral atrial wall up to the base of the atrial appendage. Through this incision, an intact tricuspid valve and fossa ovalis are inspected and assured. It is important to close a patent foramen ovale because, in the setting of elevated right heart pressures, a significant right-to-left shunt might result in early posttransplant hypoxemia. The right atrial cuff anastomosis is performed with a continuous 3-0 Prolene suture. Systemic rewarming is initiated at this time.

The pulmonary artery and aortic anastomoses are then completed in an end-to-end fashion using continuous 4-0 Prolene sutures. The caval snares are released, the head of the bed is lowered, and topical cooling is halted, permitting blood to enter the heart and lungs; any air trapped in the left-sided chambers is displaced through an aortic needle vent. Lidocaine is infused into the bypass circuit, the aortic cross-clamp is removed, and de-airing procedures are continued to vent any residual air from the heart. The left atrial line is removed, and the hole is oversewn. Spontaneous fibrillation usually occurs at this time, and electrical defibrillation is effected as necessary. All suture lines are inspected for hemostasis before cardiopulmonary bypass is weaned. The superior vena cava cannula is drawn back into the right atrium, and the inferior vena cava cannula is removed just before bypass is discontinued. An isoproterenol infusion (10 to 75 ng/kg/min) is titrated to achieve a heart rate of 90 to 110 beats/min to maximize cardiac output chronotropically and inotropically and to lower pulmonary vascular resistance. Temporary ventricular and atrial pacing wires (donor right atrium) are placed. The pericardium is left open, and mediastinal chest tubes are placed. Pleural space violations or effusions are treated with chest tubes. The sternum and overlying fascia and skin are closed in the usual fashion.

The authors have used a bicaval anastomotic technique, using separate end-to-end superior vena cava and inferior vena cava anastomoses instead of the right atrial cuff anastomosis (Fig. 10-24). In addition to the functional benefits, separate caval anastomoses are particularly useful in cases of significant donor–recipient size discrepancies and transplantation for congenital heart disease.

Heterotopic Transplantation

Originally described by Demikhov, heterotopic transplants account for about 2.5 percent of the cardiac transplants currently performed. The operative technique bypasses the left heart and involves anastomoses between the left atria, aorta, pulmonary arteries, and donor superior vena cava to recipient right atrium (Fig. 10-25). The major indication for this operation is the presence of irreversible severe pulmonary hypertension, whereby the native right heart continues to work against the elevated pulmonary vascular resistance while the graft bypasses the left heart. Other indications include cases in which diminished donor heart function is anticipated because of size mismatch or prolonged ischemic time, and the graft is to serve as a temporary support in the setting of reversible cardiac failure.

Postoperative Management

Early Postoperative Period

On completion of the cardiac transplant procedure, the intubated transplant patient is transported to the intensive care unit (ICU) where cardiac rhythm and arterial and central venous pressures are monitored. The use of Swan-Ganz pulmonary artery balloon catheters usually is reserved for recipients with significant pulmonary hypertension. Strict isolation precautions, previously enforced to reduce the incidence of infection in these immunocompromised patients, are no longer required; simple handwashing and face masks are considered sufficient. Precautions are taken to minimize patient contact with objects or persons harboring active infectious agents.

A primary objective in the immediate postoperative period is to maintain adequate perfusion in the recipient while minimizing cardiac work. Approximately 10 to 20 percent of transplant recipients have some degree of transient sinus node dysfunction, often manifested as sinus bradycardia that usually resolves within a week. Because cardiac output is primarily rate-dependent after transplantation, the heart rate should be maintained between 90 to 110 beats/min during the first few postoperative days, using temporary pacing or isoproterenol. Although uncommon (< 5 percent), persistent sinus node dysfunction and bradycardia may require a permanent transvenous pacemaker. The systolic blood pressure should be maintained between 90 to 110 mmHg, using afterload reduction in the form of nitroglycerin or nitroprusside if necessary. Renal dose dopamine (3 to 5 mg/kg/min) frequently is used to augment renal blood flow and urine output. The adequacy of cardiac output is indicated by warm extremities and a urine output greater than 0.5 mL/kg/h without diuretics. Cardiac function generally normalizes within 3 to 4 days during which parenteral inotropes and vasodilators can be weaned. Hypovolemia, cardiac tamponade, sepsis, and bradycardia should be considered and treated expeditiously in the event of reduced cardiac output and hypotension.

Several factors may contribute to some form of depressed global myocardial performance in the acute postoperative setting. The myocardium is subject to prolonged ischemia, inadequate preservation, or catecholamine depletion prior to implantation. Right heart failure is not uncommon in the early postoperative period. Although considered multifactorial in origin, an elevated pulmonary vascular resistance often is the principal cause. Inotropes with pulmonary vasodilatory effects, including isoproterenol, dobutamine, and amrinone, are effective in treating early right heart failure. The more selective pulmonary vasodilator prostaglandin E₁, combined with standard inotropes, is effective in more severe cases. Rarely, mechanical right ventricular support is necessary.

Optimizing pulmonary function is another critical objective in the acute postoperative period. When the patient arrives in the ICU, an anteroposterior chest radiograph is obtained and the ventilator is set to a 100% fractional inspired oxygen content (FiO₂), tidal volume of 10 to 15 mL/kg, an assist-control rate of 10 to 14 breaths/min, and positive end-expiratory pressure (PEEP) of 3 to 5 cmH₂O. These settings are adjusted every 30 min to achieve an arterial oxygen pressure (PaO₂) above 75 mmHg with an FiO₂ of 40 percent, arterial carbon dioxide pressure (PaCO₂) from 30 to 40 mmHg, and pH from 7.35 to 7.45. Ventilatory weaning is initiated after the patient is deemed stable, awake, and alert. Weaning usually is accomplished through successive decrements in intermittent mandatory ventilation rate, followed by a trial of continuous positive airway pressure. When acceptable ventilatory mechanics and arterial blood gas levels are achieved, the patient is extubated, usually within the first 24 h postoperatively. After extubation, pulmonary care consists of supplemental oxygen for several days, aggressive pulmonary toilet, and serial chest radiographs.

Expedient removal of vascular lines has been shown to reduce the incidence of line-related infections. Pleural and mediastinal thoracostomy tubes are removed when drainage has fallen off to less than 25 mL/h, and pacing wires are removed after 7 to 10 days if pacing is not required. After several days, the patient is transferred from the ICU to a standard cardiac surgery ward, where patient instruction, immunosuppressant dosage adjustment, an initial endomyocardial biopsy, and early rehabilitation occur. A second endomyocardial biopsy and baseline coronary arteriogram are obtained approximately 2 weeks postoperatively, just before discharge.

Graft Physiology

The grafted heart presents several unique physiologic characteristics (Table 10-13). During procurement, the heart graft is separated from the sympathetic and parasympathetic cardiac plexus of nerves located between the tracheal bifurcation and the aortic arch. Normally this plexus autonomically regulates the heart rate, contractility, and coronary arterial tone. The denervated heart graft is isolated from normal autonomic regulatory mechanisms. The resting heart rate is higher, because vagal tone, sinus arrhythmia, and carotid reflex bradycardia are absent. The denervated heart graft develops an increased sensitivity to catecholamines, possibly from an increase in beta-adrenergic receptor density and a loss of norepinephrine uptake in postganglionic sympathetic neurons. This augmented sensitivity has an important role in maintaining an adequate cardiac response to exercise and stress.

The output of cardiac allografts is at the low end of the normal range, and the measured cardiac response to exercise or stress is below normal, but the response of the cardiac allograft is adequate for most activities. During exercise the cardiac transplant recipient experiences a steady but delayed increase in heart rate, primarily from a rise in circulating catecholamines. This initial rise in heart rate is accompanied by an immediate increase in filling pressures resulting from augmented venous return. These changes result in an augmentation of stroke volume and cardiac output sufficient to sustain the increase in activity. The ability of the coronary circulation to dilate and increase blood flow in response to increased myocardial oxygen demand is normal. Conversely, graft coronary vasodilator reserve is abnormal in the presence of rejection, hypertrophy, or regional wall motion abnormalities.

The atrial cuff anastomoses also result in abnormal cardiac physiology. The normal atrial contribution to ventricular end-diastolic filling is impaired by the dissociation between recipient and donor atrial contractions. The atrial anastomoses may partially deform the atrioventricular annuli, leading to mitral and tricuspid regurgitation. Studies show a significant reduction in atrioventricular valve regurgitation and lower atrial volumes and pressures in patients with vena caval anastomoses.

Immunosuppression

Conventional immunosuppression in cardiac transplant recipients consists of the “triple-drug” combination of cyclosporine, azathioprine, and glucocorticoids. High doses of these drugs are given initially, with eventual tapering for chronic administration. Cyclosporine potently inhibits T lymphocyte activation, presumably by blocking the release of interleukin 2 from helper T cells. Cyclosporine is titrated to maintain a trough serum concentration of 150 to 250 ng/mL during the first few weeks after transplantation and 50 to 150 ng/mL thereafter. Azathioprine, a cytotoxic agent and bone marrow suppressant, is dosed to maintain the white blood cell count above 5,000/mm³. Glucocorticoids exhibit potent immunosuppressive effects by inhibiting leukocyte elaboration of inflammatory mediators (e.g., lymphokines, colony-stimulating factors). A methylprednisolone bolus (500 mg intravenously) is given intraoperatively after cardiopulmonary bypass is discontinued and during the first 24 h postoperatively (125 mg intravenously every 8 h). Prednisone is then dosed at 1.0 mg/kg/day during the first posttransplant week and, in the absence of acute rejection, tapered to a maintenance dose of 0.2 mg/kg/day.

The addition of prophylactic induction therapy with OKT3 monoclonal antibodies to its standard triple-drug regimen given over the first 10 postoperative days has delayed the time to first rejection and has reduced early rejection rates, but has not resulted in significant differences in the total number of rejection episodes, rates of infection, graft coronary artery disease, renal function, or overall recipient survival.

Judicious doses of these drugs usually are well tolerated by patients, but each drug is associated with side effects. Cyclosporine is associated with nephrotoxicity, hypertension, hepatotoxicity, hirsutism, and an increased incidence of lymphoma. The primary toxicity of azathioprine is generalized bone marrow depression manifested as leukopenia, anemia, and thrombocytopenia. Steroids are associated with a myriad of side effects, including the appearance of cushingoid features, hypertension, diabetes, osteoporosis, and peptic ulcer disease. Initial doses of OKT3 may cause significant hypotension, bronchospasm, or fever, presumably due to T-cell-mediated release of lymphokines. Patients receiving OKT3 are closely monitored and premedicated with acetaminophen, antihistamines, and corticosteroids. Most of these adverse effects are manageable or reversible with dosage reduction; however, the prevalence of adverse effects emphasizes the inadequacies of pharmacologic immunosuppression. Research is being directed toward the development of more potent, less toxic immunosuppressive agents and modes of tolerance induction. Tacrolimus (FK506), rapamycin, and mycophenolate mofetil are several promising drugs

recently approved for use in organ transplantation by the Food and Drug Administration. Like cyclosporine, tacrolimus selectively inhibits T-cell proliferation by blocking cytokine synthesis. Rapamycin inhibits the actions of cytokines and growth factors on T and B cells. By depleting nucleotides, mycophenolate mofetil interrupts DNA synthesis and glycosylation of adhesion molecules in immune cells.

Postoperative Complications (Fig. 10-26)

Acute Rejection

Acute graft rejection is a major cause of death after cardiac transplantation. The incidence of acute graft rejection is highest during the first 3 months after transplantation. At Stanford Hospital, 84 percent of cardiac transplant recipients receiving triple-drug therapy without OKT3 induction had acute rejection during this period. The addition of OKT3 therapy reduces this figure to about 75 percent. After this initial 3 month period, the incidence of acute rejection averages about one episode per patient a year.

Despite attempts at developing noninvasive means to detect acute rejection in a timely manner, the endomyocardial biopsy remains the gold standard for the diagnosis of acute rejection. Surveillance endomyocardial biopsies allow rejection to be diagnosed before significant organ damage and dysfunction occurs. The technique, performed under local anesthesia, involves the percutaneous introduction of a Caves-Schultz bioptome into the right ventricle, usually via the right internal jugular vein, under fluoroscopic guidance. Alternative access sites include the right subclavian and both femoral veins. Multiple biopsy specimens are taken from the interventricular septum per session. Safe, simple, and relatively well tolerated by the patient, endomyocardial biopsies of the cardiac allograft begin 7 to 10 days after transplantation and are repeated at progressively longer intervals.

Acute rejection is characterized histologically by lymphocytic infiltration and myocytic necrosis (Fig. 10-27). Many grading systems have evolved from different transplant groups, culminating in the uniform criteria developed by the International Society for Heart and Lung Transplantation in 1990. The Stanford classification and International Grading Systems are outlined in Table 10-14.

The timing and severity of rejection episodes dictate therapy. Severe or moderate rejection episodes occurring in the early posttransplant period are treated with pulsed steroid dosing. Methylprednisolone is given intravenously at a dose of 1,000 mg/day for 3 consecutive days. Subsequent severe or moderate rejection episodes detected on routine surveillance biopsy are treated with steroid pulsing or by increasing the oral prednisone dosage to 100 to 200 mg/day for 3 consecutive days then tapering it back to baseline dosages over 2 weeks. Mild rejection usually is not treated with augmented immunosuppression unless it is persistent.

Acute rejection refractory to steroid therapy is treated with antilymphocyte preparations in the form of ATG or OKT3 monoclonal antibody. Potent second-line therapies that are used in especially difficult, persistent cases of rejection include methotrexate and total lymphoid irradiation (TLI). Endomyocardial biopsies are repeated 10 to 14 days after antirejection therapy to assess efficacy.

Chronic Rejection

Accelerated graft coronary artery disease (CAD) or atherosclerosis is a major limiting factor for long-term survival in cardiac transplant recipients. Significant graft CAD resulting in diminished coronary blood flow may lead to arrhythmias, myocardial infarction, sudden death, or impaired left ventricular function with congestive graft failure. Typical angina from myocardial ischemia usually is not noted in transplant patients because the cardiac graft essentially is denervated. In a retrospective analysis of cardiac transplants from 1980 through 1993, the actuarial freedom from graft CAD at 1, 5, and 10 years was 95, 73, and 65 percent, respectively. Risk factors for developing this condition have included older donor age, older recipient age, incompatibility at the HLA-A1, A2, and DR loci, hypertriglyceridemia (serum concentration > 280 mg/dL), frequent acute rejection episodes, and documented recipient cytomegalovirus infection.

Multiple causes for graft CAD have been proposed primarily focusing on chronic, immunologically mediated damage to the coronary vascular endothelium. Elevated levels of antiendothelial antibodies have been correlated with graft CAD. Unlike coronary occlusive disease in the native heart, which is focal in nature, transplant atherosclerosis represents a more diffuse vascular narrowing extending symmetrically into distal branches. Histologically, transplant arteriopathy is characterized by concentric intimal proliferation with smooth muscle hyperplasia (Fig. 10-28). Coronary angiograms are performed on a yearly basis to identify recipients with accelerated CAD. Because graft CAD is manifested as diffuse coronary intimal thickening, intracoronary ultrasonography has been advanced as a more sensitive means to detect graft atherosclerosis because of its ability to assess vascular wall morphology in addition to luminal diameter.

Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used to treat discrete proximal lesions in some cases of graft CAD, but the definitive therapy for diffuse disease is retransplantation. Effective prevention of graft CAD relies on developments in improved immunosuppression, recipient tolerance induction, improved CMV prophylaxis, and inhibition of vascular intimal proliferation.

Infection

Infection is the leading cause of morbidity and mortality in post–cardiac transplantation patients. The risk of infection and infection-related death peaks during the first few months after transplantation and rapidly declines to a low persistent rate. In a retrospective study the actuarial freedom from any infection at 3 months, 1 year, and 5 years was 40, 27, and 15 percent, respectively. The actuarial freedom from infection-related death at 3 months, 1 year, and 5 years was 95, 93, and 85 percent, respectively. The most frequent agents of infections after cardiac transplantation are listed in Table 10-15.

Postoperative infections can be broadly classified into those that occur early and those that occur late after transplantation. Early infections, those occurring during the first month after transplantation, are commonly bacterial (especially gram-negative bacilli) and are manifested as pneumonia, mediastinitis, catheter sepsis, and urinary tract and skin infections. Treatment of these infections involves identification of the infective agent (e.g., cultures, antibiotic sensitivity tests), source control (e.g., catheter removal, debridement), and appropriate antibiotic regimens. In the late posttransplant period, opportunistic viral, fungal, and protozoan pathogens are more prevalent. The lungs, CNS, gastrointestinal tract, and skin are the usual sites of invasion.

Cytomegalovirus infection is widely recognized as the most common and important viral infection in transplant patients, with an incidence of 73 to 100 percent in cardiac transplant recipients. It presents as a primary infection or reactivation of a latent infection, most commonly 1 to 4 months after transplantation. By definition, primary infection results when a previously seronegative recipient is infected via contact with tissue or blood from a seropositive individual. The donor organ is thought to be the most common vector of primary CMV infections. Reactivation infection occurs when a recipient who is seropositive before transplantation develops clinical CMV infection during immunosuppressive therapy. Seropositive recipients also are subject to infection by new strains of CMV. CMV infection has protean manifestations, including leukopenia with fever, pneumonia, gastroenteritis, hepatitis, and retinitis. CMV pneumonitis is the most lethal of these, with a 13 percent mortality rate, while retinitis is the most refractory to treatment, requiring indefinite treatment. CMV is significant as an infective agent because of its role as a trigger for accelerated graft CAD and as an inhibitor of cell-mediated immunity.

Diagnosis of CMV infection is made by direct culture of the virus from blood, urine, or tissue specimens, by a fourfold increase in antibody titers from baseline, or by characteristic histologic changes (i.e., markedly enlarged cells and nuclei containing basophilic inclusion bodies). Most cases respond to ganciclovir (DHPG) and hyperimmune globulin. Both of these agents have been used prophylactically, especially in seronegative patients receiving a graft from a seropositive donor. Prophylaxis has been shown to decrease the incidence of clinical CMV infections in recipients who were seropositive before transplantation, but not in seronegative patients.

Fungal infections are less common than bacterial or viral infections. Early recognition is important because these infections are more refractory to therapy and are more lethal. Therapy consists of antifungal agents, including amphotericin B, fluconazole, and flucytosine.

Infection prophylaxis in cardiac transplant patients consists of vaccinations, perioperative broad-spectrum antibiotics, and long-term prophylactic antibiotics. Pretransplant inoculation with pneumococcal and hepatitis B vaccines and diphtheria-pertussis-tetanus (DPT) boosters are recommended. In pediatric patients immunization with live measles-mumps-rubella (MMR) and polio vaccines should be performed before transplantation. All cardiac transplant recipients should receive annual influenza vaccinations. Perioperative antibiotic regimens vary widely, but first-generation cephalosporins (e.g., cefazolin) or vancomycin are used commonly. Long-term prophylaxis typically includes nystatin mouthwash for thrush, sulfamethoxazole-trimethoprim for opportunistic bacterial and *Pneumocystis carinii* infections, and antiviral agents such as acyclovir or ganciclovir.

Neoplasms

Organ transplant recipients are at significantly higher risk for developing cancer, undoubtedly because of chronic immunosuppression. Recipients are predisposed to skin cancer, B-cell lymphoproliferative disorders, carcinoma in situ of the cervix, carcinoma of the vulva and anus, and Kaposi's sarcoma. Conversely, neoplasms of the breast, lung, prostate, and colon are not increased in these patients. On average, tumors appear approximately 5 years after transplantation.

The incidence of B-cell lymphoproliferative disorders in transplant patients is many times greater than in the normal age-matched population. Diagnosis is established by lymph node biopsy. Lymphomas frequently are observed in recipients younger than 20 years of age within a year after transplantation. Recipients older than 45 years of age diagnosed with lymphoma tend to present several years after transplant, with an average survival of 9 months after diagnosis. Thought to be caused by unchecked Epstein-Barr virus infection in the setting of T-cell suppression, B-cell lymphoproliferative disorders are treated with a reduction in immunosuppression and administration of an antiviral agent, such as acyclovir or ganciclovir. A response rate of 30 to 40 percent can be expected, and recurrence is uncommon. Chemotherapy and radiotherapy have been used successfully in some cases. Close monitoring of the graft with echocardiography combined with clinical assessment of tumor status is important during therapy.

Retransplantation

The primary indications for cardiac retransplantation are graft failure from accelerated graft atherosclerosis or recurrent acute rejection. Patients in need of retransplantation are held to the same standard criteria as initial candidates. Survival rates after retransplantation are significantly less than those achieved in primary transplant patients. At the Stanford University Medical Center, the 1-year survival rate was 55 percent after cardiac retransplantation.

Results

According to the Registry of the International Society for Heart Transplantation, 2,500 to 3,500 heart transplantations per year were performed at more than 200 transplant centers worldwide from 1990 to 1995. A review of 496 heart transplants performed at Stanford between 1980 and 1993 placed 1-year, 5-year, and 10-year actuarial survival estimates at 82, 61, and 41 percent, respectively (Fig. 10-29). Most cardiac transplant patients are fully rehabilitated to the New York Heart Association's functional class I status. The benefits of this procedure are apparent when compared to the prognosis of these patients without transplantation.

Pediatric Cardiac Transplantation

Cardiac transplantation is now an accepted therapeutic option for infants and children with end-stage heart disease. The number of children undergoing heart transplantation has increased rapidly from about 200 performed between 1978 and 1986 to well over 200 performed in 1995, with over 80 recipients less than 1 year old. The leading indications for

cardiac transplantation in children are acquired dilated cardiomyopathy and congenital heart disease (Fig. [10-30](#)). Contraindications for transplantation in this group are similar to those in adults, with the addition of some complex venous drainage anomalies.

Blood type and donor size are the most important considerations in donor–recipient matching. The paucity of pediatric heart donors, wider ranges of patient size, and severe disability of many pediatric patients on the waiting list has resulted in an expanded range of accepted donor-to- recipient weight ratios. The average ratio is 1.4 ± 0.45 , ranging from 0.75 to 3.54. Moderately oversized heart grafts are preferred for recipients with an elevated pulmonary vascular resistance.

The operative technique of orthotopic heart transplantation in the pediatric population is similar to that used in adults, with some exceptions in certain cases of congenital heart disease (e.g., aortic arch or venous drainage reconstruction). Immunosuppressive regimens are similar to those used in adults, namely, triple-drug therapy with or without antilymphocytic induction. Steroids are tapered more quickly in pediatric recipients to minimize growth retardation and infectious complications.

Acute rejection rates in children and adolescents do not appear to differ significantly from those encountered in adults, although rejection may be less frequent in neonatal patients because of immune system immaturity. Acute rejection in children is often suspected from a spectrum of signs, including fever, tachycardia, anorexia, and restlessness, coupled with echocardiographic abnormalities (e.g., left ventricular free wall thickening, decreased function). Routine endomyocardial biopsies for rejection surveillance are performed less frequently in neonates and small children, but they are used to confirm the diagnosis of rejection. Acute rejection in children is initially treated with pulsed steroids, and antilymphocyte preparations, total lymphoid irradiation, and methotrexate are reserved for refractory cases. Graft CAD in children occurs at a frequency comparable to that of adult patients and is a frequently encountered cause of death.

Actuarial 1-year, 5-year, and 10-year survival estimates are 75, 60, and 50 percent, respectively, with most survivors achieving the New York Heart Association's functional class I. Normal somatic growth rate can be maintained in these patients, and normal cardiac chamber dimensional growth also occurs.

Lung and Heart-Lung Transplantation

Historical Background

The first experimental attempt at single-lung transplantation was described in dogs by Demikhov in 1947. Although the right lower lobe transplants met with limited success in terms of long-term survival, Demikhov established the technical feasibility of lung transplantation and demonstrated that preservation of the bronchial arteries and nerves was not necessary to maintain graft viability. In 1950 Metras in France reported the first successful whole left lung allotransplantation in canines using a left atrial cuff technique, analogous to that developed by Shumway and Lower, to avoid separate pulmonary venous anastomoses. In the course of studying the pulmonary autonomic reflexes in asthmatics, Juvenelle and colleagues were the first to achieve long-term survival after whole lung reimplantation in dogs. Subsequent physiologic studies demonstrated varying degrees of deterioration in the reimplanted lung's function (e.g., pulmonary artery pressure, lung compliance, gas exchange) and abnormal respiratory patterns, possibly from lung denervation. For some time, it was feared that the decline in lung function after reimplantation would preclude isolated lung transplantation in human beings. Then, in 1963, Haglin and associates demonstrated normal and adequate pulmonary function in reimplanted lungs before and after contralateral pneumonectomy in baboons leading to long-term survival.

The initial experiences with single human lung transplantation were discouraging. Hardy performed the first human lung transplant in 1963. The patient received a single left lung transplant but survived for only 18 days, dying of renal failure. Over the next 18 years, 37 more single-lung transplants were attempted, with the longest survivor dying after 10 months. The majority of these patients died from early graft dysfunction caused by inadequate graft preservation, rejection, or bronchial anastomotic complications (e.g., dehiscence and leakage). Successful efforts in human single-lung transplantation began in 1983, when Cooper performed a right lung transplant in a patient suffering from pulmonary fibrosis.

En bloc double-lung transplantation was successfully applied clinically in the middle to late 1980s. This technique, originally intended for patients with chronic obstructive pulmonary disease, arose from concern about preferential hyperinflation and herniation of the emphysematous native lung and mediastinum that might occur with single-lung transplantation. Since 1989 chronic obstructive lung disease has been effectively treated with single-lung transplantation and currently constitutes a major indication for this procedure. When en bloc double-lung transplantation was extended to patients with septic lung disease, particularly cystic fibrosis, high mortality rates resulted from bleeding complications in the poorly visualized mediastinum. As a result, bilateral sequential lung transplantation was developed, bringing marked reductions in bleeding and airway complications and supplanting the en bloc technique. Since 1983 over 2,700 lung transplants have been reported to the International Lung Transplant Registry.

The first successful experimental heart-lung transplants also are credited to Demikhov, who developed the method of orthotopic en bloc heart-lung transplantation, establishing the technical feasibility of these operations. Cardiopulmonary transplantation using mechanical cardiopulmonary bypass was first attempted in experimental animals by Webb and Howard in 1957, and then by Lower and Shumway in 1961. The survival rates after these early attempts at heart-lung transplantation were quite low, with no animal surviving for more than 5 days postoperatively. The main problem in the canine model was respiratory paralysis and insufficiency from denervation of the heart-lung bloc, casting doubt on the feasibility of these operations. Studies by Haglin and associates showed that denervation of both lungs did not prevent a return of adequate spontaneous respiration in nonhuman primates. Reports by Castaneda and associates revealed that pulmonary ventilation and perfusion and systemic circulatory hemodynamics were preserved after heart-lung autotransplants in baboons. These studies demonstrated the ability of primates to withstand complete cardiopulmonary denervation and assume normal pulmonary function after transplantation.

Reitz described a major modification to the standard technique in the use of a retained portion of the right atrium for a single inflow anastomosis instead of separate caval anastomoses. This technique preserved the donor sinoatrial node, eliminated potential caval anastomotic stenosis, and would facilitate the operation in human beings, where the intrathoracic inferior vena cava is short. The use of cyclosporine also proved to be a key factor. The early results in monkeys suggested that the degrees of rejection in the heart and lung were similar and that the endomyocardial biopsy used successfully in cardiac transplantation might be sufficient for monitoring graft rejection in heart-lung patients. Experience later proved that heart and lung rejection often occurs asynchronously.

In 1981 Reitz performed the first successful human heart-lung transplantation in a 45-year-old woman with end-stage primary pulmonary hypertension. This success rejuvenated worldwide efforts in lung and heart- lung transplantation. Improvements in recipient selection criteria, surgical technique, perioperative management, immunosuppression, infection prophylaxis, and posttransplant surveillance accompanied the expansion of clinical heart-lung transplantation after 1981. The number of heart-lung transplants performed grew rapidly from the five operations performed in 1981 to 241 performed worldwide in 1989. Nearly 1,100 heart-lung transplants have been reported to the Registry of the International Society for Heart and Lung Transplantation (ISHLT).

Preoperative Considerations

Recipient Selection Criteria

The overriding objective in recipient evaluation is to select individuals with progressively disabling cardiopulmonary or pulmonary disease with the greatest potential for full rehabilitation after transplantation. Most recipients suffering from end-stage lung disease with or without concomitant cardiac dysfunction are considered for three broad categories of transplant operations: single-lung, bilateral single-lung, and heart-lung transplantation. The indications for each operation are listed in Table [10- 16](#).

Single-lung transplantation is most ideally suited for patients with fibrotic lung disease because the low compliance and increased vascular resistance of the native lung ensure that ventilation and perfusion are preferentially diverted to the transplanted lung. Emphysematous lung disease also is a major indication for this procedure.

Bilateral single-lung transplantation is intended for patients suffering from septic lung disease, including cystic fibrosis and bronchiectasis, or from chronic obstructive pulmonary disease. Single-lung transplantation is avoided in patients with septic lung disease because the associated chronic bilateral pulmonary infections would place the recipients at high risk for infection from the retained native lung. The extra pulmonary reserve and potential survival advantage afforded by bilateral single-lung as compared to single-lung transplantation must be weighed against the benefits of providing lungs to two patients versus one.

Heart-lung transplantation was developed initially for patients suffering from severe pulmonary vascular disease—specifically, pulmonary hypertension and Eisenmenger's syndrome stemming from congenital cardiac anomalies. The indications for this procedure have broadened to include patients with end-stage lung disease, intercurrent cardiac dysfunction, cystic fibrosis, and bronchiectasis.

Other permutations of cardiopulmonary replacement have been developed. In the so-called domino transplant procedure, the explanted heart of a heart-lung recipient is transplanted into another patient in need of a cardiac transplant. In patients who have had prior thoracic surgery, heart–single-lung transplantation has been successfully used to avoid extensive adhesions in a previously treated pleural cavity. Lobar lung transplantation (from living-related and cadaveric donors) has been developed to expand the effective donor pool, readily providing healthy lung tissue to patients with a severely limited life expectancy, and accommodating the small chest dimensions of pediatric patients.

Contraindications to lung and heart-lung transplantation are similar to those in cardiac transplantation. Among most lung and heart-lung transplant programs, upper age limits typically range from 50 to 60 years, with projected life expectancies limited to less than 12 to 18 months with the use of appropriate medical or alternative surgical strategies. With some pulmonary diseases, survival without transplantation has been estimated using certain parameters, e.g., in patients with primary pulmonary hypertension, elevated right atrial pressure, diminished cardiac output, and elevated pulmonary artery pressure are correlated with diminished survival. Mortality rates of patients on the waiting list are considerable, ranging from 10 to 30 percent.

Patients suffering from systemic disease with significant renal or hepatic dysfunction, acute illness, unresolved malignancy, or psychiatric illness are not offered transplantation. Relative contraindications include cachexia or obesity and a recent history of active peptic ulcer disease. Patients requiring systemic corticosteroids are tapered to the lowest tolerable level before transplantation. Cigarette smokers must quit smoking and be completely abstinent for several months before transplantation. During the early years of heart-lung transplantation, previous cardiothoracic surgery or pleurodesis were considered absolute contraindications to heart-lung transplantation because of bleeding from chest wall adhesions and difficulty in preserving the vagus, recurrent laryngeal, and phrenic nerves; with improved surgical technique over the years, however, these cases are now being considered. A stable, supportive socioeconomic environment is an important consideration.

All prospective cystic fibrosis recipients should have an otolaryngologic evaluation before being placed on the active waiting list. Most of these patients require endoscopic maxillary anastomies for sinus access and periodic antibiotic irrigation to decrease bacterial colonization in the upper respiratory tract. This measure has decreased the incidence of serious posttransplant bacterial infections. Previous smokers must undergo extensive screening to exclude smoking-related illnesses, specifically peripheral vascular disease and malignancy. A negative sputum cytology, thoracic CT scan, bronchoscopy, otolaryngologic evaluation, carotid duplex scan, and flexible sigmoidoscopy/colonoscopy usually are required prior to listing.

Evaluation and Management of Patients Awaiting Lung or Heart- Lung Transplantation

Because adequate cardiac function is the most important determinant of whether single-lung or bilateral single-lung transplantation will be tolerated, the first phase of the preoperative evaluation includes echocardiography with Doppler and saline-contrast flow studies, radionuclide angiography, and, possibly, Holter monitoring and cardiac catheterization.

Patients suitable for heart-lung transplantation enter a second phase of testing and are categorized and listed on the basis of clinical status, time on the waiting list, ABO blood group, and thoracic cage dimensions. The average time from listing to transplantation ranges from 1 to 2 years. Listed candidates are seen in clinic every 3 to 6 months before transplantation to maintain them in optimal medical condition.

Some patients awaiting lung or heart-lung transplantation are in some degree of heart failure. All standard therapeutic measures are applied in these cases, namely, dietary restrictions, diuretics, and vasodilators. Intravascular fluid management for patients in heart failure consists of dietary water and salt restriction and diuretic therapy. Afterload reduction in the form of vasodilators, particularly nitrates, hydralazine, and angiotensin-converting enzyme inhibitors effectively improve functional capacity and prolong survival in patients suffering from severe cardiac failure.

Despite the clinical heterogeneity among patients with primary pulmonary hypertension, conventional medical therapy targets the sequelae of the pulmonary vascular derangements associated with this disease process. Supplemental oxygen therapy is recommended for any patient exhibiting arterial hypoxemia, defined as either an arterial oxygen saturation (SaO_2) less than 90 percent or a PaO_2 less than 60 mmHg at rest, during exertion, or while asleep. Oxygen supplementation is intended to eliminate the stimuli for hypoxic pulmonary vasoconstriction and secondary erythropoiesis, lessening the burden on the right heart and diminishing the contribution of myocardial hypoxia to cardiac arrhythmogenesis. The use of pulmonary vasodilator therapy is based on the notion that pulmonary vasoconstriction is an important component of primary pulmonary hypertension (PPH). Reeves and coworkers have shown that patients in whom a reduction in pulmonary vascular resistance of more than 30 percent is achieved during an acute vasodilator trial are more likely to demonstrate sustained clinical improvement. Severely ill patients with PPH awaiting heart-lung or lung transplantation who were unresponsive to oral vasodilator therapy have received continuous infusions of prostacyclin or prostacyclin analogs, incurring reductions in pulmonary arterial pressure and pulmonary vascular resistance. Despite the favorable response to prostacyclin seen in most of these patients, many eventually become refractory to the drug's effects. Patients placed on hold for lung or heart-lung transplantation after dramatic improvements with prostacyclin therapy should be monitored closely and reactivated early if deterioration is noted.

Interstitial lung disease in patients awaiting transplantation can result from a wide variety of diffuse inflammatory processes, such as sarcoidosis, asbestosis, and collagen-vascular diseases. Increases in pulmonary vascular resistance leading to right heart failure are thought to result from interstitial inflammatory infiltrates that entrap and eventually destroy septal arterioles, reducing the distensibility of the remaining pulmonary vessels. This process, coupled with closure of peripheral bronchioles, results in arterial hypoxemia, further aggravating pulmonary hypertension. Corticosteroids are used in treating this class of diseases, but the adverse effects of steroids on tracheal healing mandate significant dose reductions (prednisone to less than 0.1 mg/kg/day) in anticipation of heart-lung transplantation. Patients with dilated cardiomyopathy, congestive heart failure, and primary pulmonary hypertension are predisposed to pulmonary and systemic thrombosis and embolization. Most centers routinely use prophylactic anticoagulation agents (e.g., heparin or warfarin) or antiplatelet agents in these patients.

The multisystem manifestations of cystic fibrosis, particularly chronic bronchopulmonary infection, malabsorption, and diabetes mellitus, pose difficult management problems in potential lung and heart-lung recipients. Aggressive chest physiotherapy, antibiotics, enteral or parenteral nutritional supplementation, and tight serum glucose control require meticulous management.

Donor Selection and Management

Potential donors must have sustained irreversible brain death, usually as a result of blunt and penetrating head trauma or intracranial hemorrhage. Because of the susceptibility of the lungs to infection and edema, particularly in the settings of brain death and trauma, suitable heart-lung blocs are more difficult to obtain than other organs. Less than 20 percent of non-thoracic organ donors possess lungs suitable for donation.

Donor evaluation consists of a directed history and physical examination, chest radiograph, 12-lead electrocardiogram, arterial blood gas determinations, echocardiogram, serologic screening (i.e., HIV, hepatitis B surface antigen [HB sAg], hepatitis C antibodies, herpes simplex virus, cytomegalovirus, and *Toxoplasma*), and direct inspection and palpation of the heart and lungs at explantation. Echocardiographic evidence of normal cardiac function and the absence of a significant cardiac history and significant coronary atherosclerosis must be established. A donor age of less than 40 years is preferred, but potential donors aged 40 to 50 years are considered with a more detailed evaluation, including coronary angiography to rule out significant coronary artery disease. A donor chest film must be entirely clear and the PaO_2 should exceed 100 mmHg on an FiO_2 of 30 percent and 400 mmHg on an FiO_2 of 100 percent. Lung compliance can be estimated by measuring peak inspiratory pressures, which should be less than 30 cmH₂O. Bronchoscopy should assure the absence of purulent secretions or signs of aspiration. Donors should receive broad-spectrum antibiotics for infection prophylaxis before explantation.

Absolute contraindications for donation include severe coronary or structural heart disease, prolonged cardiac arrest, prior myocardial infarction, a carbon monoxide-hemoglobin level greater than 20 percent, arterial oxygen saturation less than 100 percent, active malignancy (sometimes excluding primary brain and skin cancers), a significant smoking history (more than 5 pack-years or 1 pack per day over the past year), and HIV seropositivity. Relative contraindications include thoracic trauma, sepsis, prolonged severe hypotension (i.e., less than 60 mmHg for more than 6 h), noncritical coronary artery stenosis, HB sAg or hepatitis C antibodies, multiple resuscitations, severe left ventricular hypertrophy, and a prolonged high inotropic requirement (e.g., dopamine in excess of 15 mg/kg/min for 24 h). Correctable metabolic or physiologic causes of cardiac rhythm disturbances and electrocardiographic anomalies (e.g., brain herniation, hypothermia, hypokalemia) should be ruled out.

The primary objective in managing the lung or heart-lung donor is the maintenance of hemodynamic stability and pulmonary function. Patients suffering from acute brain injury often are hemodynamically unstable from neurogenic shock, excessive fluid losses, and bradycardia. Donor lungs are subject to neurogenic pulmonary edema, aspiration, nosocomial infection, and contusion. Continuous arterial and central venous pressure monitoring, judicious fluid resuscitation, vasopressors, and inotropes usually are required.

Meticulous fluid management prevents intraoperative blood pressure instability and minimizes the need for inotropes and vasopressors, which are myocardial stressors. Intravascular fluids should be given to maintain the central venous pressure at 5 to 8 mmHg, being careful not to administer fluids at rates far in excess of the hourly urine output. Crystalloid fluid boluses should be avoided. Diabetes insipidus is common in organ donors, requiring the use of intravenous vasopressin (0.8 to 1.0 U/h) to reduce excessive urine losses.

To maintain adequate perfusion pressures, dopamine is the standard inotropic agent used, although alpha agonists (e.g., phenylephrine) often are appropriate. Blood transfusions should be used sparingly to maintain the hemoglobin concentration about 10 g/dL to ensure adequate myocardial oxygen delivery. The use of CMV-negative and leukocyte-filtered blood should be used whenever possible. Hypothermia should be avoided because it predisposes to ventricular arrhythmias and metabolic acidosis.

In mechanical ventilation, FiO_2 levels in excess of 40 percent, especially 100% oxygen "challenges," should be avoided, because these oxygen levels may be toxic to the denervated lung. Ventilator settings should include positive end-expiratory pressures (PEEP) between 3 and 5 cmH₂O to prevent atelectasis.

Donor-Recipient Matching

Donor-recipient matching parameters include ABO compatibility and body size. Donor-to-recipient lung volume matching is based on the vertical (apex to diaphragm along the midclavicular line) and transverse (level of the diaphragmatic dome) dimensions on chest roentgenogram as well as body weight, height, and chest circumference. Matching donor and recipient height seems to be the most reproducible method of selecting the appropriate donor lung size. The dimensions of the donor lungs should not be greater than 4 cm over similar measurements in the potential recipient and, preferably, should be smaller than those of the recipient. In a series of 82 heart-lung transplants, Tamm and colleagues recorded recipient lung volumes after transplantation and compared them to preoperative and predicted volumes to evaluate the influence of donor lung size and recipient underlying lung disease. The investigators showed that 1 year after transplantation total lung capacity (TLC) and dynamic lung volume returned to values predicted by the patients' sex, age, and height. They proposed that the simplest method of matching donor lung size to the recipient is to use their respective predicted TLC values.

When an appropriate donor-recipient pairing has been made, the recipient is screened for preformed antibodies against a panel of random donors. A panel-reactive antibodies (PRA) level greater than 50 percent prompts a prospective specific crossmatch between the donor and recipient. The relationship of heart-lung allograft-related death and chronic rejection to HLA matching was studied in 40 consecutive heart-lung transplant recipients. This study revealed a significant increase in graded obliterative bronchiolitis (OB) with total mismatch at the HLA-A locus. There was a slightly increased frequency, severity, and mortality with respect to OB in these mismatched patients. The incidence of OB is correlated with the number or severity and persistence of acute rejection episodes after lung and heart-lung transplantation, but prospective HLA matching currently is not feasible in cardiopulmonary transplantation.

Operative Techniques

Donor Lung and Heart-Lung Bloc Procurement

In single-lung and bilateral single-lung procurement operations, the chest is entered via a median sternotomy. Donor lungs usually are procured in conjunction with the heart (Fig. 10-31). First, the aorta and venae cavae are encircled with umbilical tapes in preparation for inflow occlusion and cardioplegic arrest. For each lung to be procured, the pleura is opened longitudinally, and the entire pericardium is excised from the diaphragm to the pleural apex, extending posteriorly through the phrenic nerve to the hilum. The inferior pulmonary ligament is incised to the inferior pulmonary vein. The right or left pulmonary artery is dissected free from the pulmonary artery bifurcation to the pulmonary hilum. Pulmonoplegia solution, most commonly Euro-Collins solution at 2 to 4°C, is rapidly flushed into the main pulmonary artery simultaneously with cardioplegic infusion into the ascending aorta. The tip of the left atrium is cut to vent the pulmonoplegia solution. Iced saline solution is then poured over the heart and lungs. The superior and inferior venae cavae, the ascending aorta, and common the pulmonary artery are divided, leaving the heart attached only to the pulmonary veins. In single-lung procurement, the contralateral pulmonary veins are divided and a left atrial cuff surrounding the two remaining pulmonary veins is created. In bilateral single-lung procurement, all four pulmonary veins are left intact with the atrial cuff. After removal of the heart, the trachea is clamped or stapled at its midpoint and divided.

In combined heart-lung transplantation, the heart and lungs are excised en bloc through a median sternotomy that is extended into the abdomen. Both pleural spaces are entered anteriorly, and the pericardium is trimmed, leaving both phrenic nerves on pedicles. After cannulating the heart, cardiopulmonary bypass is instituted and ventilation is stopped to facilitate the remainder of the operation. After inflow occlusion and cardioplegic/pulmonoplegic arrest, the ascending aorta, pulmonary artery, and venae cavae are dissected free. The innominate artery and vein are ligated and divided, facilitating exposure of the underlying trachea. The trachea is divided about 6 to 8 cm above the carina. The heart-lung bloc is dissected free from the esophagus, both pulmonary ligaments are divided inferiorly, and the posterior hilar attachments are divided. The respective organ or organs are removed from the chest after stapling of the trachea and immersed in a bag containing ice-cold saline solution at 2 to 4°C which in turn is transported in an ice-filled cooler.

Heart-Lung Transplantation

Heart-lung transplantation is performed with the recipient on cardiopulmonary bypass. After the chest is entered through a median sternotomy, both pleural spaces are opened anteriorly. The anterior portion of the pericardium is excised, preserving the lateral segments to support the heart and to protect the phrenic nerves (Fig. 10-32). The ascending aorta and both venae cavae are cannulated, and hypothermic cardiopulmonary bypass is instituted, cooling the patient to about 30°C.

The native heart and lungs are excised from the thorax. The native heart is arrested and excised at the ascending aorta just above the aortic valve, through the main pulmonary artery, and both atria. After the left and right phrenic nerves are dissected free, the pulmonary ligaments are divided inferiorly and the pulmonary artery and vein are divided in each hilum. The left and right bronchi are stapled and divided, and the lungs are removed. A portion of the pulmonary artery is left intact adjacent to the underside of the aorta near the ligamentum arteriosus to preserve the recurrent laryngeal nerve.

The donor heart-lung graft is then prepared by irrigating, aspirating, and culturing the tracheobronchial tree and by trimming the trachea to leave one cartilaginous ring above the carina. The heart-lung graft is lowered into the chest, positioning the right lung below the right atrial cuff and right phrenic nerve. After opening the recipient trachea just above the carina, the tracheal anastomosis is performed with a running polypropylene suture. Next, a donor right atrial cuff is constructed and anastomosed to the retained recipient right atrial cuff. At this point the patient is rewarmed toward 37°C and the aortic anastomosis is performed, completing the implantation. After the ascending aorta and pulmonary artery are cleared of air, the aortic cross clamp and caval tapes are removed. Isoproterenol usually is administered on graft reperfusion to increase the heart rate and to lower pulmonary vascular resistance. Ventilation is resumed, starting with an FiO_2 of 50 percent. Cardiopulmonary bypass is discontinued and decannulation performed after normothermia and satisfactory cardiopulmonary function have been achieved. Temporary right atrial and ventricular pacing wires are placed. Right and left pleural chest tubes are placed, and the chest is closed.

Single-Lung and Bilateral Single-Lung Transplantation

The single-lung transplant procedure (Fig. 10-33) is performed under single-lung anesthesia with the aid of a bronchial blocking device or double-lumen endotracheal tube. The side receiving the lung graft is not ventilated during implantation. Cardiopulmonary bypass usually is not required, but it is often indicated in cases of significant pulmonary hypertension. A posterolateral thoracotomy is used for single-lung grafting. Sequential bilateral single-lung transplants are performed through a bilateral anterotheracosternotomy or “clamshell” incision.

Excision of the recipient's diseased lung begins with the temporary occlusion of the ipsilateral pulmonary artery. If the patient's blood pressure, contralateral pulmonary artery pressure, and arterial blood gases are satisfactorily stable during this maneuver, the case can proceed. If significant perturbation of one or more of these parameters occurs, cardiopulmonary bypass will be required. The pulmonary veins are isolated lateral to the pericardium and the mainstem bronchus is mobilized just proximal to the upper lobe bronchus. After complete hilar mobilization, cardiopulmonary bypass is instituted if needed; otherwise, the pulmonary artery is clamped as proximally as possible and divided just distal to the first upper lobe branch. The two pulmonary veins are ligated extrapericardially. The mainstem bronchus is then divided just proximal to the upper lobe bronchus, and the recipient's diseased lung is removed from the chest.

Lung graft implantation begins with clamping the recipient's left atrium to isolate the ligated pulmonary vein stumps. The recipient left atrial cuff is then fashioned and, after the graft is placed in the chest, anastomosed to the donor cuff. The bronchial anastomosis is completed end-to-end with a running polypropylene suture. Omental wrapping of the bronchial anastomosis usually is not performed. The pulmonary artery anastomosis is constructed end-to-end, leaving the running suture untied to permit flushing and backbleeding. The left atrial clamp is released gradually, permitting backbleeding through the untied pulmonary artery suture line. After the pulmonary artery clamp is momentarily flashed to flush the pulmonary artery, the suture line is tied and the clamp is removed, restoring circulation to the lung graft, which is then ventilated. A second sequential lung transplant is performed in the same manner. After all anastomoses are completed and hemostasis is assured, the patient is weaned from bypass if it was required. Thoracostomy tubes are placed and the chest is closed. All bronchial anastomoses are checked endoscopically before the patient leaves the operating suite.

The “Domino” Operation

Because of the severe shortage of thoracic organs for transplantation, the so-called domino operation has been developed. This approach involves the use of the explanted heart from a patient undergoing heart-lung transplantation for primary lung disease for a second recipient in need of a heart transplant. More than 50 percent of heart-lung transplant recipients possess hearts with normal or near-normal left ventricular function and some degree of right ventricular hypertrophy resulting from elevated pulmonary artery pressures. The use of hearts explanted from patients with pulmonary hypertension has theoretic appeal in that the right ventricle already is adapted to elevated pulmonary vascular resistances, decreasing the likelihood of acute donor right heart failure in recipients with preexisting pulmonary hypertension. Starnes and Kells reported preservation or improvement of right ventricular function among seven domino heart transplant recipients. Oaks and associates described their experience with 32 domino heart transplants. No difference was observed in the 3-month and 1-year survival rates between domino and nondomino cardiac transplant recipients. Yacoub and colleagues reported an actuarial 1-year survival rate of 75 percent among recipients of domino hearts from cystic fibrosis patients who underwent heart-lung transplantation.

The domino donor cardiectomy differs slightly from the standard technique described by Lower and Shumway. In preparing the heart-lung recipient for cardiopulmonary bypass, the venous cannulas are placed into the inferior vena cava extrapericardially close to the diaphragm, and into the high superior vena cava at least 4 or 5 cm above the sinoatrial node. This modification enables the excision of the domino heart high on the superior vena cava to preserve the sinoatrial node for the domino recipient.

Living-Related Lobar Transplantation

In 1994 Starnes and associates described bilateral lobar transplantation with donor lobes from related donors. The technique is most commonly performed in recipients with end-stage cystic fibrosis. Early survival rates are equivalent to those in cadaveric bilateral single-lung transplants. This procedure provides an alternative for patients who may otherwise not survive before a suitable organ donor is identified.

Management of Recipients

Early Postoperative Period

Ischemia and reperfusion injury in the transplanted lung result in increased vascular permeability and impaired mucociliary clearance mechanisms, prompting special considerations in postoperative management. After the operation the patient remains intubated and is transported immediately to the intensive care unit. Monitoring of the recipient includes a pulmonary artery catheter, a peripheral arterial catheter, a pulse oximeter, and an end-tidal CO_2 monitor.

Proper ventilator management is of paramount importance during this period, as barotrauma and high airway pressures that might compromise bronchial mucosal flow must be avoided. Lower tidal volumes and flow rates may be necessary to limit peak airway pressures to less than 40 cmH₂O. Pulmonary toilet with endotracheal suctioning is an effective means of reducing mucus plugging and atelectasis. After the patient is fully awake, he or she is weaned from the ventilator and is extubated when blood gases and ventilatory mechanics are satisfactory. Most patients are extubated within 3 days and weaned from supplemental oxygen by 10 days after transplantation. Early ambulation is encouraged.

A diffuse interstitial infiltrate often is found on early postoperative chest x-rays. Previously referred to as a “reimplantation response,” this finding is better defined as graft edema due to inadequate preservation, reperfusion injury, or early rejection. It appears that the degree of edema is inversely related to the quality of preservation. Judicious administration of fluids and loop diuretics is required to maintain fluid balance and minimize this edema. Early lung graft dysfunction manifested by persistent marginal gas exchange without evidence of infection or rejection occurs in less than 10 percent of transplants. Histologic analysis revealing diffuse alveolar damage suggests that this phenomenon is a result of ischemia or reperfusion injury. Technical causes of graft failure should be considered.

Immunosuppression

Immunosuppression protocols for lung and heart-lung transplant recipients are similar to those used in cardiac transplantation. Triple-drug therapy begins immediately after operation and is tapered according to standard protocols. Induction therapy with antilymphocytic antibody preparations can be used.

Postoperative Complications

Early morbidity and mortality after lung and heart-lung transplantation are most commonly caused by infection, graft failure, and heart failure. Mortality after 1 year is caused most commonly by obliterative bronchiolitis, infection, and malignancy.

The majority of acute rejection episodes in lung transplant recipients occur during the first 3 months after transplant. Biopsy-proved rejection occurs in 60 to 70 percent of patients in the first month. In the early posttransplant period, the diagnosis of acute rejection usually is based on clinical parameters. Signs of rejection include fever, dyspnea, impaired gas exchange manifested by a decrease in PaO_2 , a diminished forced expiratory volume in 1 second (FEV_1 , a measure of airway flow), and the development of an interstitial infiltrate on chest x-ray. Fiberoptic bronchoscopy with transbronchial parenchymal lung biopsy and bronchoalveolar lavage is used routinely to diagnose acute rejection or rule out infection. Acute lung rejection is characterized histologically by lymphocytic perivascular infiltrates.

In the case of heart-lung transplantation, the results of simultaneous endomyocardial and transbronchial surveillance biopsies have been compared. Pulmonary and cardiac rejection presented asynchronously in most cases. Transbronchial biopsy had a sensitivity of 89 percent in predicting cardiac rejection, and endomyocardial biopsy had a sensitivity of 34 percent in predicting lung rejection.

Episodes of acute rejection are treated with a short course of intravenous steroid boluses. After steroid therapy improvement often is rapid and dramatic and is considered confirmatory of rejection. Persistent rejection is treated with ATG or OKT3 monoclonal antibodies.

Chronic lung allograft rejection is the greatest limitation to the long-term benefits of lung and heart-lung transplantation. Chronic lung rejection most commonly presents as obliterative bronchiolitis (OB), a pulmonary corollary to cardiac graft atherosclerosis. Diagnosed in 20 to 50 percent of long-term lung transplant survivors, OB is histologically characterized by dense eosinophilic submucosal scar tissue that partially or totally obliterates the lumina of small airways (Fig. 10-34). Physiologically, OB is manifested as decreases in PaO_2 and FEV_1 . Experimental and clinical evidence points to injury of the bronchial epithelium by several mechanisms as the cause of OB, including infection, particularly by CMV, toxic fume inhalation, chronic foreign body exposure stemming from impaired mucociliary clearance, and immunologic mechanisms. A working formulation for the clinical staging of chronic lung graft dysfunction based on the ratio of the current FEV_1 to the best posttransplant FEV_1 has been proposed by Cooper and associates (Table 10-17). Often there is no correlation between the histologic and the physiologic manifestations of OB.

There is no effective treatment for OB. Augmentation of immunosuppression constitutes current therapy. Pulmonary function can be stabilized in most patients, but significant improvement occurs infrequently. Relapse rates exceed 50 percent, and progressive pulmonary failure or infection resulting from increased immunosuppression are the most common causes of death after the second year. Efforts at preventing the development of OB focus on improved immunosuppression, aggressive treatment of acute rejection episodes, and infection prophylaxis.

Infection

Bacterial, viral, and fungal infections are the leading causes of morbidity and mortality in lung and heart-lung transplant recipients. Bacterial infections, particularly those caused by gram-negative bacteria, predominate during the early postoperative period, but the risk of bacterial pneumonia persists throughout the recipient's life. Most common are pulmonary bacterial infections involving the allograft. The absence of the cough reflex in the denervated lung, abnormal mucociliary clearance mechanisms, and deficiencies in lymphatic drainage predispose grafted lungs to infection. Between 75 and 97 percent of bronchial washings obtained from donor lungs before organ retrieval will culture at least one organism. Posttransplant invasive infections frequently are caused by organisms cultured from the donor. Conversely, bacterial infections developing in patients with septic lung disease, particularly cystic fibrosis, most commonly originate from the recipient's airways and sinuses. Therapy consists of identifying the offending organism and instituting antibiotic therapy on the basis of sensitivity studies.

CMV is the most common and most clinically significant viral pathogen. Infections occur most frequently between 2 weeks and 100 days after transplantation. Primary and reactivation CMV infections in lung transplant recipients encompass a wide range of severities and variegated clinical presentations. Primary infection in previously seronegative recipients is more serious than reactivation or reinfection in seropositive patients. The diagnosis of CMV pneumonitis, usually the most severe manifestation of CMV infection, is made from a positive viral culture or cytologic evidence obtained from bronchoalveolar lavage or transbronchial biopsy, respectively. Ganciclovir is the treatment of choice. Herpes simplex pneumonia, which presents similarly to CMV pneumonitis, is treated with acyclovir.

In one series, CMV infections developed in approximately 90 percent of seronegative recipients who received lungs from seropositive donors, compared to about 10 percent who received lungs from seronegative donors. CMV infections occur in the majority of patients who are seropositive before lung transplantation. Because of organ scarcity, most transplant centers perform transplants across CMV serologic barriers. CMV prophylaxis includes ganciclovir, acyclovir, and polyvalent immune globulin. Lung and heart-lung transplant patients also are at a higher risk for developing lymphoproliferative disease, particularly in association with Epstein-Barr virus infection. Treatment consists of lowering immunosuppression and administering acyclovir. Certain lymphomas have been treated successfully with chemotherapy and radiotherapy.

Fungal infections, the most infrequent but most deadly of infectious complications in transplant patients, peak in frequency between 10 days and 2 months posttransplant. Fungal species encountered in these patients include *Candida albicans* and *Aspergillus*. Treatment consists of fluconazole, itraconazole, or amphotericin B. Prophylaxis with inhaled amphotericin B has greatly reduced early fungal infections. *Pneumocystis carinii* pneumonia has been effectively prevented in lung transplant patients since the institution of prophylaxis in the form of oral trimethoprim-sulfa or, for sulfa-allergic patients, inhalational pentamidine. The highest risk of infection with *Pneumocystis* occurs during the first transplant year; infections do occur late after transplant, however, prompting the continued use of prophylaxis indefinitely.

Improvements in surgical technique and posttransplant management have resulted in a relatively low incidence of airway complications after lung and heart-lung transplantation. The rates of lethal airway complications and late stricture have been reported at 3 percent and 10 percent, respectively. The most common airway complications are partial anastomotic dehiscence and stricture. Such complications usually are diagnosed during bronchoscopic examination. Airway dehiscence is treated by reoperation or close observation and supportive care. Strictures are treated with laser ablation or dilation with rigid bronchoscopy or balloon and bougie dilators. Most strictures are stented after dilation. Cystic fibrosis patients are at a higher risk for developing airway complications after transplantation.

Retransplantation in patients who have developed end-stage obliterative bronchiolitis has yielded poor results. In a collected series of pulmonary retransplantation performed at centers in North America and Europe, actuarial 1-year and 2-year survival rates are 41 percent and 33 percent, respectively. The most common causes of death after retransplantation were infection and OB.

Results

According to the International Heart-Lung Registry, the 6-year actuarial survival rate for single-lung and bilateral single-lung transplants performed worldwide from 1982 to 1995 is about 40 percent (Fig. 10-35). At Stanford, the 1-year, 5-year, and 10-year actuarial survival rates after adult heart- lung transplantation performed from 1981 to 1994 are 68, 43, and 23 percent, respectively (Fig. 10-36). Most recipients are able to resume an active lifestyle without supplemental oxygen. Pulmonary function measured by spirometry and arterial blood gases is improved significantly in patients after transplantation, with a normalization of ventilation and gas exchange after 1 to 2 years. The improvements in these parameters are greater in bilateral versus single-lung transplant recipients, but significant differences in exercise testing parameters have not been observed.

Pediatric Lung and Heart-Lung Transplantation

More than 350 children have undergone single-lung, double single-lung, or heart-lung transplantation worldwide since 1982. Heart-lung transplantation is indicated for children suffering from end-stage pulmonary vascular or parenchymal diseases, particularly pulmonary hypertension (primary and associated with congenital heart defects) and cystic fibrosis. Single or bilateral single-lung transplantation has become an established option with preserved right ventricular function.

The selection criteria for pediatric recipients are similar to those used in adult lung and heart-lung transplantation. Potential recipients generally have a life expectancy of less than 1 year, have normal hepatic and renal function, are free of active systemic infection, and are in a stable psychosocial environment. Blood group and lung size are the primary criteria used for donor–recipient matching. Size matching is particularly difficult in the pediatric population because of wider size disparities. The recent development of lobar transplantation has permitted the grafting of lung lobes from living-related or cadaveric adult donors into children. Early experience with lobar transplantation has been encouraging. The operative techniques for lung and heart-lung transplantation in children are essentially the same as those used in adult thoracic transplantation. Triple- drug therapy is the mainstay of postoperative immunosuppression. Some also use OKT3 induction therapy.

The incidence of acute rejection in pediatric lung and heart-lung patients does not differ significantly from that seen in adults. Surveillance for rejection in children and adolescents consists of serial transbronchial biopsies with lavage and pulmonary function studies. Routine invasive bronchoscopy is not performed in neonates for technical reasons, shifting emphasis to clinical and radiographic signs in diagnosing pulmonary rejection. The diagnosis of acute pulmonary rejection in the pediatric population is based on a combination of clinical signs, laboratory tests, and histologic analysis. Pyrexia, fatigue, dyspnea or oxygen desaturation, an interstitial or perihilar infiltrate on chest radiography, and a decreasing FEV₁ are suggestive of rejection.

Long-term survival in pediatric lung and heart-lung recipients is limited by infection, obliterative bronchiolitis, and accelerated graft coronary artery disease. For pediatric lung and heart-lung transplants performed at Stanford from 1986 to 1993, actuarial 3-month, 12-month, and 24-month survival rates of 78, 55, and 41 percent, respectively, have been observed. Somatic growth in the pediatric transplant population generally is improved after transplantation despite the harmful effects of steroids and cyclosporine on bone metabolism. This is most likely because of the marked improvement in cardiopulmonary status after transplantation. Corresponding growth of the transplanted organs also occurs.

KIDNEY

Anthony M. D'Alessandro and Mark H. Deierhoi

Preoperative Management

Renal transplants are the most common solid organ allografts performed, and transplantation has become the preferred treatment of chronic renal failure for many patients. Graft and patient survival have steadily improved, and relative and absolute contraindications to transplantation have consequently receded.

Transplant Recipient Evaluation

Not all patients with end-stage renal disease are transplant candidates. A thorough evaluation is essential for all potential candidates in order to assess their general health, to identify any comorbid conditions that might increase operative risk and the risk in long-term immunosuppression, and to determine the benefits that might be derived from transplantation. Evaluation also provides an opportunity to educate the potential candidate about the risks of immunosuppression and the importance of compliance with medication regimens.

Patients should be referred for transplant evaluation as they are approaching end stage but before dialysis therapy is initiated. The timing is not critical, because long-term dialysis usually is well tolerated and transplantation is not an immediately life-saving procedure. If the patient presents at end stage with the need for immediate dialysis, it is better to delay evaluation to avoid an overwhelming flood of information and subsequent anxiety.

The pretransplant evaluation can be performed in an outpatient setting with occasional admission for specific diagnostic procedures such as cardiac catheterization. Evaluation should include a careful and complete history and physical examination, with attention directed to the history of renal disease, prior surgery, and comorbid conditions, such as heart disease, peripheral vascular disease, and diabetes. Any history of cancer or recent infection should be documented. Laboratory studies should include standard chemistries, complete blood counts, urinalysis, serologic studies for hepatitis B and C, cytomegalovirus, and HIV. A chest x-ray and electrocardiogram also are included for adult candidates.

Evidence of risk factors for surgery should prompt more thorough investigations. Specific tests for associated conditions may include noninvasive cardiac studies such as an echocardiogram or a stress test, evaluation for peripheral vascular disease with noninvasive vascular studies, and pulmonary function tests for patients with a significant history of chronic pulmonary disease. Cardiac catheterization may be required for assessment of coronary disease. Urine cultures should be obtained and a urologic evaluation performed if there is evidence of urologic anatomic abnormalities or prior urologic surgeries, such as ureteral reimplantation or creation of an ileal conduit in a patient with a neurogenic bladder.

Evaluation for long-term risks posttransplant focuses on conditions that could be exacerbated by immunosuppression, such as malignancy and infections. A metastatic work-up is appropriate for a patient with a remote history of malignancy, and any sign of recent malignancy should prompt aggressive evaluation with studies such as endoscopy or even biopsy. The chief infectious risks are tuberculosis, chronic fungal infections, and viral infections such as hepatitis and HIV. Other conditions requiring in-depth evaluation include peptic ulcer disease, cholelithiasis, and diverticulosis.

The majority of patients require immunosuppressive medication for the life of their allograft. Some attempt should be made to assess the patient's risk for noncompliance. This should include evaluation by social workers and psychiatrists and a record of any history of substance abuse. If the potential for substance abuse is unclear, a drug screen is indicated. Compliance on dialysis also should be documented.

Patients should understand the long-term commitment to follow-up and immunosuppressive therapy. Patients should be given comprehensive information regarding the risks and benefits of transplantation and should be educated regarding immunosuppressive medications and their side effects.

In certain situations, surgery may be required in preparation for transplantation. Cholecystectomy should be performed on any patient with symptomatic gall bladder disease and in any diabetic with documented gallstones. Some patients are evaluated for diverticulosis and have elective colon section. Bilateral nephrectomy may be required in specific situations, including recurrent urinary tract infections with reflux, uncontrollable hypertension, and polycystic kidney disease with recurrent bleeding and infections. There is an occasional patient with polycystic disease whose kidneys are so massive that they fill the abdomen and must be removed to allow room for the transplant. Occasionally, patients with urinary tract abnormalities require bladder augmentation or creation of an ileal conduit.

Indications and Contraindications

There are a number of absolute and relative contraindications to transplantation (Table [10-18](#)). Absolute contraindications include recently treated cancer other than squamous and basal cell carcinoma of the skin, HIV infection, hepatitis with evidence of cirrhosis or of chronic hepatitis on biopsy, and severe ischemic cardiac disease not amenable to bypass surgery or angioplasty. Patients with severe peripheral vascular disease requiring bypass surgery usually are not candidates. Relative contraindications include obesity, history of noncompliance with other medical therapy, a history of tuberculosis, and several renal diseases, including oxalosis and sickle cell disease, which have a high incidence of recurrence.

Management on Dialysis

Pretransplant management also may include the provision of access for dialysis therapy. Dialysis techniques include hemodialysis through some sort of vascular conduit and peritoneal dialysis. The choice of technique depends to a large extent on patient preference and the patient's ability to follow medical regimens. Peritoneal dialysis and home hemodialysis require significant patient involvement in care but are more compatible with an active lifestyle. Both forms are compatible with transplantation. The choice of dialysis access usually is not based on the patient's eligibility for transplant.

Hemodialysis access may be gained through various intravenous catheters, the creation of native arteriovenous fistulas, or the placement of a prosthetic conduit, such as polytetrafluoroethylene (PTFE) grafts, to create an arteriovenous fistula. A long-term plan should be worked out with the patient before the institution of hemodialysis therapy. This is important if grafts are required, because the grafts have a limited life span. When a patient is identified with renal failure, it is imperative that he or she be instructed regarding the preservation of extremity vasculature, which may be needed for future access surgery. The most critical vessels are the cephalic vein in the forearm and upper arm and the veins of the antecubital space.

A number of catheters are available for temporary or long-term access. These are placed in a large central venous site, preferably the internal jugular vein, followed by subclavian, femoral, and inferior caval placement. Temporary catheters may be required if the patient presents with end-stage disease and the urgent need for dialysis. They also may be required if a long-term conduit, such as a fistula or graft, fails. In this situation, catheters can be used for dialysis while a new long-term access site matures. Repeated cannulation or long-term placement of a catheter in the subclavian vein frequently leads to stenosis, which can preclude the use of that extremity for long-term dialysis. All attempts should be made to place temporary catheters in the internal jugular veins. In the potential transplant recipient who is nearing end stage and has an identifiable living donor, a catheter might be suitable for short-term use until transplantation. Long-term use of catheters may be necessary in patients with severe peripheral vascular disease and calcification. In some instances, success with dialysis via catheters has been maintained for periods exceeding 12 months.

The usual choices for long-term dialysis include an arteriovenous fistula and PTFE graft placement. If a fistula site and a suitable vein are available, fistula creation is the overwhelming choice for longevity and suitability for dialysis. The classic Brescia-Cimino fistula is created by anastomosing the cephalic vein and the radial artery at the wrist side-to-side or end-to-side. If a large cephalic vein is present in the upper arm, a brachiocephalic fistula created in the antecubital space also is appropriate. Some surgeons use transposed basilic vein as a fistula conduit. This fistula is created by dissecting the basilic vein in the upper arm and positioning it in a subcutaneous tunnel with anastomosis end-to-side to the brachial artery just proximal to the antecubital space.

PTFE grafts are now the standard conduit used in patients who do not have suitable anatomy for a fistula. These may be placed in upper and lower extremities. The initial site usually is the forearm of the nondominant arm; a graft can be fashioned from the radial artery at the wrist to an antecubital vein, or in a loop fashion from the brachial artery to the antecubital space. Subsequent grafts are placed in the upper arm in a straight or looped configuration with subsequent progression to the use of the femoral vessels if all upper extremity sites have been used.

Short-term complications include infection and distal limb ischemia from preferential flow in the conduit. This occurs most often with fistulas or large-diameter grafts placed in the upper arm. Infection generally requires graft removal, and distal limb ischemia is treated by revising the graft to provide a smaller inflow diameter. Venous hypertension may occur as a result of placement of a graft distal to subclavian venous stenosis. Relief often can be obtained with angioplasty and stenting of the vein. Severe untreatable venous hypertension necessitates ligation of the graft.

Long-term patency is significantly greater for fistulas than for grafts. The mean survival of fistulas is 10 years, whereas for PTFE grafts it is 18 to 24 months. Fistulas fail secondary to proximal stenosis or pseudoaneurysm formation from repeated cannulation in the same sites. The most common cause of failure of the PTFE graft is intimal hyperplasia of the venous anastomosis. Development of pseudoaneurysms from repeated cannulation, venous stenosis proximal to the anastomosis, and infection all can lead to graft thrombosis and loss. Intimal hyperplasia is best treated by following patients with pressure measurements on dialysis, identifying stenoses with Doppler ultrasonography, and revising the anastomoses with patch angioplasties or jump grafts. Interventional radiology has had some success in dilating stenoses with occasional stent placement. Interventional techniques have been developed for clot lysis and angiography, even when a graft has thrombosed.

Peritoneal dialysis is another important option for renal failure therapy. A catheter is placed intraperitoneally and a dialysis fluid of variable composition is instilled. This technique uses the filtering capabilities of the peritoneal lining and osmotic gradients to draw the by-products of uremia into the peritoneal fluid. Patients must perform six to eight exchanges per day to maintain homeostasis. Peritoneal dialysis has the advantage of freeing the patient from scheduled time on a dialysis machine. In addition, it is continuous and easily portable therapy. Catheters are placed in an outpatient setting and require 2 to 3 weeks to mature before the institution of therapy. Complications of peritoneal dialysis include tract infections and peritonitis. This can be a devastating problem, particularly if the infection is fungal. These infections tend to cause exudative peritonitis with formation of multiple adhesions. Patients undergoing peritoneal dialysis require significant involvement in their own care and an understanding of sterile technique.

Histocompatibility Testing

The work-up of a potential transplant recipient begins with blood group typing and HLA typing. Blood group typing is essential because renal endothelial cells express major blood group antigens and the preformed natural antibodies to these antigens can result in hyperacute rejection. In cadaveric transplantation, absolute blood type matching is required, but type O donors are universal donors. For living donor transplants, there is an exception in that the ABO subtype A2 appears less antigenic. With plasmapheresis and preoperative preparation of the patients, an A2 donor kidney can be transplanted into a non-A2 recipient.

HLA typing is performed routinely on all cadaveric and living donor recipients. The standard typing procedure is a lymphocytotoxic serologic test in which the potential recipient's cells are tested against a battery of sera, most obtained from multiparous women or as monoclonal antibody preparations. These sera have been selected because of reactivity against specific HLA antigens. All cadaveric and potential living donors are HLA typed as well. Standard tests include typing for the class I antigens HLA-A, B, and C, and the class II antigens HLA-DR, DP, and DQ. In many centers, typing for the class II antigens is being performed with molecular techniques. With polymerase chain reaction technology and multiple probes for the DNA genetic sequences of specific antigens, more accurate typing can be obtained.

HLA typing can be of significant importance in living donor transplantation by allowing identification of the best match from multiple potential donors. Because all of the HLA antigens are found together on the major histocompatibility complex on chromosome 6, it is not necessary to type for every antigen in a living-related donor situation; typing for HLA-A, B, and DR is sufficient. Typing from multiple family members identifies the segregation of antigens and allows the selection of the best donor. Because the antigens segregate together, this set of antigens known to be on the same chromosome is identified as a haplotype. HLA matching for living donors is defined by haplotypes. A living-related transplant between siblings could have zero-, one-, or two-haplotype match. Transplants between parents and children will always be a one-haplotype match, but one-haplotype matches also can exist between more distant relatives.

For cadaver donor allocation, matching also has an important role. It is possible to type for at least six antigens, but in practical terms, typing for organ allocation involves HLA-A, B, and DR. Typing for the other antigens increases the complexity of finding a good match without significant benefit in terms of graft survival.

In living donor transplantation, an HLA match is correlated with short-term and long-term graft survival. Recipients of two-haplotype-matched living donor kidneys have near 100 percent graft survival with an extremely low rate of acute rejection. A two-haplotype match transplant should be used whenever possible, but excellent results have been achieved with completely mismatched living-related donors. If a healthy donor is available that is blood-group-compatible, the patient should be considered even with a poor match. In cadaveric transplantation, matching is used to facilitate organ allocation. There is a correlation between the degree of HLA matching and the assurance of long-term graft survival, particularly when no mismatches for HLA are found between the donor and the recipient. In the United States there is a national system for organ retrieval and allocation with mandatory sharing of six-antigen matches on a national basis. Improvement in graft survival can be seen with progressively better HLA matching in cadaveric transplantation, but with improvements in immunosuppression, the survival differences have been decreasing each year. The 1-year survival advantage for six-antigen matches over completely mismatched cadaveric transplants is about 5 percent.

Serum screening is another important histocompatibility test in renal transplantation. As a result of sensitizing events, such as blood transfusions, pregnancies, and previously failed transplants, patients may produce anti-HLA antibodies. The risk of sensitization varies with the nature of the sensitizing event. Multiparous women who have lost a transplant are at highest risk for sensitization. The consequences of sensitization are the production of antibodies against specific HLA antigens. Serum screening is performed by testing a patient's serum against a panel of lymphocytes selected to represent the known HLA antigens. Activity is defined on the basis of the percentage of cells in the panel against which detectable antibodies can be found. Sensitization is designated by the patient's panel reactive antibodies (PRA) level, which is a reflection of the percentage of cells on the panel against which the sera react. Serum screening is an important factor in predicting the likelihood of finding a suitable donor for a given recipient. A patient whose PRA level is more than 90 percent will likely have reactivity against 90 percent of potential donors. This significantly lessens the likelihood of finding a suitable donor and prolongs the patient's time on the waiting list. This is important information for counseling cadaveric transplant recipients about the likelihood of their receiving a transplant. A greater knowledge of sensitization can lessen the likelihood of patients being admitted for transplants unnecessarily.

The most important histocompatibility test in renal transplantation is the final crossmatch. This is very similar to the crossmatch test performed for blood transfusions. Cells from a potential donor and serum from a recipient are incubated together. Antibody binding is then detected using a cytotoxic technique or another procedure, such as flow cytometry or the antihemophilic globulin (AHG) test. Both of these tests depend on binding of a second antibody to anti-HLA antibodies that have already bound to the target cell.

Crossmatching is performed just before proceeding with transplantation. The use of sensitive crossmatch techniques has essentially eliminated hyperacute rejection as a problem in

renal transplantation. There are several confounding factors that must be recognized. Autoantibodies directed against lymphocytes can affect interpretation. These generally are not relevant but will generate a positive crossmatch. T and B cells are tested separately to identify class I and class II antigens, because class II antigens are found only on B cells. Positive T-cell crossmatches are responsible for the classic anti-HLA class I antibodies that are correlated with hyperacute rejection. The importance of anti-B cell antibodies is unclear, but there are isolated reports of hyperacute rejection when specific anti-class II antibodies, such as an anti-DR antibody, are identified. A positive T-cell crossmatch is considered an absolute contraindication to transplantation, and in some settings a positive anti-B-cell crossmatch may be as well. Along with blood typing, the final crossmatch constitutes the most important histocompatibility test and is mandatory before all renal transplants.

Renal Donor

Evaluation of the Living Donor

According to recent statistics from the United Network of Organ Sharing (UNOS), there are over 30,000 patients awaiting renal transplants in the United States. The cadaveric donor pool has remained static over the past 5 years, with only 4,000 to 5,000 donors realized each year. Because of the shortage of cadaveric donors, live donors, related and unrelated, have a larger role in many renal transplant programs. Although live donors account for approximately 25 percent of kidneys transplanted in the United States, in some programs the figure is as high as 50 percent.

Because of the widening gap between the cadaveric renal supply and potential recipients, definitions for who can be a live donor have expanded. Initially, only HLA-identical or one-haplotype matches were considered for live donation, and more distantly related or unrelated transplants were discouraged. Recent results with zero-haplotype-matched siblings and unrelated donors are similar to six-antigen-matched cadaver donors and approach results of one-haplotype-matched donors. What is important in live donation is not only matching but also the excellent condition of live- donor kidneys. Live-donor kidneys result in less warm ischemia and allow for longer preservation times compared to cadaveric kidneys. Living-related donors can be grandparents, aunts, uncles, siblings, and cousins. Unrelated donors may be adopted siblings, friends, spouses, or anyone with a strong emotional relationship to the recipient. The importance of this emotional relationship cannot be overstated, because this discourages financial incentives to donate kidneys. Countries that permit and even encourage financial incentives for emotionally unrelated transplants have significantly inferior results.

When patients with end-stage renal disease present for evaluation, it is important to discuss in detail the advantages and disadvantages of living- related, living-unrelated, and cadaveric renal transplantation. The advantages of live donation are excellent immediate graft function and avoidance of posttransplant dialysis, better short-term and long-term results, preemptive transplantation (i.e., avoidance of dialytic support), avoidance of waiting time for a cadaveric kidney, and in the case of HLA- identical transplants, a reduction in immunosuppressive therapy. The risks to the donor are relatively low, but there is a 1/10,000 risk of death and a 10 percent or less risk of morbidity. No definitive long-term morbidity has been demonstrated for live donors, but minor concerns have been raised about the development of mild hypertension, proteinuria, and potential trauma to the remaining kidney.

During the initial evaluation, a careful family history will eliminate obviously inappropriate donors. The presence of diabetes, hypertension, malignancy, significant cardiopulmonary disease, a history of renal disease, and age over 65 years are the primary reasons not to proceed with live donation. Potential donors can be excluded during the work-up phase of live donation as a result of proteinuria > 250 mg/24 h, a creatinine clearance of less than 80 mL/min, and significant urologic abnormalities.

The donor and the recipient should not feel pressured to donate or accept a kidney. A well-conducted evaluation of the potential donor and recipient and an in-depth explanation of live donation will help to alleviate fears.

If more than one potential donor is available, the initial determination usually is made by selecting the best match (i.e., two-haplotype is preferred to one-haplotype, which is preferred to zero-haplotype). Related donors are chosen over unrelated donors, and older donors chosen over younger donors, when the haplotype match is the same.

Once a potential donor has been initially screened and evaluated, surgical evaluation is necessary. Intravenous pyelogram and arteriograms formerly were a necessary part of the surgical evaluation, but newer CT technology can produce images of the collecting system, ureters, and bladder and enumerate the renal arteries and veins in a noninvasive manner. If minor urologic abnormalities are detected in one kidney, this would be the kidney chosen for donation. Multiple renal arteries (usually fewer than three) are not a contraindication to donation, because ex vivo techniques are available to manage multiple renal arteries. The kidney with the fewest number of renal arteries usually is chosen but the left kidney is preferable because the renal vein is longer, making the kidney easier to transplant. Table [10-19](#) summarizes the evaluation of the living donor.

Evaluation of the Cadaver Donor

There has been a significant increase in the number of live renal donations, but cadaveric donations account for approximately 75 percent of all kidneys transplanted. Cadaveric donation, however, has not kept pace with the number of recipients added to the waiting list. Identification of potential cadaveric donors by health care professionals, a sensitive approach to requesting donation by trained procurement professionals, and education are paramount to maintaining and increasing organ donation levels. Any patient who has been declared brain dead or is to be withdrawn from support, usually for a severe neurologic injury, should be considered a potential donor. Inappropriate donors may then be ruled out by the Organ Procurement Organization (OPO) on the basis of known absolute and relative contraindications (Table [10-20](#)).

Because of the extreme shortage of organs, many centers have used kidneys from every category of listed relative contraindications. Before the waiting list grew so long, only ideal donors were used. Ideal donors are young, normotensive, brain dead, free of any disease, with minimal warm ischemic time. However, increasing experience is being obtained with marginal donors. Marginal donors usually are older and may have other diseases not affecting the kidneys, including low-grade brain tumors. They also may have mild renal dysfunction or acute tubular necrosis and may have longer periods of warm ischemia as a result of cardiac arrest or prolonged hypotension. There has been renewed interest in non-heart- beating donors (NHBDs), donors whose organs are removed after cardiopulmonary arrest. Brain death cannot be declared in these patients, usually because of the presence of brain stem reflexes. Before the establishment of brain death criteria in the late 1970s, this was the sole method of organ retrieval. Because NHBDs must have cardiopulmonary cessation prior to organ retrieval, there is a longer warm ischemic period. Some centers have reported similar organ function (kidney, pancreas, and liver) from NHBDs to that of organs retrieved from heart-beating donors (HBDs). It is estimated that an increase in transplanted organs of nearly 20 percent could be expected with widespread use of NHBDs.

Donor Nephrectomy

The donor operation is carried out through a flank incision and retroperitoneal approach. The ureter is dissected as far distally as possible and up to the level of the renal vein. The renal vein, and then the renal artery, are dissected. The importance of renal angiography or spiral CT cannot be overstated in identifying multiple renal arteries and veins. Care is taken not to manipulate the kidney and renal artery excessively in order to prevent vasospasm and resultant acute tubular necrosis. Before removal of the kidney, mannitol and furosemide usually are given, and in selected cases (e.g., multiple renal arteries and a difficult dissection) systemic heparin is used, with subsequent protamine reversal. The renal artery and vein are clamped and the kidney is removed and flushed with a cold solution; any necessary ex vivo work (such as renal artery reconstruction) is completed, and the kidney is transplanted.

The most common complications after live donation include urinary tract infections, wound infections, and pneumothorax. More serious complications are rare. Long-term follow-up of live donors has not demonstrated any adverse health effects.

In the case of cadaveric donation, with the exception of older donors, whose liver and pancreas may not be used for transplantation, retrieval of kidneys usually is part of a multiorgan procurement that includes the heart, lung, liver, pancreas, and, most recently, the intestine. Fig. [10-37](#) illustrates intraabdominal multiorgan procurement of the liver, pancreas, and kidneys.

During a multiorgan procurement, the kidneys are dissected minimally to avoid arterial vasospasm. Donors usually are given 10 to 20 mg of the alpha-adrenergic blocker phentolamine to prevent renal and hepatic vasospasm, and 10,000 to 20,000 units of heparin. Many donors are given mannitol or furosemide to assure adequate diuresis before the kidneys are removed. The usual sequence of organ removal after dissection of intrathoracic and intraabdominal organs is the heart and lungs, then the liver and pancreas, and en bloc removal of the kidneys.

During in vivo flushout, and while waiting to remove the intraabdominal organs, topical sterile ice is used to cool organs more rapidly, thereby helping to minimize warm ischemic times.

Retrieval of kidneys without retrieval of other intraabdominal organs can be performed in a manner similar to multiorgan procurements, with the placement of an aortic, and occasionally a vena cava, cannula for removal of venous effluent. Alternatively, kidneys can be removed individually or en bloc without cannula placement or in vivo flushout after systemic heparinization. Ex vivo flushout is performed after the kidneys have been removed.

With brain-dead donors there is adequate time for complete dissection of the intrathoracic and intraabdominal organs. However, in donors who have had cardiac arrest just before organ retrieval, or in non-heart-beating donors, adequate time is not available for organ dissections. In these situations rapid en bloc techniques of retrieval have been developed that minimize warm ischemia and operative time while maintaining the viability of transplantable organs (Fig. [10-38](#)). All intraabdominal organs are removed en bloc after division of proximal aorta and vena cava; this is followed by retroperitoneal dissection and then division of the sigmoid colon, distal ureters, and distal aorta and vena cava. This technique is rapid, but it does require extensive ex vivo dissection for separation of the individual organs. This can be safely done because the organs have been flushed with preservation solution and have been cooled to 4°C.

Organ Preservation

The success of organ transplantation is the result of a number of factors, including the ability to preserve organs from the time of removal from the donor until transplantation into the recipient. The goal of hypothermic organ preservation is to maintain organ viability long enough that organ transport, tissue typing, and recipient preparation can be performed. The length of preservation also must be brief enough that no organ is ever discarded as a result of having exceeded the safe period of preservation.

Although the mechanisms of injury during organ preservation involve multiple factors that are complex and not fully understood, several have been shown to be important. Hypothermia is the cornerstone of organ preservation, but during hypothermia metabolic functions, such as the sodium-potassium pump, are slowed. This allows hypothermia-induced cell swelling to occur, which is injurious to preserved cells. Preservation solutions were designed to prevent this swelling and have improved the quality of preservation. Of other important factors, four have received the most attention as probable causes of injury. One is the loss of energy- generating capabilities resulting from mitochondrial damage because of a loss of precursors for adenosine triphosphate (ATP) regeneration. If the organ cannot rapidly restore a near-normal energy balance, irreversible injury with cell and tissue death results. The role of oxygen free radicals in reperfusion injury to cold-stored organs also has gained much attention. Some studies have shown that these cytotoxic agents might be involved in preservation injury, but suppression of oxygen free radical generation with various pharmacologic agents has met with limited success.

Another mechanism of preservation injury might be the activation of catabolic enzymes, such as those in lysosomes, phospholipases, and proteases. The activation of the arachidonic acid cascade and production of cytotoxic products, such as thromboxane and leukotrienes, may have a role in reperfusion injury of preserved and transplanted organs.

There are two basic methods of kidney preservation: cold storage and machine perfusion, developed in the mid-1960s by Collins and Belzer, respectively. Until 1987 the majority of renal transplant centers cold-stored kidneys with Collins' solution while a smaller number of centers machine- perfused kidneys with Belzer's machine perfusate. In 1987 Belzer developed the University of Wisconsin (UW) solution primarily to extend the preservation times of extrarenal organs such as the liver and pancreas. UW solution has essentially replaced Collins' solution for cold storage preservation of kidneys, because 85 percent of organ retrievals are multiorgan, and the UW solution also is effective in renal preservation (Table 10-21).

Citing simplicity and reduced expense, the majority of kidney transplant centers still cold-store kidneys. Machine perfusion results in a reduced incidence of delayed graft function and reduced expense for posttransplant dialytic support. The need for dialytic support after transplantation of cold- stored kidneys is 25 to 30 percent, but only 5 to 10 percent with machine- perfused kidneys, even with longer preservation times. Evidence also indicates that good immediate function is as important as matching in predicting improved long-term results. With the increasing use of kidneys from non-heart-beating donors, which have longer warm ischemic times, machine perfusion has been shown to result in dialysis requirements equal to those for cold-stored kidneys from heart-beating donors.

Surgical Procedures

Preoperative Preparation

Patients with long-standing diabetes, those with a history of cardiac disease, and those over 50 years of age should undergo cardiac stress testing or cardiac catheterization. Thallium, adenosine, and dobutamine stress tests may be used as screening tools before proceeding with cardiac catheterization. In patients with long-standing diabetes, there is evidence that cardiac catheterization should be the primary modality used to eliminate false-negative stress tests. Patients with a history of peripheral or cerebrovascular disease should have carotid Doppler ultrasonography, and pulse-volume recordings (PVRs) of their lower extremities, and a vascular surgery consultation.

Patients with poorly controlled hypertension or with chronic pyelonephritis and hydronephrosis, most likely will require a bilateral native nephrectomy before transplantation. Patients with polycystic kidney disease may require bilateral native nephrectomy if pain, hematuria, and urinary tract infections accompany their disease.

Nephrectomy poses a special problem for patients who are not yet on dialysis and who do not have a live-donor kidney that can be transplanted 10 to 14 days after nephrectomy. These patients are relegated to dialysis and must wait an average of 18 to 24 months for a cadaveric kidney.

In patients with a urologic history, a cystoscopy, cystometrogram, or voiding-cystourethrograms (VCUG) may be required to assess the bladder and upper urinary tract before transplantation. Myelomeningocele patients with an ileal loop or other urinary reservoir should undergo a loop contrast study because the transplanted ureter will be implanted into the urinary reservoir.

A history for gastrointestinal disease should be elucidated, and patients with symptoms of active peptic ulcer disease should undergo upper endoscopy. Patients with a history of pancreatitis will need a pancreatic ultrasound or CT scan and a work-up for hyperparathyroidism. Patients with symptomatic cholelithiasis should undergo laparoscopic cholecystectomy before transplantation. Some renal transplant centers also recommend cholecystectomy in asymptomatic diabetic patients with cholelithiasis because posttransplant cholecystitis is difficult to diagnose and may be associated with a higher complication rate.

Potential transplant candidates with a history of diverticulitis, especially patients with polycystic kidney disease, who have a higher incidence of diverticulosis and diverticulitis, may require a pretransplant sigmoid colectomy. Patients with a previous history of colonic polyps should have yearly colonoscopy while awaiting transplantation. Patients with active hepatitis or chronic liver disease and cirrhosis are not renal transplant candidates, but patients with hepatitis B who are Hb eAg-negative and those with chronic persistent hepatitis C may be considered.

Waiting times for cadaveric kidneys can be long, so it is important to work with local nephrologists in maintaining patient health before transplantation. A patient's transplant may need to be canceled because of the presence of active sepsis. Sepsis can occur as a result of infected dialysis grafts or catheters, urinary tract infections, dental caries, sinus infections, and pneumonias. Because of the powerful effects of immunosuppression, it is unwise to proceed with transplantation when there is active sepsis or infection.

Anesthesia

Intraoperative management of the anephric patient depends on the cause of renal failure and the presence or absence of cardiac disease. Older patients and patients with significant hypertension, diabetes, or previous coronary bypass procedures or angioplasty will require additional monitoring. This usually is accomplished with the placement of a Swan- Ganz catheter and an arterial line. Significant hypertension should be avoided, and care must be taken to prevent lower blood pressures and underperfusion of the transplanted kidney. Renally excreted anesthetics or muscle relaxants, such as gallium triethiodide, are rarely used and should be avoided. The muscle relaxant succinylcholine may be used if the patient is normokalemic. If the patient is hyperkalemic, succinylcholine should be avoided, because hyperkalemia can be exacerbated and result in cardiac arrest. The muscle relaxant atracurium is preferred. Most inhalational anesthetics are suitable for use in the anephric patient.

Intraoperative fluids should be administered under the assumption of delayed graft function even if dialysis rarely is required. This approach prevents fluid overload and the need for urgent postoperative dialysis. Renal-dose dopamine (3 to 5 mg/kg/min) may be used to enhance renal transplant perfusion. Patients usually are given methylprednisolone, mannitol, and furosemide before removal of vascular clamps and reperfusion of the kidney. If blood is needed intraoperatively, leukopoor cells should be administered to prevent sensitization of the recipient.

Surgical Technique

Usually a right curvilinear incision is made, extending from the pubic tubercle to a point just medial to the iliac crest, to the tip of the eleventh rib. The right side is preferable because the right iliac artery and vein take a slightly more superficial course than the left. The right side affords another technique of minimal dissection of the distal vena cava and common iliac artery. This technique is more rapid than dissection of the external, internal, and common iliac arteries and veins. Once the retroperitoneum is entered, the lymphatics overlying the iliac artery are ligated in an attempt to prevent postoperative lymphocele formation. Most centers transplant either kidney on the right side, but some prefer to transplant a left kidney on the right side and a right kidney on the left side, allowing the renal pelvis to be anterior in the event that a ureteral repair become necessary in the future. Others prefer to transplant a right kidney on the right side and a left kidney on the left. In the event of a second transplant, the opposite side is used. If three or more transplants are necessary, a transabdominal approach is used. In small children who receive an adult kidney, the transabdominal approach is used. The standard renal transplant is depicted in Fig. 10-39.

The donor renal artery may be anastomosed end-to-side to the common or external iliac artery or end-to-end to the hypogastric artery with 5-0 or 6-0 polypropylene sutures. Occasionally in children the donor renal artery is sewn to the distal aorta. When the kidney is from a cadaveric donor, a patch of aorta (Carrel patch) with the donor renal artery attached is sewn to the iliac artery. Multiple renal arteries are handled with a variety of ex vivo techniques, including placing all the arteries on a single Carrel patch, attaching the arteries side-to-side or end-to-side, using donor iliac artery grafts, and implanting each artery on the recipient iliac artery separately.

The renal vein is sutured with 5-0 or 6-0 polypropylene sutures to the common or external iliac vein or the distal vena cava. The presence of multiple renal veins is managed differently than with arteries. Small renal veins can be ligated because of intrarenal venous connections, but if two renal veins of equivalent size are present, some prefer to suture them together to prevent venous hypertension.

The ureteral anastomosis is performed most commonly on the recipient's bladder. A few centers routinely perform native-to-donor ureteroureterostomy or native-to-donor ureteropyelostomy. The ureter also may be anastomosed to an existing ileal or colonic loop. Two antireflux techniques commonly are used for the ureteral anastomosis. The Liche extravescical technique is preferred over the Leadbetter-Politano intravesical technique, because of simplicity. In the Liche technique, a submucosal antireflux tunnel is fashioned from the outside, whereas in the Leadbetter- Politano technique it is from an intravesical approach. Usually 4-0 or 5-0 absorbable sutures, such as chromic catgut or polydioxanone, are used in two layers (mucosa and muscle) with both techniques. A 6-mm by 17-cm double J stent may be used and can be sutured to the tip of the Foley catheter. The Foley catheter usually is removed after 1 to 3 days with the Liche technique and 5 to 7 days after a Leadbetter-Politano neoureterocystostomy.

Postoperative Care

Immediate Care

The early postoperative management of the renal transplant recipient does not differ significantly from the management of nontransplant surgical patients. Vital signs are monitored frequently along with hourly urinary output. Central venous pressure is monitored via a central line usually placed at the time of transplantation. Because of the obligatory diuresis that occurs with a well-functioning renal transplant, urine output usually is replaced with half-normal saline solution with 5% dextrose without potassium. A good rule of thumb is to replace urine output plus 30 mL/h (insensible losses) not exceeding 200 mL/h. Placing a limit on replacement of urinary losses helps to prevent excessive fluid administration. Once the early obligatory diuresis is over, fluid management is similar to that in other surgical patients. Because early delayed graft function occurs in approximately 25 percent of cadaveric transplants, fluid replacement linked to urinary output will help to prevent fluid overload and the need for urgent hemodialysis.

Most renal transplant patients can be cared for adequately on the ward, but older patients, those with a cardiac history, or those with Swan-Ganz catheters or arterial lines placed intraoperatively need a short stay in an intensive care or a step-down unit. Diabetic patients need to have blood glucose level monitored closely, and insulin may be given via a sliding scale or an insulin drip. Patients also need to have their blood pressure monitored closely, because moderate hypertension is common in the postoperative period. This results from preexisting hypertension from long-standing renal disease, postoperative pain, fluid administration, and medications that are known to cause hypertension, such as prednisone, cyclosporine, and tacrolimus (FK506). Hypertension can be treated with sublingual nifedipine, intravenous labetalol, esmolol, enalapril, or, in severe cases, nitroprusside.

Most cadaveric and nearly all related and unrelated renal transplants will function immediately, but delayed graft function can result in anuria or oliguria. The presence of anuria or oliguria in a live donor kidney should alert the surgeon to a serious problem, because these kidneys are expected to function immediately. If the patient is a first-time renal transplant recipient without high levels of circulating antibodies, emergent exploration might be indicated. Assessment of anuria or oliguria must also be evaluated with knowledge of the patient's pretransplant urine output. A normal urine output may be inadequate after transplantation if the patient produced a significant amount of urine before transplantation. The first step in assessing low urinary output is to be sure that the Foley catheter is not obstructed with blood clots. The catheter can be irrigated free of clots, or a larger catheter or one with irrigating capacity may be placed. The volume status of the patient is assessed by measuring the central venous pressure (CVP) or the pulmonary capillary wedge pressure. If the CVP is less than 12 mmHg, a 500-mL fluid bolus of isotonic saline solution should be given and repeated as necessary until the CVP rises. If this fails to increase urinary output or if the initial CVP is less than 12 mmHg, an intravenous dose of furosemide (up to 200 mg) is administered. If urine output increases, then replacement is resumed.

If urine output does not increase, especially in a kidney that was expected to function well, then a Doppler ultrasound scan to assess blood flow is indicated. If blood flow is adequate, then obstruction or a urine leak, usually at the ureterovesical junction, should be assessed with ultrasonography or nuclear scintigraphy.

If the evaluation is unremarkable, then the diagnosis is delayed graft function, which may need to be managed with hemodialysis, particularly in the presence of hyperkalemia and volume overload. Peritoneal dialysis may be used, but this usually is avoided in the immediate postoperative period because of the possibility of infection and peritoneal leakage around the newly transplanted kidney.

Technical Complications

Refinements in surgical technique and in pre- and postoperative management have significantly decreased technical complications. Early technical complications include graft thrombosis, urine leaks, bleeding, and wound infections; late complications include lymphoceles, ureteral strictures, and renal artery stenosis.

Graft thrombosis is from an arterial or venous thrombosis and in the early postoperative period is technical in origin. Unless diagnosed and operated on rapidly, there is little hope of salvaging the kidney. Diagnosis is made by abrupt cessation of urine output (which may be difficult to diagnose in a patient with good pretransplant urine output), and by Doppler ultrasonography. Graft thrombosis occurring more than 2 weeks after surgery usually is the result of severe acute rejection.

Early postoperative bleeding is unusual but may occur as a result of small vessels that were in spasm at the time of surgery. Uremic patients also have dysfunctional platelets that may contribute to bleeding. Patients should be well dialyzed before transplantation. At the time of operation, if the operative field is not dry, desmopressin acetate (DDAVP) may be administered to help with platelet function. Patients with significant bleeding manifested by hypotension, severe graft tenderness, and swelling, even in the presence of a normal hematocrit level, should undergo surgical reexploration immediately. Less significant bleeding may be present with fewer symptoms. The diagnosis usually can be made with ultrasonography, but clots may have the same echogenicity of surrounding tissues, making the diagnosis more difficult. A CT scan will delineate the hematoma and is indicated if there is a high index of suspicion. Late bleeding may occur because of a mycotic aneurysm, which is rare, or a ruptured kidney from severe acute rejection, an uncommon presentation.

Urine leaks occur most commonly at the ureterovesical junction but may occur anywhere along the length of the ureter or from the renal pelvis. Technical failure results from a ureteral anastomosis that is too loose or too tight, or from a bladder closure that is less than watertight. Urine leaks also occur because of distal ureteral slough from inadequate blood supply. This complication usually can be prevented by ensuring that ureteral length is not excessive and by preserving all lower polar renal arteries. The diagnosis can be made from decreasing urine output, lower abdominal pain, scrotal or labial edema, and a rising serum creatinine level. Ultrasonography may have determined a fluid collection that should be aspirated and analyzed for creatinine. A renal scan may demonstrate extravasation of the radioisotope beyond the confines of the collecting system and bladder. Early exploration and repair usually is required for urine leaks. Ureterovesical leaks can be repaired by reimplanting the transplant ureter, and bladder leaks repaired by primary closure. A distal transplant ureteral slough requires a ureteroureterostomy or a ureteropyelostomy from the native ipsilateral or contralateral ureter to the transplant ureter or pelvis. This usually is done over a double J stent that is left in place for 4 to 6 weeks.

Lymphoceles are perinephric collections of fluid that occur in approximately 5 percent of renal transplants, usually as a result of excessive iliac dissection and failure to ligate the lymphatics overlying the iliac artery. Less commonly, lymphoceles occur as a result of lymphatic leakage from the transplanted kidney. Lymphoceles may present with swelling over the transplant, unilateral leg edema caused by iliac vein compression, and an increased creatinine level as a result of ureteral compression. Even small inferomedial lymphoceles can cause ureteral obstruction from compression. Ultrasonography will show a homogeneous perirenal fluid collection, often with hydronephrosis. Venous Doppler ultrasonography may demonstrate compression of the iliac vein by the lymphocele (Fig. [10-40](#)). The diagnosis can be confirmed by simple aspiration, because a lymphocele has a high protein content and a creatinine concentration equal to that of serum.

Small asymptomatic lymphoceles do not require treatment, but lymphoceles that cause obstruction or venous compression must be drained. When lymphoceles are aspirated, a small catheter often is left attached to a closed drainage system. This catheter may be used to sclerose the lymphocele with povidone-iodine or tetracycline, but in most centers the preference is to create a peritoneal window surgically to drain the lymphocele intraabdominally. Lymphoceles that develop early within 2 to 4 weeks or are multiloculated may be approached via the transplant incision. Unilocular and inferomedial lymphoceles usually are approached laparoscopically. This approach results in decreased morbidity and shorter hospitalizations. If a drainage catheter was previously placed, it can be filled with saline or methylene blue to better delineate the lymphocele cavity.

Renal artery stenosis occurs in approximately 10 percent of renal transplants, usually within the first 6 months. The presentation of renal artery stenosis is sometimes subtle and the diagnosis difficult to make. Renal artery stenosis primarily presents with hypertension, which is difficult to control. Fluid retention manifested by peripheral edema, sensitivity to cyclosporine or tacrolimus, renal dysfunction, and a bruit over the transplanted kidney also may be present, but many renal transplant recipients with a normal renal artery have these manifestations. Another observation leading to the diagnosis of renal artery stenosis is worsening renal function when angiotensin-converting enzyme inhibitors, such as enalapril or captopril, are used to treat hypertension. The definitive diagnosis of renal artery stenosis usually is made angiographically (Fig. [10-41](#)). Ultrasonography and MRI angiography may be used as screening tools.

Renal artery stenosis may occur distal to the anastomosis as a result of rejection, atherosclerosis, and clamp or perfusion cannula injury. Renal artery stenosis at the anastomosis occurs more frequently when end-to-end, rather than end-to-side, anastomoses are performed. This usually is a result of faulty surgical technique or an intense fibrotic reaction to the suture used. The majority of renal artery stenoses (> 80 percent) can be corrected with balloon angioplasty at the time of angiography. Those that cannot be approached angiographically and those that have failed balloon angioplasty are repaired surgically.

Ureteral obstruction, whether early or late, usually presents with a rising creatinine level and evidence of hydronephrosis on ultrasonography. In the absence of a lymphocele, the cause of obstruction usually is a stricture in the distal ureter. Mild early hydronephrosis may be a result of postoperative edema and can resolve without treatment. Distal ureteral strictures usually are the result of ischemia and sometimes of rejection. The most effective way to diagnose a ureteral stricture is with an antegrade pyelogram (Fig. [10-42](#)).

A nephrostomy tube usually is left in place at the time of antegrade pyelography for access to the distal ureter when the hydronephrosis is relieved. Most short structures (< 2 cm) are amenable to balloon dilation and endourologic incision, but longer strictures typically require surgical repair. Strictures tend to be less amenable to ureteral reimplantation, as opposed to surgical treatment of early leaks. Native ureteroureterostomy or ureteropyelostomy are the most commonly used surgical procedures for repairing a transplant ureteral stricture.

Immunosuppression

New immunosuppressive agents have permitted immunosuppression to be tailored to the type of transplant and according to specific recipient needs. The immunosuppressive agents in use include antithymocyte globulin (ATG), OKT3, cyclosporine, tacrolimus (FK506), azathioprine, mycophenolate mofetil, and prednisone.

The number of agents available has resulted in numerous immunosuppressive protocols. After cadaveric renal transplantation, triple therapy is used for maintenance immunosuppression. Previously, triple therapy included azathioprine, cyclosporine, and prednisone, but mycophenolate mofetil, with its ability to prevent rejection, has replaced azathioprine in most protocols. Cyclosporine is administered orally (5 to 8 mg/kg) twice daily, and trough levels are monitored. Monitoring of cyclosporine trough levels can be done by high-performance liquid chromatography (HPLC), radioimmunoassay, or by fluorescent polarization immunoassay (FPIA). Mycophenolate mofetil also is given orally in doses of 1,000 or 1,500 mg twice daily, but gastrointestinal symptoms or leukopenia should prompt a lowering of the dosage. Prednisone may be given in large doses (500 to 1,000 mg) intravenously followed by a rapid taper to 5 to 10 mg daily after 3 to 6 months. Protocols that withdraw steroids completely or those that avoid steroids altogether are uncommon in cadaveric renal transplantation. The risk of acute rejection and long-term deterioration of graft function are too great to offset any gains from avoiding steroid-related side effects.

In addition to triple immunosuppressive therapy, quadruple therapy protocols use a powerful anti-T-cell agent, such as ATG or OKT3, after transplantation. The rationale for using this induction therapy is to avoid the nephrotoxic effects of cyclosporine and tacrolimus. In these protocols, ATG and OKT3 usually are used in a sequential manner. Cyclosporine or tacrolimus is not given until the creatinine level falls below 3.0 mg/dL, and it is overlapped with the administration of ATG or OKT3 until target cyclosporine levels are achieved. Although 1-year graft survival rates with the use of induction therapy exceed 90 percent, a higher incidence of viral infections, particularly cytomegalovirus and Epstein-Barr virus, has been documented.

Most two-haplotype living-related protocols have changed to a cyclosporine-based protocol with azathioprine or mycophenolate mofetil. Many two-haplotype identical protocols also include early steroid withdrawal with excellent results. One-haplotype and living-unrelated renal transplant protocols are similar to cadaveric renal transplant protocols. Some centers also have eliminated induction with OKT3 or ATG in one-haplotype living-related transplants since the introduction of mycophenolate mofetil.

Treatment of Rejection

High-dose steroids, usually methylprednisolone, are the first line of treatment for first rejection episodes. With the exception of HLA-identical transplant recipients, first rejection occurs in 40 to 50 percent of renal transplant recipients. Reports indicate that mycophenolate mofetil combined with cyclosporine and prednisone may reduce the incidence of first rejection episodes by 20 to 25 percent. Methylprednisolone is given in doses of 500 to 1,000 mg for 3 to 5 days. Some centers taper steroid doses over a longer period (7 to 10 days), but there is little evidence that a longer taper is more effective than a shorter course of pulsed high-dose steroids.

When a rejection episode is resistant to high-dose steroids, which usually is evident after 1 or 2 days, OKT3 is effective in reversing 90 percent of these rejection episodes. Rather than recycling high-dose steroids, it is better to use OKT3 earlier when the rejection appears resistant. Although OKT3 is highly effective in first rejection episodes, most centers prefer to use steroids because they can be used in an outpatient setting and are associated with fewer side effects. In patients who have antibodies to OKT3 or who have had serious side effects from OKT3-induced cytokine release, polyclonal preparations such as ATG may be used. In patients who have biopsy-proved evidence of vascular rejection, OKT3 should be considered as first-line treatment, because this form of rejection is difficult to treat. Patients who are being treated for rejection, and who are not on mycophenolate mofetil, should be switched to this agent because, unlike azathioprine and cyclosporine, it has the ability to treat established rejection. Patients with rejection refractory to steroids and OKT3 also may be treated with tacrolimus. Reversal of refractory rejection has been documented in 75 percent of patients treated with tacrolimus.

Chronic rejection, which must be differentiated from other forms of late graft dysfunction, has no specific treatment. Prevention of acute rejection episodes and earlier treatment of acute rejection episodes with OKT3 may reduce the incidence of chronic rejection. The effect of mycophenolate mofetil on the development of chronic rejection remains to be seen. Mycophenolate mofetil not only reduces the incidence of acute rejection but also may prevent the progressive arteriolopathy seen in chronic rejection.

Long-term Complications

The three most common causes of death after renal transplantation are cardiovascular disease, infectious disease, and malignancy, which are known to be increased significantly in

transplant recipients and reflect chronic long-term immunosuppression, particularly the infectious and malignancy-related deaths.

The two most common causes of graft loss are death with a functioning graft and chronic rejection. Improvements in immunosuppression and in the management of cardiovascular disease should result in longer patient graft survivals. When chronic rejection is better understood, strategies directed at its prevention and treatment will yield improved long-term graft survival.

Noncompliance, particularly in adolescent transplant recipients, may be responsible for 10 to 15 percent of late graft losses. The development of a late acute rejection episode, especially in an adolescent, should arouse suspicion. Pre- and posttransplant education and counseling may improve compliance.

Recurrent disease, especially recurrent glomerulonephritis, may result in late graft loss. The incidence of recurrence varies with the type of glomerulonephritis and occurs in 10 to 30 percent of transplants, but graft loss from recurrent disease occurs less frequently and accounts for approximately 2 percent of late graft losses.

Cardiovascular disease after renal transplantation is more common in patients with diabetes, hypertension, elevated serum cholesterol and triglyceride levels, and in patients who smoke. The risk of ischemic heart disease is three or four times greater in posttransplant patients without recognized pretransplant disease or risk factors than in the general population.

Because cardiovascular disease is a common cause of death after transplantation, elimination or reduction of risk factors through preventive measures or treatment strategies is important. Hyperlipidemia in obese patients can be improved by diet and weight loss. Minimized use of steroids, treatment of hypertension (which is known to predispose to cardiovascular disease), and exercise may help in the prevention of cardiovascular disease. If posttransplant hyperlipidemia is unresponsive to dietary modification, pharmacologic treatment with lovastatin, pravastatin, or simvastatin is indicated. These agents are hydroxymethylglutaryl (HMG)–CoA reductase inhibitors that reduce total and low-density lipoprotein (LDL) cholesterol levels. Because hepatotoxicity can occur with these agents, liver enzymes should be monitored.

Hepatic dysfunction is common after renal transplantation and may be secondary to hepatitis B, hepatitis C, or drug toxicity, particularly with azathioprine and cyclosporine. Patients who have hepatitis B before transplantation can be considered for transplantation if they are HBsAg-negative or HBV DNA-negative, because these are markers of active viral replication. Progression to cirrhosis is variable, but patients need to be informed that immunosuppression, particularly with steroids, may enhance viral replication and hasten progression to cirrhosis. Surveillance with liver enzyme determinations and possibly liver biopsies is necessary to monitor disease activity. Long-term hepatitis B immune globulin (HBIG), interferon- α , and lamivudine may be effective in limiting progression of the disease.

Hepatitis C also may lead to cirrhosis and has been more common than hepatitis B since the hepatitis B vaccine was introduced. Chronic liver disease after renal transplantation can be attributed to hepatitis C in the majority of patients, but immunosuppression appears to have a lesser role in the rapid advancement of disease than it does with hepatitis B. Patients known to be hepatitis C-positive should have liver enzymes monitored closely and perhaps a baseline liver biopsy performed before transplantation. Interferon- α has limited effectiveness, and trials with other antiviral agents, such as ribavirin, are under way.

Hepatotoxicity related to azathioprine or cyclosporine is uncommon. When other causes of hepatotoxicity have been ruled out and the pattern is cholestatic, azathioprine may be responsible and should be discontinued. Cyclosporine hepatotoxicity, manifested by increased bilirubin and transaminase levels, usually responds to a reduction in dosage.

Other gastrointestinal diseases that can lead to hepatic dysfunction include pancreatitis, cholelithiasis, and choledocholithiasis. Pancreatitis may be a result of immunosuppression, hyperlipidemia, hyperparathyroidism, stones, and viral infections. The presence of symptomatic cholelithiasis or choledocholithiasis is an indication for cholecystectomy and ERCP with papillotomy.

After transplantation, bone and mineral metabolism can be adversely affected. Early manifestations include hypophosphatemia and hypercalcemia, which may be from persistent secondary hyperparathyroidism. Asymptomatic patients with serum calcium levels in the range of 10.5 to 12.5 mg/dL should not undergo subtotal parathyroidectomy within the first year because the majority of patients will have resolution of their hypercalcemia. Patients with severe mental status changes, renal stones, fractures, pancreatitis, and those who have a serum calcium of 12.5 mg/dL or greater after 1 year should undergo a subtotal parathyroidectomy.

Long-term bone disease usually is manifested as severe osteopenia or osteonecrosis. Osteopenia with significantly decreased bone mineral density is a result of long-standing renal disease and is worse in postmenopausal women, in patients with persistent hyperparathyroidism, and in patients who have had large cumulative doses of prednisone. Minimizing steroid dosage and correcting hyperparathyroidism decreases bone loss; pediatric patients may require vitamin D supplementation, and postmenopausal women should be treated with estrogen and calcium supplements. In more severe cases, calcium-lowering agents, such as etidronate and nasal calcitonin, may be effective.

Osteonecrosis, particularly of the femoral head, is a significant long-term complication after renal transplantation, related primarily to steroid therapy. It may present with hip pain and limitation of movement, and the diagnosis is made with MRI. In severe cases a total hip arthroplasty is required.

Another common problem after renal transplantation is hyperglycemia, which requires treatment with oral hypoglycemic agents or insulin. Although 20 percent of patients develop hyperglycemia, only 5 to 10 percent require treatment, and only 1 to 2 percent require treatment beyond the first year. Steroids increase the production of glucose, impair peripheral use, and increase glucagon levels, while cyclosporine and tacrolimus decrease beta cell excretion and cause peripheral insulin resistance. Tacrolimus has a higher diabetogenic potential than cyclosporine.

Transplant-associated malignancies related to long-term immunosuppression, particularly lymphomas, are a long-term concern for renal transplant recipients. The overall incidence of malignancy is approximately 6 percent; 1 to 2 percent are lymphomas. Carcinoma of the colon, rectum, prostate, breast, and lung do not appear to have an increased incidence in transplant recipients. But skin cancer, particularly squamous cell carcinoma, has an incidence up to 20 times higher in immunosuppressed patients than in immunocompetent individuals and usually is more aggressive and presents more frequently with metastatic disease. Transplant recipients also have a higher incidence of Kaposi's sarcoma and genital neoplasms, such as vulvar, vaginal, and cervical carcinomas. Long-term transplant recipients should have dermatologic surveillance, and female recipients should have annual pelvic examinations and Pap smears.

Posttransplant lymphoproliferative disease (PTLD) is a spectrum of B-cell abnormalities that are driven by the Epstein-Barr virus (EBV). The first stage resembles infectious mononucleosis, with polymorphic B-cell hyperplasia. This is followed by the production of a subpopulation of B cells with nuclear atypia and cytogenic abnormalities, and then by the development of a malignant monoclonal B-cell lymphoma. The development of posttransplant lymphomas occurs more frequently in heavily immunosuppressed patients, especially those who have received antilymphocyte preparations, such as ALG, ATG, and OKT3. Treatment consists of drastically lowering or stopping immunosuppression, thereby restoring host immunity. Polyclonal lymphomas also may respond to antiviral treatment with acyclovir or ganciclovir, but monoclonal lymphomas respond less favorably. The development of rejection is a risk, which in renal transplant patients is not as problematic as in heart or liver transplant patients, in whom graft loss results in death. Once a monoclonal lymphoma develops, chemotherapy and radiotherapy can be used with acyclovir or ganciclovir, but the mortality rate nevertheless exceeds 80 percent.

Results

Figure 10-43 illustrates the current 5-year survival rates of patients receiving living-related, living-unrelated, and cadaveric renal transplants.

Special Problems

Several situations deserve special consideration, because the management can deviate from the standard treatment of renal transplant recipients.

Diabetes

Diabetes, particularly juvenile onset diabetes, is the single most common cause of renal failure in the United States. Diabetics account for as many as 30 percent of the patients awaiting renal transplantation. Diabetics are at significantly higher risk for heart disease and peripheral vascular disease and should be evaluated accordingly. All diabetics should undergo some form of noninvasive cardiac evaluation for ischemia, because many patients have no history of chest pain as a result of autonomic neuropathy that occurs as part of their diabetic neuropathy. The incidence of significant coronary disease is over 25 percent in patients who have had diabetes for more than 25 years, are over the age of 45 years, and have a smoking history. Coronary disease that is correctable with angioplasty or bypass is not a contraindication to transplantation. If the patient has diffuse disease with left ventricular dysfunction and is not a candidate for revascularization, then transplantation is high risk and probably contraindicated. Diabetics may have significant gastrointestinal tract problems, including gastroparesis and diabetic enteropathy. These problems frequently have a uremic component and may improve with transplantation, although severe gastroparesis can cause significant problems in the postoperative period. Diabetic candidates for renal transplantation should be evaluated for combined kidney-pancreas transplantation.

A compelling argument for transplantation in juvenile diabetics concerns the long-term outcome of these patients. Long-term survival rates of juvenile diabetics on hemodialysis are dismal, at approximately 30 percent at 5 years. In contrast, juvenile diabetics with transplants have 5-year survival rates upwards of 80 percent.

Pediatric Patients

Renal failure can be particularly devastating to children, because of its interference with normal growth patterns and, particularly in young children, the impairment of intellectual development. The time requirements for dialysis also impose particular stresses on a child's life. Pediatric patients with functioning kidneys grow more normally, have significant catch-up growth (particularly if growth hormone is administered), and potentially can have more normal lifestyles. All pediatric diabetics should be considered as candidates for transplantation.

The work-up of a pediatric patient is similar to that for an adult, but there is less need for evaluation for comorbid conditions, such as heart disease, pulmonary disease, and malignancies, because they are significantly less likely in this population. Particular attention should be given to patients' urologic status, because reflux from posterior urethra valves or neurologic problems, such as spina bifida, are the cause of many pediatric patients' renal failure. Reconstructive procedures on the urinary tract should be completed before transplantation.

Certain technical aspects of transplantation merit consideration in the pediatric patient. With very small children, the use of an adult kidney may require selection of unusual sites of anastomoses. The size of the aorta and iliac vessels also makes the procedure technically more demanding. Very small children have been successfully managed with peritoneal dialysis, intensive nutritional support, and administration of growth hormone. It is recommended that children under the age of 1 year be allowed to grow before consideration for transplantation. An allograft can be considered in patients who do poorly on peritoneal dialysis or have a complication requiring its termination.

Pediatric patients have poorer overall graft survival than adult patients, particularly in cadaveric transplantation. Consideration must be given to the type of immunosuppressive protocol used. Some clinicians recommend the use of an induction protocol with OKT3 or ATG, and triple therapy with cyclosporine, azathioprine, and prednisone. Because the outcome of transplantation for pediatric patients is considerably better with living- donor transplants, every effort should be made to identify a living-related donor.

Pediatric patients also must be monitored very closely. In the very small child, in whom posttransplant creatinine levels may be in the range of 0.3–0.5 mg/dL, biopsies may be required to diagnose rejection, as the serum creatinine level is relatively insensitive in identifying early rejection. Issues such as body image problems from drug side effects and the constraints of a strictly applied medication regimen put all younger patients, but particularly those in the teenage years, at an extremely high risk for noncompliance. Patients and their families should be counseled extensively about the risks of noncompliance.

The results of transplantation in pediatric patients have progressively improved, and 1-year graft survival rates for living donor and cadaveric transplants are in the range of 90 percent and 80 percent, respectively.

Retransplant Patients

Patients who have lost one renal allograft can be considered at high risk for retransplantation, but a significant number of these patients are pediatric and young adults who potentially can benefit from retransplantation. It is difficult to consign these patients to a life of dialysis if an initial transplant has failed. Large transplant registries have demonstrated that retransplant recipients have poor overall graft survival compared to first transplant recipients; therefore, a special approach must be taken for these patients.

Patients with a known history of heart disease or peripheral vascular disease should be reevaluated for these problems at the time they are considered for retransplantation. A number of factors can be identified that increase the risk of graft loss for retransplant candidates. These include extremely short survival of the first transplant with loss because of acute rejection in less than 6 months, and high panel-reactive antibodies levels, indicating generalized sensitization from a previous failed graft.

There is considerable evidence that extremely sensitive crossmatch techniques, such as the antiglobulin technique or flow cytometry, can reduce the risk of delayed function and early graft loss in retransplant recipients. These techniques should be used routinely for anyone receiving a second or third graft. The best outcomes have been demonstrated with induction therapy, and the use of OKT3 or ATGAM can be recommended for these patients.

ORGAN PRESERVATION

Hans W. Sollinger

Because the majority of organs transplanted are from a cadaveric source, the organ inevitably must be stored for some time after removal from the organ donor until the recipient is prepared for the transplant procedure. The organ donor and the recipient often are not in the same location, and time is needed for transport of the donor organ to the hospital where the recipient is being prepared for transplantation. This requires the use of effective, safe, and reliable methods to preserve the organ ex vivo until the transplant procedure can be performed. Acceptable preservation times vary with the organ. Most surgeons prefer to transplant the heart within 5 h after donor cardiectomy; the kidney can be stored safely for 40 to 50 h, but earlier transplantation is preferable. For the pancreas, preservation times up to 30 h have been reported, but most pancreas transplants are performed after 10 to 20 h of preservation time. Liver transplants usually are performed within 6 to 12 h after donor hepatectomy.

Preservation of the organ begins at the time a donor is identified, and the donor must be adequately maintained hemodynamically so that the organ is not injured before procurement and preservation. Injury to the organ could occur because of cardiovascular instability and hypotension. It is the donor surgeon's responsibility to assure the adequacy of organ function. During the operation to remove the organ, warm ischemia time must be reduced to a minimal amount, and the organ must be cooled rapidly, either in situ or by a well-timed back table flushout.

Hypothermia and the composition of the organ preservation solution are key factors in successful organ preservation. In cold storage of organs, the organ is rapidly cooled to approximately 4°C by flushout of the vascular system with an appropriate organ preservation solution. The flushout should remove blood as completely as possible, be delivered at a pressure that is not damaging to the organ (usually 60 to 100 cmH₂O), and in a volume that is not excessive. The volume used for each organ varies, but the liver usually is flushed with approximately 2 to 3 L, the kidney with 200 to 500 mL, and the pancreas with a similar amount. The organ is then placed in a sterile container and kept cold at 4 to 6°C.

Hypothermia is beneficial because it slows metabolism. Organs exposed to normothermic ischemia remain viable for relatively short periods (for most organs, 1 h or less). In warm ischemia, the absence of oxygen leads to a rapid decline in the energy content (adenosine triphosphate [ATP]) of the organ, a redistribution of electrolytes across the cell membrane, and a decrease in biosynthetic reactions. But biodegradable reactions continue, including the accumulation of lactic acid, a decrease in intracellular pH, proteolysis, and lipolysis. These events contribute to changes in the concentration of intracellular metabolites, and structural alterations in cellular membranes contribute to loss of viability on restoration of blood reperfusion of the organ. With hypothermia, the degradative reactions are slowed. A 10°C decrease in temperature slows the metabolic rate approximately by a factor of two. Cooling an organ from 37°C to approximately 0°C slows metabolism by a factor of 12 to 13. Hypothermia alone is not sufficient for adequate preservation for the time necessary for optimal use of cadaveric organs; the organ also must be flushed with an appropriate preservation solution.

Two requirements of any ideal preservation solution are: (1) the presence of impermeant molecules that suppress hypothermically induced cell swelling, and (2) an appropriate biochemical environment. Impermeants are agents that remain outside the cells and are sufficiently active osmotically to retard the accumulation of water by the cell. Under conditions of cold storage (cold ischemia), there is a loss of ATP, which is necessary to drive the ion pumps (sodium, potassium, ATPase) required to maintain normal cell volume. Hypothermia slows the activity of the ion pumps but has little effect on the permeability of cell membrane electrolytes, so there is a relatively rapid accumulation of sodium in exchange for potassium, a loss of the electrical potential across the membrane, and entry of chloride down its chemical gradient. This results in the accumulation of water in the cell, and this cell swelling is a major detriment to successful preservation of organs.

The University of Wisconsin (UW) solution contains lactobionic acid as the primary impermeant. Lactobionic acid has a relatively large molecular mass (358 kD) and is negatively charged. It remains outside most cells and suppresses hypothermically induced cell swelling. The UW solution also contains raffinose, a trisaccharide; hydroxyethyl starch as a colloid; and adenosine, to stimulate ATP synthesis during reperfusion of the organ.

In addition to simple cold storage, organs can be preserved by continuous hypothermic perfusion. This method, developed by Belzer in 1967, uses a machine to pump a perfusion fluid continuously through the organ. In this way, oxygen and substrates are continuously delivered to the organ, which maintains metabolism, including the synthesis of ATP and other molecules, and ion pump activity. Machine perfusion for kidneys gives superior results compared to simple cold storage. With simple cold storage, approximately 25 to 30 percent of transplanted kidneys have delayed graft function, but with machine perfusion, the rate of delayed graft function is less than 10 percent. The perfusate is similar to the UW solution, except for the impermeant. For continuous perfusion, gluconate is used in place of lactobionic acid.

CHAPTER 11 - Surgical Complications

Josef E. Fischer
Elliott Fegelman
Jay Johannigman

OPERATIVE RISK

Operative risk is defined as the sum total of abnormalities of all organ systems and their interactions that determine the outcome of an operation. The approach used in determining operative risk is to identify the patient at risk, identify the organ system(s) at risk, prevent or protect against the complication or the failure of that organ system (especially those aspects of organ instability or inadequacy that are reversible), and improve the outcome. The organ systems that determine outcome include: (1) cardiac, (2) pulmonary, (3) renal, (4) hepatic, (5) hemostatic, (6) nutritional-immunologic, and (7) vascular.

Cardiac Risk

One means of estimating cardiac risk is to use Goldman's cardiac risk index (Table 11-1). The focus of the Goldman classification in patients undergoing general anesthesia is the history of a previous myocardial infarction. If the patient has not had any previous myocardial infarction, the risk of cardiac death is between 1 and 1.2 percent. If more than 6 months has elapsed between the cardiac infarction and the current operation, there is a 6 percent risk. If a transmural infarct has occurred less than 3 months before operation, the risk of cardiac death is between 16 and 37 percent.

Factors that predispose to the occurrence of life-threatening cardiac events in the perioperative period include a history of any of the following: (1) infarction within 6 months, (2) congestive heart failure, (3) arrhythmias, (4) aortic stenosis, (5) emergency or major surgery, (6) age greater than 70 years, and (7) poor medical condition.

Significant peripheral vascular disease should alert the surgeon to consider the cardiac risk. If the patient gives a history of angina pectoris, it should be determined whether there has been new onset of unstable angina.

The electrocardiogram (ECG) and hematocrit level are significant. A cardiac stress test is indicated to identify those patients at coronary risk. A positive cardiac stress test includes any or all of the following: an ST depression of more than 0.2 mV, an inadequate heart rate response to stress, or hypotension. The most sensitive examination of cardiac risk is the inability to perform a bicycle exercise for 2 min and achieve a heart rate higher than 100. Data from rest and exercise radionuclide ventriculography provide little additional information but can provide useful information.

The principal form of treatment for patients with cardiac risk because of an antecedent myocardial infarction is (if possible) to delay operating for approximately 6 months after the myocardial infarction. Some patients should be admitted to the intensive care unit the day before operation, and oxygen consumption, oxygen delivery, mixed venous oxygen saturation, and cardiac output should be optimized. In patients with significant angina, angioplasty or coronary bypass procedure may be necessary before any major surgical procedure is undertaken. In some situations simultaneous cardiovascular revascularization and carotid endarterectomy are performed.

For patients in congestive failure, the use of calcium channel blockers or beta blockers, digitalization with cardiac glycosides, and diuresis are part of the therapeutic armamentarium. Patients with rapid atrial fibrillation should have their cardiac rates controlled. If the cardiac rhythm cannot be returned to normal sinus rhythm with the use of glycosides, quinidine, or procainamide hydrochloride (Pronestyl), cardioversion should be considered. If cardioversion is attempted, the patient should first be given anticoagulants to prevent embolization.

Pulmonary Risk

Pulmonary risk factors include smoking, obesity, advanced age, and industrial exposure. The patient at pulmonary risk can be identified by simple functional tests such as walking up a flight of steps or blowing out a match with unpursed lips from a distance of 8 to 10 inches (20–25 cm). If arterial blood is drawn with the patient inspiring room air, it is not the reduced P_{O₂} that identifies a patient significantly at risk but rather a P_{CO₂} of greater than 45 mmHg, suggesting a serious diffusion defect. Other easily identifiable risk factors include a *maximum breathing capacity (MBC)* of less than 50 percent of that predicted, or a *1-second forced expiratory volume (FEV₁)* of less than 2 liters. MBC is a highly subjective test, depending on the patient and the encouragement of the examiner exhorting the patient to breathe maximally. Patients with pulmonary artery pressure higher than 30 mmHg also are at increased pulmonary risk (Table 11-2).

The most sensitive test for patients undergoing thoracotomy is the exercise oxygen consumption (V_{O₂}). Patients with a maximum V_{O₂} of less than 15 mL/kg/min usually will have great difficulty; if the consumption is greater than 20 mL/kg/min, postoperative pulmonary complications are less likely.

The use of saturated solutions of potassium iodide as an expectorant, incentive spirometry, chest physical therapy, and postural drainage should be considered. Antibiotics are appropriate for patients with bronchiectasis. In the postoperative period humidified gas, chest physical therapy, incentive spirometry, and postural drainage are beneficial. Use of patient- controlled analgesia (PCA), which minimizes narcotic use or postoperative epidural analgesia, decreases the incidence of pulmonary complications.

Because most lung damage is a result of smoking or industrial pollution, cessation of smoking is essential for patients who are to undergo long elective procedures; 8 weeks cessation preoperatively is required for maximal benefit. Pulmonary physical therapy may improve the operative risk. Expectorants, physical therapy, incentive spirometry, humidified air (humidified oxygen is not necessary), and, in the case of bronchiectasis, antibiotics based on cultures of the patient's sputum flora are all appropriate to improve operative risk. With good preparation, thoracotomy can be carried out in patients with an FEV₁ of less than 1.0 L and an MBC of 35 to 40 percent.

Renal Risk

Renal abnormalities are reflected by elevations in blood urea nitrogen (BUN) and creatinine levels. Serum abnormalities are not manifest until more than 75 to 90 percent of the renal reserve is lost (Fig. 11-1). An elevation of BUN or creatinine that is not because of dehydration generally means that renal function is compromised by 75 to 90 percent. Increased levels of BUN or serum creatinine in a hydrated patient should be quantified by measuring creatinine clearance:

Cl_{Cr} = (140 - age) × weight (kg)(mL/min) / 72 × Cr (serum) mg/dL

Reversible causes of renal insufficiency should be identified and corrected. These include infection, uncontrolled hypertension, obstruction, and dehydration. The patient should be admitted preoperatively to a monitored bed the night before surgery, a pulmonary artery catheter placed, and the patient hydrated with intravenous saline solution to the optimal filling pressure in order to protect the kidneys. Aminoglycosides should be avoided whether administered systemically or for bowel preparation.

In the postoperative period, if severe hyperkalemia supervenes (greater than 7.5 mEq/L), with accompanying ECG changes, intravenous calcium should be administered and followed shortly thereafter by 50% dextrose, 10 units of insulin, and intravenous bicarbonate. Sodium polystyrene sulfonate (Kayexalate) can be given by mouth or by enema; 5 g should be administered. Essential amino acids and hypertonic dextrose solution, given as total parenteral nutrition (TPN), may lower the potassium level. As potassium enters the cells, it might be necessary to add potassium. If the BUN level approaches 100mg/dL, there are difficulties with clotting factors and platelets are dysfunctional, resulting in gastrointestinal bleeding, which further elevates the BUN level. Peritoneal, hemodialysis, or continuous ultrafiltration occasionally is required.

Hepatic Risk

Hepatic dysfunction is best estimated by the Child-Pugh criteria, which enumerate synthetic functions, including albumin, prothrombin time, excretory functions (bilirubin), nutritional status, the presence or absence of ascites, and encephalopathy (Table 11-3). In cirrhotic patients, the mortality accompanying noncardiac surgery is less than 5 percent for Child-Pugh Class A, between 5 and 10 percent for Class B, and between 20 and 50 percent or higher for Class C categories. When the blood ammonia concentration is higher than 150 ng/dL, an 80 percent mortality can be expected. When the albumin level is below 2.0 g/dL, a similar mortality is anticipated. Few patients with a bilirubin level higher than 4 mg/dL as a result of hepatic dysfunction survive an operation requiring a general anesthetic. Similarly, with a prothrombin time prolonged more than 2 seconds, a mortality of 40 to 60 percent can be expected. A point system for patients with liver disease undergoing nonshunt operations uses serum albumin concentration, prothrombin time, the presence of encephalopathy, and a history or presence of varices (Table 11-4, Fig. 11-2). Patients with hepatic dysfunction generally die of a high-output cardiovascular failure and low peripheral resistance.

In an elective situation, abstinence from alcohol, where alcohol is the damaging agent, is probably the most important feature for improving hepatic function. Patients with cirrhosis receive a large proportion of calories from carbohydrate, especially from alcohol, a cycle that it is necessary to break. These patients often are intolerant to the protein that they need because they are hypercatabolic, requiring 1.1 g of amino acids/kg/24 h, instead of the normal 0.55 g of amino acids/kg/24 h. Protein tolerance may be improved by the use of branched-chain amino acid–enriched nutritional mixtures or branched-chain amino acids alone. In patients with ascites, the conversion of uncontrollable ascites to ascites that can be controlled with medications substantially improves the operative risk. Spironolactone (Aldactone) and furosemide (Lasix) combined with fluid restriction to 1500 mL/day are therapeutic. Restriction of sodium to 500 mg/day is desirable but rarely achievable without the use of salt- free foods. A sodium limit of 2 g/day is more realistic.

Hemostatic Risk

See Chap. 3.

Nutritional-Immunologic Defects

The difficulty in assessing nutritional risk is that it is impossible to predict which malnourished patient is at risk for the immunologic abnormalities that accompany malnutrition. Statistically, malnourished patients as a group experience a higher complication rate. The defining characteristics of a severely malnourished patient include a weight loss of more than 15 percent over the previous 3 to 4 months, a serum albumin level of less than 3.0 g/dL, anergy to *injected* skin-test antigens, and a serum transferrin level of less than 200 mg/dL. If these characteristics are present, enteral or parenteral nutrition to improve the patient's well-being should be undertaken for 4 to 5 days preoperatively to normalize retinol-binding protein, thyroxin-binding prealbumin, and transferrin. Patients who do not have severe malnutrition should not be prepared for operation with total parenteral nutrition; in this group TPN increases the risk of nosocomial and non-catheter-related infections without improving other outcomes sufficiently to risk the increased infection rate. In a Veterans' Affairs Cooperative Trial, the severely malnourished patients' improvement in nutritional status was found to be correlated with a lower mortality and fewer septic complications.

Once the malnourished patient has been identified, nutritional preparation and reparation are undertaken. This may be achieved via nasoduodenal feeding tube at home for 7 to 10 days in most elective cases. If parenteral nutrition is required, patients can be discharged on home parenteral nutrition prior to operation.

Vascular Risk (Thromboembolism)

See Chap. [21](#).

DIABETES MELLITUS

Diabetes mellitus occurs in 2 to 3 percent of the general population, with a higher rate among older people. In two series the disease was discovered in the perioperative period in 16 percent and 23 percent of patients. The most commonly associated operative procedures were related to vascular disease, but in a high proportion of patients diabetes was discovered before an emergency procedure. Diabetic patients represent a special challenge during surgical care because impairment of the homeostatic mechanism for glucose may result in ketoacidosis if untreated or hypoglycemia if overtreated, and also because of the associated incidence of generalized small-vessel vascular disease.

Pathophysiology

The basic defect in diabetes is a lack of metabolically effective circulating insulin. The elevated blood glucose level is a result of deficient utilization on the part of peripheral tissues and increased output of glucose by the liver. In diabetes the breakdown of fatty acids is increased. Metabolism of the ketone bodies is limited, accumulating in the bloodstream and eliminated via the kidneys. Glycosuria produces an osmotic diuresis that is enhanced by the presence of ketone bodies with the associated loss of sodium and potassium. Evaluation of decompensated diabetes includes not only measuring the blood glucose level but also measuring serum acetone and electrolyte levels, carbon dioxide combining power, and blood pH.

Anesthesia may affect carbohydrate metabolism. Hyperglycemia may be increased by an accelerated breakdown of liver glycogen and a concomitant catabolism of muscle glycogen, with the formation of lactic acid. The anesthetic agents affecting glucose catabolism cause an exaggerated hyperglycemic epinephrine response and an increased resistance to exogenously administered insulin.

The stress of an operation aggravates hyperglycemia because of the increased secretion of epinephrine, growth hormone, and glucocorticoids. Increased epinephrine secretion results in an increased breakdown of liver glycogen to glucose, which is released into the general circulation. The glucocorticoids also increase hepatic glucose output via mobilized protein and exert an anti-insulin effect by stimulating a circulating insulin antagonist. The effects of epinephrine and glucocorticoids are offset by an increased secretion of endogenous insulin in the normal person but can require the administration of larger doses of insulin in diabetic patients. Treatment is directed at preventing ketoacidosis, hyperosmolar nonketotic coma, decreased cardiac output with associated poor peripheral perfusion, electrolyte imbalance, impaired polymorphonuclear leukocyte phagocytosis, and decreased wound healing, all of which are related to uncontrolled diabetes.

Management

For the diabetic patient essential laboratory studies include hemoglobin level determination, white cell count, urinalysis for glucose and acetone, fasting and timed postprandial blood glucose level determination, serum electrolyte levels, including potassium and carbon dioxide combining power, BUN level, and, for older patients, serum cholesterol level determination and electrocardiography. Measurement of arterial blood gases may be necessary if there is suspicion of ketoacidosis. Diabetic patients should have preference on the operative schedule to minimize the effects of fasting and ketosis. Preoperative medication should be kept to a minimum because diabetic patients, particularly elderly ones, are sensitive to narcotics and sedatives, and there is a danger of hypercapnia and hypoxia. The choice of anesthesia should not be influenced by the presence of diabetes. Spinal anesthesia has little tendency to evoke hyperglycemia apart from the stress of the operation. Nitrous oxide, trichloroethylene, and halogenated hydrocarbons have the least effect on carbohydrate metabolism. The degree of control during the perioperative period should be assessed by serial determination of the blood glucose level and urinalysis for glycosuria and acetonuria. It is safer to permit mild glycosuria and minimal elevation of the blood glucose level in the perioperative periods, particularly in the elderly and in cardiac patients. In the patient with postoperative hypotension, blood glucose level should be measured to rule out hypoglycemia as a cause.

Patients with mild diabetes mellitus frequently do not require insulin, and dietary control is sufficient. The cornerstone of all diabetic management is the dietary or parenteral intake. The preoperative diabetic intake should contain 140 to 200 g of carbohydrates, 60 to 100 g of protein, and with adequate vitamins and minerals should furnish 1200 to 2100 kcal daily. If parenteral fluids are required, there is some advantage to using fructose or sorbitol, which can be taken in amounts up to 50 g daily in the diabetic patient, but fructose can cause lactic acidosis. The goal of the dietary or parenteral fluid regimen is to keep the patient free of acetonuria without excessive hyperglycemia. Patients using oral agents with well-controlled diabetes should continue the use of these drugs until the day before operation, particularly if the medication is tolbutamide or phenformin. With longer-acting agents, such as chlorpropamide, the drug should be discontinued 72 h preoperatively if the administration of insulin is contemplated. Patients who take tolbutamide preoperatively usually require insulin during and immediately after a major operation. Patients receiving chlorpropamide usually do not require insulin during the immediate perioperative period.

Insulin Therapy

Several protocols for the administration of insulin have been proposed (Table [11-5](#)). One popular method of treatment uses a regimen in which the daily carbohydrate requirement is divided into four equal doses and given parenterally as 5–10% dextrose in water every 6 h. This initiation of the parenteral glucose infusion is accompanied by the subcutaneous injection of unmodified regular insulin in doses equal to approximately one-fourth the dose of insulin that the patient required prior to operation. Urine is checked regularly, and supplementary doses of crystalline insulin are given as indicated. Depending on the extent of glycosuria, 4 to 10 units of additional insulin is provided for each unit of positivity. Larger doses may be indicated when acetonuria, severe stress, infection, or marked hyperglycemia is present. The advantage of this method is that glucose and insulin are given at regular intervals, permitting adjustment in the dose during the day. It is preferable to monitor blood glucose levels. The major disadvantage of this regimen is that inadvertent interruption of glucose infusion may result in hypoglycemia. With this regimen, slight glycosuria is preferable provided there is no acetonuria.

The second basic regimen is for patients whose diabetes is under control with single-injection therapy using long-acting insulin and in whom a complicated postoperative course is not anticipated. On the day of operation, the patient receives 50 g of glucose in 1000 mL of solution. When the intravenous solution is started, insulin is administered at one-half the daily dose of that previously required. After operation and return to the recovery room or ward, the remainder of the usual daily dose of insulin is given subcutaneously. The amount of insulin given on the day of operation approximates that given the previous day. On the day after operation, the usual dose of insulin is given in the morning before breakfast or at the same time that an intravenous infusion is started. Modifications of this approach use small doses of regular insulin subcutaneously during the postoperative period based on the extent of glycosuria or, preferably, the serum glucose level. In patients treated with single daily injections but whose diabetes is not under control before operation, conversion to a regimen of soluble insulin is indicated.

Severe hyperglycemia in patients undergoing major operations is more effectively managed with intravenous regular insulin. The problem of insulin absorption by the fluid container has been overcome by the use of plastic containers, high concentrations of insulin, small amounts of albumin, and flushing the system. A specific infusion protocol is outlined in Table [11-6](#).

A simplified protocol has been proposed by Woodruff and associates. The patients receive their evening dose of insulin the preoperative day, but no subcutaneous insulin on the morning of surgery. The patient is scheduled as the first case of the day. Insulin and glucose are controlled with two separate infusion pumps; one pump infuses 5% dextrose in lactated Ringer's solution at 2 mL/kg/h, and the other dispenses insulin from a plastic bag containing 250 mL sodium chloride to which 50 units of U-100 regular insulin has been added. The rate of insulin infusion is based on the serum glucose level. Twenty units per hour is infused for glucose levels above 200 mg/dL, but no insulin for levels below 80 mg/dL. The surgical procedure is not begun until the level is below 200 mg/dL. Insulin therapy during emergent surgery or surgery complicated by infection requires greater amounts of insulin to maintain serum glucose levels below 200 mg/dL. In extreme cases, bolus injection of 0.1 to 0.4 unit/kg may be required as an additive.

Ketoacidosis

The preparation for surgical treatment of a patient with ketoacidosis is critical. Ketoacidosis may masquerade as a surgical emergency. The patient with frank diabetic coma is no candidate for surgical treatment regardless of the indication. Crystalline insulin should be used in all cases to establish control. Page and associates reported effective management of diabetic coma with continuous low-dose insulin infusion using an average of 7.2 units/h. Plasma glucose, ketone bodies, and free fatty acids decreased 58 percent in 4 h. The associated dehydration and electrolyte abnormality must be corrected; most patients with advanced coma require an average of 2 to 4 liters of fluid to overcome the dehydration. The serum potassium concentration should be determined at 6 to 8 h intervals. Potassium is added to the fluid in quantities of 40 mEq/L administered at a rate no higher than 25 mEq/h. The need for potassium usually does not exceed 80 mEq. There generally is no need to add glucose to intravenous fluid unless the blood glucose level falls below normal. Gastric atony is a frequent accompaniment of diabetic ketoacidosis, and suction frequently is required to minimize pulmonary aspiration. It is possible to correct ketoacidosis in sufficient time that the patient's surgical status is not compromised.

Nonketotic Hyperglycemic Hyperosmolar Coma

Hyperosmolar dehydration and coma is a relatively uncommon syndrome that usually occurs in elderly diabetic or nondiabetic obese patients and in patients receiving total parenteral nutrition. It may be an early indication of sepsis. The blood glucose level is frequently above 1000 mg/dL, and ketone bodies are absent from the plasma and urine. Treatment consists of large amounts of hypotonic solutions and intravenous insulin, often as much as 200 units of regular insulin per 24 h. If total parenteral nutrition is an inciting agent, it should be stopped. Marked lowering of the blood glucose level can result with small doses of insulin; a test dose of 10 units can be given to determine responsiveness. Sodium and potassium also must be given because large amounts of these ions are lost in the urine.

GENERAL CONSIDERATIONS

The response to injury and surgical procedures includes antidiuresis, an increase in extravascular volume, fever, and tachycardia. These are known to be the result of the release of cytokines and other agents. In patients undergoing general anesthesia, fever on the first postoperative night is usually attributed to atelectasis, but is probably the result of a resetting of the central thermostat to combat the hypothermia that occurs in the operating room. As heat preservation techniques become more widespread, it is possible that such fever will be eliminated.

Urine output falls, normally because of the release of *antidiuretic hormone (ADH)*. A tendency to hyponatremia is present in the immediate postoperative period. After intraabdominal procedures, diuresis that occurs on the second to the fourth postoperative day is a signal of normal convalescence, with reabsorption of fluid not only from within the bowel with return of function but also from within the third space and the peritoneal cavity. Diuresis coincides with decreased secretion of aldosterone and ADH because of refilling of intravascular volume. Because the degradation rate of albumin normally is related to the amount in the extravascular space, the outflow of albumin from the intravascular space to the interstices results in increased catabolism of albumin.

Ileus of the colon and stomach persists for 2 to 5 days after open intraabdominal procedures, but for a considerably shorter period after minimally invasive surgery. Return of intestinal motility is one area in which minimally invasive surgery appears to have a distinct physiologic advantage, explaining the shorter length of hospital stay. After open abdominal procedures, the small bowel continues to function throughout the postoperative period, allowing the use of enteral nutrition in the immediate postoperative period.

Wound pain can be severe for approximately 48 to 72 h. A considerably reduced requirement for pain medication can be achieved by the use of a subcuticular closure reinforced with Steri-Strips. The metabolic response to surgery and the postoperative wound pain can be improved by the use of adequate amounts of local anesthesia, even if the patient is undergoing general, epidural, or spinal anesthesia. Use of these agents at the beginning of the procedure decreases the metabolic response to surgery. When used at the end of the procedure, a mixture of short- and long-acting agents decreases the use of pain medication in the immediate postoperative period, and in small incisions may completely obviate the use of narcotics.

Postoperative fatigue may be the result of general anesthesia as much as the operation. It is essentially absent in patients in whom the afferent nerves have been severed, e.g., patients with paraplegia. In the elderly, it may take up to 2 or 3 months for the patient's fatigue to ameliorate. Absence of physical activity during convalescence results in extended fatigue. Infection or other untoward events in the postoperative period also result in a prolongation of fatigue.

FEVER

Pathophysiology

Fever is a disorder of normal body thermoregulation that is controlled by the anterior hypothalamus. Core temperature and its diurnal variation are centered on a set point, normally between 98 and 99°F (37°C). There is speculation that the evolution of fever arose as a protective mechanism to combat infection. It is recognized that certain organisms, such as bacteria and viruses, are heat-sensitive and can be destroyed in vivo by artificially inducing fever. Various pathophysiologic mechanisms, such as pyrogens, are responsible for the generation of fever. Pyrogens may arise from infectious agents such as viruses, bacteria, or fungi as a result of substances released by these organisms or because of the presence of these organisms. In addition, antigen-antibody complexes, steroids, and other inorganic substances have been demonstrated to produce experimental fevers.

All pyrogens appear to evoke a common mediator, endogenous pyrogen or interleukin-1, a monokine produced by leukocytes. Temperature-sensitive preoptic neurons reside within the hypothalamus. Interleukin-1 generates fever by altering the activity of temperature-sensitive neurons located in the anterior hypothalamus. When the set-point is raised, the body's mechanisms for increasing temperature, including heat conservation and increased heat production, are brought into play. The actual body temperature reaches that point a few hours after the set- point has raised. Interleukin-1 is extremely potent; only a few nanograms can affect the hypothalamus and increase core temperature.

When the hypothalamic thermostat is suddenly raised to a higher setting by pyrogen, the blood temperature remains relatively low. The individual feels chills and the skin is cold because of the vasoconstriction induced to conserve body heat. Shivering can occur, a powerful mechanism of heat production. This continues until the blood temperature reaches the set- point. If the set-point drops suddenly, the patient then goes through the flush phase, or *crisis*. During this phase the body attempts to rid itself of excess heat by vasodilatation and sweating. Before the advent of antibiotics, physicians anxiously awaited the flush phase, knowing that the fever would soon resolve.

Fever per se usually is not a significant physiologic problem unless core temperature is elevated above 105°F. The most important role for fever in a critically ill surgical patient is providing an early-warning sign for infection or inflammation. Potential sources include injury, catheters, urinary tract, lungs, surgical sites such as wounds or anastomoses, or thrombophlebitis in the pelvic veins. Drug reactions are another common cause of fever.

Perioperative Fever

(Table 11-7). Between 27 and 58 percent of patients develop a fever for at least 24 h after an operative procedure of modest magnitude. Persistence of a fever for 24 h is not cause for alarm unless it is high and associated with systemic symptoms such as rigor, hypotension, disturbances in mentation, decreases in urine output, or septic shock. If the fever persists for 48 h, it is considered significant. Fever in the immediate postoperative period usually is not serious, is not very high, and is self-limited. It is more likely that the postoperative fever is the result of overcompensation of the set-point in a patient who was cold.

The presence of fever on the first postoperative night is common, usually ascribed to atelectasis, but the usual sources of serious fever, which include wound cellulitis, urinary tract infection, preexistent central venous catheter fever, or drainage spread of an infected focus should not be disregarded. A delayed transfusion reaction, allergic in nature, can be the cause of fever.

Malignant Hyperthermia

This is a rare anesthetic complication that was first reported in 1960, when ten members of an Australian family died after being exposed to a general anesthetic. The incidence is estimated to be approximately 1 in 100,000 general anesthetic procedures. The syndrome consists of a rapid rise in body temperature, usually during the initiation of a general anesthetic after administration of succinylcholine or potent inhalation agents, particularly halothane. Metabolic acidosis and electrolyte imbalances quickly develop, with associated hypercalcemia. In most patients there is hypotonicity of skeletal muscle resulting in the acidosis. The final stages of the event are marked by temperatures approaching 42°C, oxygen desaturation, hypercapnia, and cardiac dysrhythmia.

Prevention is the safest method of limiting the risk to susceptible patients. A family history of complications associated with anesthetics is a warning of this possibly lethal complication. Once the syndrome unfolds, dantrolene is administered intravenously in a dose of 1 mg/kg and repeated as necessary to a total dose of 10 mg/kg. Support measures are initiated promptly, including positive pressure ventilation on 100 percent oxygen, correction of the acidosis and electrolyte imbalance, cooling blankets, monitoring of urine output, and treatment of possible myoglobinuria. After the acute episode, oral administration of dantrolene up to 1 to 2 mg/kg four times a day may be necessary for 1 to 3 days to prevent recurrences.

Fever Within 24 Hours

These fevers usually are attributed to atelectasis or the failure to clear pulmonary secretions. The sources, including wound, thrombophlebitis, urinary tract infection, and catheter sites, also should be evaluated. It is a waste of resources to obtain routine chest x-rays on patients who have a postoperative fever without systemic symptoms or supportive physical findings. The practice of culturing sputum, blood, urine, and blood withdrawn from a catheter in the absence of systemic symptoms is unnecessary. White blood counts are often elevated after operations and rarely determine whether the fever is a manifestation of a significant complication. High fevers with systemic symptoms, such as rigors, hypotension, and changes in mentation, usually are associated with severe wound complications, such as necrotizing fasciitis or an intestinal leak.

Fever at 24–48 Hours

Fever at 24 to 48 h usually is attributed to respiratory complications. Catheter-related problems, especially preexistent catheters or catheters placed in the operating room, also might be the source of fever. The pattern in catheter septic complications is that the fever generally does not cross the baseline. The wound should be carefully inspected for cellulitis and evidence of necrotizing fasciitis or clostridial myositis.

Fever After 48–72 Hours

In patients who are afebrile during the first 72 h, fever usually is a manifestation of a significant complication. Fever can be related to thrombophlebitis, especially in patients with previous episodes of thrombophlebitic complications.

The most common cause of fever after 72 h is wound infection, which may be latent or may be associated with increased wound pain. Urinary tract infections should also be suspected, particularly in patients with catheters. Less common infectious complications include pneumonitis, acute cholecystitis (especially acalculous cholecystitis in patients who are immobile or have received large volumes of blood), idiopathic postoperative pancreatitis (though this occasional complication usually is manifest in the immediate postoperative period), and drug allergy. Unusual nosocomial infections can occur in immunocompromised patients, especially transplant patients. An occasional patient sustains liver necrosis from a chlorinated hydrocarbon, but usually these are evident in the early postoperative period. Hepatitis B, hepatitis C, cytomegalovirus, and other viral illnesses may develop after transfusion.

Candidiasis may complicate intravenous total parenteral nutrition. *Candida* may not grow out on initial blood cultures while the patient is ill. If *Candida* is discovered growing from one or two other sites, such as skin, sputum, or urine, the patient should be treated with amphotericin B, and the TPN line should be removed.

Fever occurring after 1 week is almost always an indication of serious complications unless it is the result of a drug allergy. Late infections can be the result of a leaking anastomosis, an abscess adjacent to the anastomosis, or a deep wound infection that is suppressed by antibiotics.

WOUND COMPLICATIONS

Wound Infection

Predisposing Factors

Wound contamination occurs in the operating room, but not all wounds harboring bacteria become infected. While much of the contamination takes place within the operative field (e.g., a violated hollow viscus), the other major source of wound contamination is the environment. Efforts should be taken to reduce the bacterial count in the operating room. Deterrents include barriers, changes of clothing, appropriate covering of facial and other hair, and the use of scrub suits that minimize the shedding of personal bacteria. Shoe covers also can be worn, but their efficacy is questionable. Floors and walls should be mopped down between cases with antiseptic solution to decrease the bacteria ambient in the operating room. Ultraviolet light at entrances to sterile areas may be efficacious; frequent air changes to 20 times a minute are important.

Sterilization should be adequate. Breaks in technique are particularly important. The contamination of gowns, gloves, and instruments should be promptly remedied. Gloves should be immediately changed when holes are detected. It is important to wall off the wound and viscera and to keep them moist, especially during long procedures.

Staphylococcus aureus is the most frequently involved offending organism. Enteric organisms frequently contaminate wounds when bowel operations are performed. Hemolytic streptococci are responsible for 3 percent of wound infections. Occasionally “surgical scarlet fever,” may complicate these infections. Other less common pathogens include enterococci, *Pseudomonas*, *Proteus*, and *Klebsiella*.

The incidence of wound infection developing in clean, atraumatic, and uninfected wounds is between 3.3 and 4 percent. Clean wounds without emergent operation, drained wounds, or stab wounds have an incidence of 7.4 percent. The figure rises to 10.8 percent when the bronchus, gastrointestinal tract, or oropharyngeal cavity is entered in procedures with unusual contamination. Classification of wounds is given in Table 11-8.

With breaks in surgical technique, infection rates rise to 16.3 percent, and in operations involving perforated viscera, the rate of infection is reported as high as 28.3 percent. In the

latter situation, consideration should be given to delayed primary closure or to prolonged closed-suction drainage of a primary closure.

The rate of wound infection rises from 4.7 percent in the subpopulation of patients who are 15 to 24 years of age to 10 percent in patients over the age of 65 years. Diabetes is not an independent risk factor when adjusted to age, while steroids increase general wound infection rates from 7 to 16 percent. Obesity doubles the infection rate. Remote infections increase wound infection rates. Duration of operation is an important variable; 3.6 percent of procedures that take 30 min or less become infected, while 18 percent of procedures over 6 h in duration are followed by infection. Patients who are malnourished have an increased incidence of infection, but many factors, including cancer and prolonged operations, contribute as variables. Temperature is an important determinant of wound infection; patients who are kept warm during operation have a much lower incidence than patients who are allowed to get cold. Carriers of *S. aureus*, operating room personnel, or the patients themselves increase wound infection. Factors influencing wound infection are presented in Table [11-9](#).

Prevention

Wound infection rates can be minimized in a variety of ways, including (1) skin preparation, (2) bowel preparation, (3) prophylactic antibiotics, (4) meticulous technique, (5) temperature maintenance, and (6) appropriate drainage.

Any damage to the skin, particularly if skin preparation is performed the night before surgery, increases wound infection rates. Fine hair removal is not necessary unless it technically interferes with wound closure. If hair removal is required, clipping immediately before surgery or the use of a depilatory agent results in a wound infection rate of 2 percent versus 5 percent after shaving or clipping the night before or shaving preoperatively.

Bowel preparation decreases wound infection. Mechanical preparation with clear liquids and cathartics is most effective. Although it is difficult to demonstrate reduced wound infection rates with the use of adequate and appropriate systemic perioperative antibiotics, most authorities believe that there is a cumulative beneficial effect. The Condon-Nichols erythromycin base–neomycin is most commonly used, but metronidazole-based regimens are being used with increasing frequency.

Systemic antibiotics should be given immediately before the incision is made and serum levels maintained throughout the procedure above the minimally inhibitory concentration. Redosing is necessary in long procedures. Table [11-10](#) lists appropriate antibiotics. There is disagreement over continued use of antibiotics after the wound closure. Many believe that this is not necessary except in massive contamination, in which case prophylactic antibiotics become therapeutic. Some authorities believe that the infection rate after a clean elective operation can be halved from 4 to 2 percent with a single dose of a first-generation cephalosporin; others are concerned about the spread of resistant organisms and believe that widespread prophylaxis is unnecessary.

Meticulous technique, hemostasis, and gentle handling of tissues contribute to a lower infection rate. Tissues should be kept warm and moist, especially during long procedures. Evidence suggests that wound infections might be prevented if hypothermia does not occur. While warming techniques have improved, they have not completely obviated hypothermia. All exposed parts of the patient should be covered, and a warming pad should be placed before the procedure. Administered fluids and irrigation should be warmed.

Wounds requiring drainage are more likely to become infected (11 percent versus 5 percent in undrained wounds), but it cannot be concluded that the drains are responsible for the infection. The drains may have been used because of concern for adequate hemostasis.

Clinical Manifestations

Wound infections are classified as minor, e.g., purulent material around skin suture sites, or major, e.g., discrete collections of pus within the wound. Superficial infections are limited to the skin and subcutaneous tissue; deep infections involve areas of the wound below the fascia.

Clinical manifestations of a wound infection include *rubor*, *calor*, *tumor*, and *dolor*. The patient may have pain (*dolor*) that is unusually severe given the magnitude of the procedure or the length of time it remains after the procedure. The wound may be warm to the touch (*calor*), it may be swollen and edematous (*tumor*), and there may be surrounding redness and cellulitis (*rubor*). If drainage is not prompt, the resulting wound abscess may be accompanied by substantial cellulitis. Fever to 101–102°F (to 39°C) usually is present with some increase in pulse rate.

Wound infections usually are evident between the fifth and eighth postoperative days. When patients have received antibiotics, wound infections may become manifest weeks after an operative procedure. In cases of severe necrotizing fasciitis or clostridial myositis, manifestations may occur within 24 h.

Management

Management of wound infections depends on the extent of destruction and the type of wound infection. A simple collection of purulent material in the skin and subcutaneous tissue without major surrounding cellulitis is treated by opening the incision. The incision is opened enough to provide adequate drainage, and a wick is placed in the wound to prevent the skin and superficial subcutaneous tissue from closing before complete drainage.

Opening the wound alone is insufficient in severe clostridial myositis or necrotizing fasciitis with loss of viability of the fascia or muscle. Radical debridement is necessary to save the patient's life. Discharge of "dishwater pus" should alert the surgeon to the possibility of necrotizing fasciitis. A Gram stain will reveal a mixed flora of gram-negative rods and gram-positive cocci. Clostridial myositis is manifest by crepitus (gas in the tissues), which also may be present in necrotizing fasciitis, and vesicles on the skin. In both situations, the patient is more sick than expected with a simple wound infection. When wound infections are associated with surrounding cellulitis and edema, the use of antibiotics in addition to opening and debriding the wound is necessary. A Gram stain may identify some of the offending organisms. In the absence of specific information, the wound should be cultured and the patient placed on ampicillin (or clindamycin), gentamicin, and metronidazole or a combination of antibiotics that covers the organisms most likely to be present. If hemolytic streptococcus is the offending organism, penicillin should be administered for 1 week.

Diabetic patients are prone to Fournier's gangrene, which is a form of necrotizing fasciitis of the perineum or groin. These patients require wide debridement. Fournier's gangrene often is fatal, with mortality rates of 30 to 75 percent.

Wound Hematomas

Wound hematomas are caused by inadequate hemostasis. Anticoagulation, fibrinolysis, polycythemia vera, myeloproliferative disorders, and decreased or inadequate clotting factors all contribute to hematoma formation. Great care must be taken in closing incisions in a patient who is in shock or in induced hypotension, or wounds in which epinephrine has been used. Hematomas provide good culture media for bacteria that might contaminate the wound and a barrier to the apposition of the wound edges. When the hematoma resolves, an untoward cosmetic result may occur.

Wound hematomas are manifest by pain and swelling of the wound. Drainage, if present, usually is serosanguinous, indicating a collection of bloody material within the wound. In certain locations, such as the neck, a large hematoma can be life threatening, and the hematoma must be evacuated immediately.

When the hematoma is discovered early postoperatively, the patient should be returned to the operating room and, under sterile conditions, the wound opened, the hematoma evacuated, the responsible vessel found and ligated, and the wound closed primarily. If hematomas are discovered late, heat should be applied to the wound and the patient managed expectantly with the hope that the hematoma has not become contaminated. If the surgeon suspects the possibility of a postoperative hematoma because of predisposing factors or difficult hemostasis, a closed-suction drain should be used. The catheter should exit through a separate stab incision remote from the primary wound.

Wound Seromas

Seromas are lymph collections usually resulting from, and associated with, operations in which large areas of lymph-bearing tissues are transected. Examples include axillary dissection and groin dissection. Closed-suction drains are placed to prevent seromas and are kept in place until drainage stops, but drains are not foolproof. Seromas are fertile ground for bacteria to create wound infections. If seromas are discovered in the postoperative period, repeated aspiration is indicated, or, preferably, closed-suction drains are placed percutaneously until fluid no longer accumulates, and the skin flaps are allowed to adhere. Pressure dressing may be helpful in conjunction with aspiration and continuous closed-suction drainage.

Wound Dehiscence

Dehiscence is separation within the fascial layer, usually of the abdomen, whereas *evisceration* indicates extrusion of peritoneal contents through the fascial separation. The incidence of wound disruption is between 0.5 and 3.0 percent, averaging 2.6 percent when all abdominal procedures are considered. Dehiscence occurs in 1.3 percent of patients under 45 years of age, and 5.4 percent of patients over 45 years of age. Many patient characteristics may contribute to a fascial dehiscence, but generally dehiscence is caused by a technical factor. Patient characteristics that contribute to fascial dehiscence should sensitize the surgeon to take precautions using a mass closure or anterior fascial retention sutures, which may not prevent dehiscence but may prevent evisceration.

Malnutrition, hypoproteinemia, morbid obesity, malignancy with immunologic deficiency, uremia, diabetes (especially with poorly controlled blood glucose levels), coughing with increased abdominal pressure, and remote infection are contributory factors. Dehiscence occurs in over 5 percent of patients with cancer, compared with less than 2 percent in patients with benign conditions. Jaundice has been associated with an increased incidence of wound dehiscence, but it is unclear whether this is a direct effect of the bilirubin or is the effect of all of the deficiencies that are associated with end-stage liver disease. Preoperative biliary drainage does not result in a decrease in wound complications or dehiscence. Ascites increases the incidence of wound disruption.

Local factors increasing wound disruption include hemorrhage, infection, excessive suture material, and poor technique. Series are contradictory as to whether dehiscence is increased in vertical as compared with horizontal incisions, but all agree that when a stoma is brought out through an incision the incidence of disruption is increased.

A multicenter, randomized, prospective trial compared interrupted versus continuous polyglycolic acid suture closure of midline abdominal incisions. The overall dehiscence rate was 1.6 percent in the continuous suture group and 2.0 percent in the interrupted suture group. The dehiscence rate was significantly higher in the interrupted suture group when wounds were contaminated. Monofilament sutures have a lower incidence of disruption than braided sutures.

Vitamin C is essential for collagen synthesis and fibroblast formation, bacterial destruction, and superoxide production by neutrophils. Many elderly patients are subclinically scorbutic, a condition associated with an eightfold increase in the incidence of wound dehiscence. Zinc is a cofactor for various enzymatic and mitotic processes, particularly of the epithelial cells and the fibroblasts. Patients with diarrhea, hepatic insufficiency, or chronic stress may be subject to zinc deficiency that is associated with poor healing. Steroids,

administered topically or systemically, have a deleterious effect on wound healing, interfering with wound healing at every level, including inflammation, wound macrophage function, capillary proliferation, and fibroplasia. Vitamin A may counteract these effects.

Chemotherapeutic agents inhibit wound healing. In patients with neoplastic disease, chemotherapeutic agents should not be used during the first week and probably also during the second and third weeks after operation. In breast disease, the use of 5- fluorouracil in the first postoperative week results in an increased incidence of skin dehiscence and delayed healing. A trial of 5-fluorouracil in patients with colon cancer, administered during and after operation, however, did not have a deleterious effect on wound healing. Radiation is known to affect wound healing adversely because of a variety of factors, including interference with normal protein synthesis, mitosis, migration of inflammatory factors, and maturation of collagen. Radiation therapy also results in obliteration of the small vasculature and fibrosis, which contribute to the vicious cycle of local hypoperfusion and hypoxia.

Clinical Manifestations

Dehiscence without evisceration can be detected by the “classical” appearance of salmon- colored fluid draining from the wound, which occurs in about 85 percent of cases about the fourth or fifth postoperative day. With the appearance of such fluid, the patient should be returned to the operating room and the wound opened under sterile conditions. Dehiscences may become manifest when skin sutures are removed and evisceration of abdominal contents occurs. If evisceration occurs, moist sterile towels are applied to the extruded intestines or omentum and the patient returned to the operating room. Dehiscence presents late as an incisional hernia.

Treatment

Management depends on the patient's condition. In some circumstances, if there is no evisceration, it is preferable to treat the patient nonoperatively with a sterile occlusive wound dressing and binder, accepting a postoperative hernia. Repair of dehiscences varies but generally involves a mass closure. There is little reason to attempt to redo a closure in which sutures, appropriately placed 1 cm apart, have pulled through. Perioperative (preferably broad-spectrum) antibiotics should be given. The mortality associated with wound disruption has been reduced from over 30 percent to below 1 percent. The incidence of reported postoperative hernia is inaccurate but is probably over 30 percent.

COMPLICATIONS OF THE GENITOURINARY SYSTEM

Urinary Retention

Urinary retention frequently complicates operations in males, but rarely in females. While the incidence of urinary retention after major abdominal surgery ranges from 4 to 5 percent, the incidence after anorectal surgery may be greater than 50 percent. Voiding requires a coordinated interaction between release of the alpha-adrenergic receptors in the smooth muscle of the bladder neck and urethra and parasympathetic stimulation so the bladder can contract and the urine can exit. Stress, pain, spinal anesthesia, and various anorectal reflexes conspire to increase alpha- adrenergic stimulation, which prevents release of the musculature around the bladder neck. In one study using phenoxybenzamine, there were no episodes of urinary retention in 58 older male patients after inguinal herniorrhaphy, compared to a 26 percent incidence of retention in 44 control patients. A similar study using bethanechol to stimulate parasympathetic activity, however, showed no benefit. Use of prazosin hydrochloride in a randomized prospective trial of male patients undergoing surgery for hip and knee prostheses resulted in a significant decrease in the incidence of postoperative urinary retention: 21 percent in the treated group, compared to 59 percent in the control group.

Another influence on urinary retention, especially in older patients, is the volume of infused fluid. A minimal volume of fluid should be infused in situations in which blood loss is likely to be minimal and the patient is not dehydrated.

In urinary retention, patients experience urgency, discomfort, and fullness, and an enlarged bladder can be percussed above the pubic symphysis. Straight catheterization is undertaken initially and then usually a second time. The bladder should not be allowed to distend beyond 6 h, because this will impair the patient's ability to void when the catheter is removed. If catheterization is required more than twice, a Foley catheter is placed and left to drain for at least 2 to 7 days.

Acute Renal Failure

Etiology

Inadequate Resuscitation

In the presence of hypotension, catecholamine release and norepinephrine stimulation by the sympathetic nervous system decreases renal blood flow. In addition, the renin-angiotensin system is activated with shunting of blood away from the afferent arterioles, depriving the cortex and the tubules of blood flow. A basic dictum in the care of emergency patients is ensuring significant and adequate urine output before going to the operating room and, if there is time, resuscitating such patients. In the elderly, it should be remembered that it is not *rapid* rehydration or transfusion, but *overhydration* and *overtransfusion* that are responsible for congestive failure. If there is any question in the surgeon's mind about the patient's volume status before going to the operating room, a pulmonary artery catheter should be passed, the patient's fluid and volume status optimized, and the operation delayed so that urine output is adequate before general anesthesia is induced. In the presence of transfusion reaction, sepsis, myocardial dysfunction, or crush injury, diuresis should be established using mannitol and furosemide (the latter given only when volume status is restored). Bicarbonate should also be administered to alkalinize the urine. Other causes of acute renal failure are listed in Table [11-11](#).

Drug Toxicity

A second important cause of acute renal failure in the surgical setting is the use of nephrotoxic drugs, most commonly the aminoglycosides, vancomycin, amphotericin B, and occasionally high doses of penicillin G or sulfonamides. Pharmacokinetic monitoring is used to determine the minimal inhibitory concentration in the plasma required for the organism in question. Pharmacokinetic monitoring does not prevent and may not substantially decrease vestibular toxicity or the incidence of renal failure. Heroin, thiazides, lithium, and occasionally vitamin D also are responsible for renal dysfunction. Acetaminophen in high doses, in addition to causing hepatic failure, also may cause interstitial nephritis (Table [11-12](#)).

Pathophysiology of Renal Dysfunction

Prerenal Dysfunction

Prerenal dysfunction is characterized by a BUN-to-creatinine ratio of 20:1 or greater. This is commonly observed with dehydration, e.g., after a bowel preparation or fulminant diarrhea, or underresuscitation of patients before or after an operative procedure. If the patient with prerenal azotemia is taken to the operating room inadequately resuscitated, there is an increased likelihood of acute renal failure. The diagnosis is fairly clear when the patient is hypotensive, overtly hypovolemic with decreased skin turgor and has sunken eyes and flaccid skin.

Another type of prerenal azotemia is a complication of liver disease. The hepatorenal syndrome is divisible into two forms. The first is basically hypovolemic, and the second is a maldistribution of blood flow (Fig. [11-3](#), Table [11-13](#)). In Type I, there is a deficiency in intravascular volume secondary to the presence of a high-grade outflow block in the liver leading to production of ascites and an inability of the liver to return the lymph to the systemic circulation. Lymph leaks from the surface of the liver into the peritoneal cavity. The patients have a low cardiac output, a tendency to high peripheral resistance, a urinary sodium concentration below 10 mEq/dL, and they appear underperfused and vasoconstricted. The patients generally improve with ascites reinfusion, volume challenges, or a side-to-side type portal decompression. The Type II hepatorenal syndrome usually is associated with a failing liver, an elevated bilirubin level, and other stigmata of cirrhosis such as an elevated prothrombin time and a low serum albumin level. In contrast to the intravascular depletion seen in Type I, the intravascular volume may be adequate. Cardiac output is increased, and there is low peripheral resistance. Hepatorenal syndrome is a hemodynamic rather than a renal disease. Kidneys from patients with hepatorenal syndrome are normal. They can be transplanted with prompt function, which has been shown repeatedly. Recovery from hepatorenal syndrome is rare and depends on the recovery of the intrinsic liver disease.

Intrinsic Damage

Intrinsic damage in the surgical setting includes a series of merged forms of tubular damage, known as acute tubular necrosis. In addition to acute tubular necrosis, pigment nephropathy and drug nephrotoxicity are prominent. The most common cause of acute tubular necrosis in the surgical setting is diminished renal perfusion secondary to prolonged and sustained hypotension in the presence of sepsis, blood loss, hypovolemia, dehydration, or myocardial infarction. This results in prolonged ischemia of the renal parenchyma. The kidney attempts to maintain glomerular blood flow and filtration by afferent arteriolar dilatation and efferent arteriolar vasoconstriction. As hypotension continues, the renin-angiotensin system attempts to correct for the perceived hypoperfusion, increasing angiotensin. Release of norepinephrine by the sympathetic nervous system with angiotensin causes afferent arteriolar vasoconstriction. Tubular ischemia and hypoperfusion of the renal cortex result; if tubular hypoperfusion persists, acute tubular necrosis results. In the traumatic setting, the presence of myoglobin and, in the case of transfusion reaction, free hemoglobin also complicates the renal injury.

The use of large amounts of radiocontrast medium causes reversible renal failure that usually clears after 3 to 10 days if the patient is maintained in a state of adequate hydration. When added to renal hypoperfusion from other causes, however, the damage may be prolonged and irreversible. Another cause of acute tubular necrosis that is commonly observed in the surgical setting is the showering of atheromatous emboli during aortic vascular surgery. The application of a clamp close to the renal artery may break off plaque that showers the renal vasculature, resulting in multiple infarcts and obstruction of various arterioles.

Postrenal Failure

Postrenal failure is rare in the surgical setting but may result from ureteral clots or stones. Chronic postrenal obstruction may result from benign prostatic hypertrophy. Prolonged Foley catheter intubation can result in a posterior urethral stricture.

Prevention of Acute Renal Failure

For patients with chronic urinary tract infection, specific antibiotics selected on the basis of cultures and sensitivities should be administered to eradicate the infection. Patients with chronic obstruction from benign prostatic hypertrophy should be treated with preemptive balloon dilatation or transurethral resection. In patients with chronic renal impairment, saline loading and adequate diuresis are established before general anesthesia. A pulmonary artery catheter is placed after the patient is adequately hydrated and sodium-containing fluids administered until a urine output of 50 to 100 mL/h is obtained. A patient with inadequate urine output should not be subjected to general anesthesia, because acute tubular necrosis can result.

If an angiographic workup is necessary, it is best performed several days before the operation so that if renal failure complicates the angiogram the effect is minimized. Use of radiographic contrast agents has an incidence of renal failure of 1 to 10 percent. Injury is due to direct nephrotoxic effect and hypovolemia from osmotic diuresis. Prestudy hydration is partially protective. If possible, antibiotics that are not nephrotoxic should be used.

In low-flow states, mannitol, bicarbonate, and diuresis induced by furosemide should be used. Mannitol is known to increase renal cortical blood flow and produce an osmotic diuresis. It may protect the tubules by preventing precipitation of metabolites within them. Renal perfusion may be increased by a “renal dose dopamine” of 2 to 5 mg/kg/min. If there

is any question concerning the volume status, central venous pressure monitoring or, preferably, monitoring of left-sided filling pressure with a pulmonary artery catheter is appropriate.

Manifestations

Acute renal failure usually presents in the postoperative period as oliguria with a urine output of 0.4 to 0.5 mL/kg/h in an adult. Anuria, while uncommon, as a manifestation of acute tubular necrosis probably is the result of renal artery thrombosis or obstructive uropathy. The diagnosis of acute tubular necrosis is made by spot measurement of urinary sodium and potassium levels and osmolality. The fractional excretion of sodium (FE_{Na}) is calculated using levels of sodium and creatinine in the urine or plasma as follows:

$$FE_{Na} = U_{Na} \times V / P_{Na} \times (U_{Cr} \times V / P_{Cr}) \times 100\%$$

where:

U_{Na} = urinary sodium

P_{Na} = plasma sodium

U_{Cr} = urinary creatinine

P_{Cr} = plasma creatinine

V = urine volume in mL

An FE_{Na} of greater than 1 indicates intrinsic renal damage. Measurement of urinary specific gravity may be helpful in the absence of pigment or contrast; urinary specific gravity in acute tubular necrosis is approximately 1.010. A urinary sodium level of less than 10 mEq/L indicates a prerenal cause or intrinsic liver disease. BUN and creatinine levels also are elevated. In the case of renal failure, tubular cells and casts, red blood cells, and white blood cells on urinalysis are diagnostic. The urinary sodium level usually is greater than 40 mEq/L, the potassium level is about the same figure, osmolality is approximately between 300 and 350, and the fractional secretion of sodium is greater than 3. The BUN-to-creatinine ratio is less than 20. The following formula may be used to calculate the creatinine clearance: C_{cr} = V × U_{Cr}/P_{Cr}, where V = volume, U_{Cr} = urinary creatinine, and P_{Cr} = plasma creatinine.

Management

The management of renal failure can be divided into two periods, the first when the diagnosis is uncertain, and the second when the diagnosis has been made. If the patient is oliguric and thought to be hypovolemic, a volume challenge is in order. If the initial volume challenge results in elevation of jugular neck veins, skin turgor, and eyeball depth, a pulmonary artery catheter should be placed to measure the patient's true volume status. Once adequate volume status has been established, furosemide (20 to 40 mg) should be given to improve urine output. Mannitol can be given to increase renal cortical blood flow, provided the patient is not volume overresuscitated. Ethacrynic acid or a furosemide drip can be used to prevent renal failure and perhaps “wash out” those tubules in which urine flow can be reestablished. “Renal dose dopamine” also may be used in conjunction with diuretics; bicarbonate is given in an attempt to slightly alkalinize the patient. Any nephrotoxic drugs (see Table [11-12](#)) should be stopped immediately.

Management of Established Renal Failure

When the patient has been diagnosed with renal failure, there are a number of goals:

- (1) Avoid overhydration, which results in congestive heart failure and the need for hemofiltration or dialysis.
- (2) Avoid dialysis if possible.
- (3) Avoid toxic ionic damage, such as hyperkalemia.
- (4) Provide nutritional support.

The most immediate threat in many patients with acute renal failure is hyperkalemia. Serum electrolyte levels should be monitored frequently. When serum potassium level reaches 5.5 mEq/ dL, there is need for concern, because rapid rises to the point where ECG changes occur can happen very quickly. ECG changes include peaked T waves with progression to a sinus bradycardia and a sine wave rhythm, with hypotension and death. Deaths from hyperkalemia are avoidable. The emergency treatment of hyperkalemia includes the infusion of calcium, hypertonic dextrose solution, and insulin. Thereafter, sodium polystyrene sulfonate (Kayexalate) 5 g as enema or by mouth should be administered. Infusion of hypertonic dextrose solution and essential amino acids in the form of total parenteral nutrition will lower the serum potassium level. Administration of fluids should be limited to below measured and calculated losses.

Maintenance of nutrition is an essential part of the treatment of patients with acute tubular necrosis. Nutrition can be administered enterally or parenterally. Increased survival in patients with acute tubular necrosis has been demonstrated only with intravenous nutritional support. An intravenous “Giordano-Giovannetti diet” of essential amino acids and hypertonic dextrose solution, with a minimum of fat, decreases mortality in patients with acute tubular necrosis. The most significant improvement is seen in the more severely affected patients with complications and in those with oliguric renal failure requiring dialysis. There is some, but not statistically significant, improvement in patients with non-oliguric renal failure. Nutritional support may delay the need for dialysis or cellular filtration because it minimizes the free water produced by muscular breakdown. It is not clear whether semiessential amino acids, such as arginine and histidine, should be included in this essential amino acid diet. While it is true that these amino acids may become deficient with chronic dialysis, plasma amino acid patterns in patients with acute renal failure do not reveal any evidence of amino acid deficiency.

Dialysis is undertaken in patients with acute renal failure for critical ionic excesses, volume overload, or a BUN concentration higher than 80 to 100 mg/dL. Volume overload may be prevented by continuous hemofiltration. Under most circumstances, hemodialysis is the procedure of choice, but chronic peritoneal dialysis may be successful after the retroperitoneum is sealed.

Dialysis is not innocuous; it has an annual mortality of 5 to 10 percent. The hypotension that usually is seen at the termination of the dialysis run, when patients are dehydrated, can be injurious to the kidneys. There is an advantage to delaying dialysis until patients are hemodynamically stable. Once patients are on chronic dialysis, essential and nonessential amino acids are given by TPN or, preferably, enterally.

RESPIRATORY COMPLICATIONS

Pathophysiology

Respiratory complications are among the most common complications of surgery and the most lethal, responsible for 5 to 35 percent of postoperative deaths. Upper abdominal and thoracic incisions result in a significant decrease in vital capacity and functional residual capacity, most prominently in the first 24 h after operation. After upper abdominal surgery, vital capacity may be reduced by as much as 50 to 60 percent, while functional residual capacity is reduced by approximately 30 percent. The cause of these changes is multifactorial. Postoperative pain alters the mechanics of respiration; upper abdominal and thoracic incisions have the greatest impact. Narcotic analgesia carries it own inherent risks because it eliminates sighing and promotes atelectasis. Even if pain is eliminated by epidural anesthesia, there remains a demonstrable decrease in vital capacity and functional residual capacity, an observation that has led some to suggest diaphragmatic dysfunction. Diaphragmatic inhibition can result from inhibitory reflexes arising from sympathetic, vagal, or abdominal receptors.

Closing volume (lung volume at which airway closure is first detectable) decreases in the postoperative period. Loss of functional residual capacity, elimination of sighing (by narcotic analgesics), and the change to a postoperative breathing pattern of small frequent breaths combine to lower the end-tidal point to a level that falls below closing volume. This results in a rapid loss of alveolar volume and subsequent alveolar collapse. This predilection is accentuated in smokers, who characteristically have a higher closing volume as a result of their diseased airways.

In addition to altered mechanics and decreased closing volume, other physiologic causes that contribute to respiratory insufficiency include diffusion defects, abnormalities in the ventilation-perfusion ratio, reduction in cardiac output with concomitant persistent shunt, alterations in the hemoglobin level and persistent shunt, and shunting that is anatomic or related to atelectasis.

Measurements of ventilation and oxygenation have been applied to assess the pathophysiologic events. Ventilatory mechanics are evaluated by measuring the ventilatory rate, the vital capacity (VC), total volume (VT), and dead space (VD). VD/VT, which also is influenced by cardiac output, is used to assess CO₂ elimination. Compliance is a measurement of the distensibility of the lung.

The partial pressure of CO₂ in arterial blood (Pa_{CO2}) can be considered as a reciprocal function of ventilation and is normally 40 mmHg. The adequacy of intrapulmonary blood-gas exchange is determined by measuring the Pa_{CO2} and Pa_{O2} in relation to the fraction of inspired oxygen (FI_{O2}). One method of estimating the efficacy of oxygen exchange in the lung is to measure the alveolar-arterial oxygen tension difference [(A - a)D_{O2}]. Factors influencing the (A - a)D_{O2} include the degree of mismatching of ventilation to perfusion, shunts around the lung, the difference between the arterial and mixed venous oxygen content, the mixed venous oxygen content (which may reflect oxygen consumption), the cardiac output, the inspired oxygen concentration (FI_{O2}), the position of the oxygen hemoglobin dissociation curve, and the position of the Pa_{O2} on the curve. A nomogram can be used to define the calculated amount of blood shunted around the lung as a fraction of the total cardiac output (*Q* /*Q*_T) based on the measurement of Pa_{O2} and pulmonary alveolar oxygen tension (PA_{O2}) (Fig. 11-4). Small changes in the *Q* /*Q*_T are more readily detected when the patient is breathing 100 percent oxygen for 20 to 30 min. This may result in absorption atelectasis, which increases *Q* /*Q*_T. Therefore, “shunt fraction” usually is measured at the inspired O₂ concentration (FI_{O2}) required to maintain an adequate arterial P_{O2} (60 to 70 mmHg or greater). The ratio of arterial P_{O2} to alveolar P_{O2} is independent of inspired FI_{O2}. Determinations are affected by alterations in the cardiac output and pH.

Predisposing Factors

A number of recognized risk factors predispose the patient to the development of pulmonary complications. Some of these risk factors cannot be appreciably altered (age, cardiac disease, or surgical site), but many risk factors may be favorably influenced during the preoperative period.

Smoking

The surgeon should distinguish chronic parenchymal lung changes from the short-term, potentially reversible effects. Patients who smoke are encouraged to stop before their operation. A patient must abstain from smoking for at least 8 weeks to achieve any demonstrable benefit. Patients who have stopped smoking for more than 8 weeks before surgery have as low a risk of pulmonary complications as patients who have never smoked. Less than 20 percent of patients who are requested to stop smoking preoperatively actually are able to do so.

Age

It is difficult to determine the risk attributable to age independent of the associated changes that accompany the aging process. Advanced age alone should not govern the decision for or against surgery. Overall poor physical status, rather than advanced age, is the most important risk factor in determining perioperative respiratory complications.

Obesity

The predilection for development of postoperative respiratory complications in obese patients is related to the underlying pulmonary dysfunction characteristic of this patient population. Patients who exceed their ideal body weight by more than 30 percent have a demonstrable decline in their functional residual capacity, which is the result of a reduction in chest wall compliance. This intrinsic loss of functional residual capacity, when combined with supine positioning, renders the obese patient particularly prone to hypoventilation and hypoxemia in the postoperative period.

Chronic Obstructive Pulmonary Disease (COPD)

Patients with preexisting pulmonary disease are at increased risk of postoperative complications. Pulmonary function tests provide a means to quantify objectively existing pulmonary abnormalities. Specific findings on pulmonary function tests that should alert the surgeon include abnormalities in FEV_1 , forced vital capacity (FVC), peak expiratory flow rate, and FEV_1/FVC ratio (see Table [11-2](#)).

In patients with recognized COPD, the surgeon must plan to improve the likelihood of a successful outcome. This includes careful planning of the incision, use of local anesthetic agents, careful closure of the wound, placement of gastrostomy tube, and postoperative pulmonary toilet techniques. A transverse incision is preferable to a vertical incision. Use of local anesthetics such as lidocaine or bupivacaine decreases intraoperative and postoperative incisional pain. In selected patients it is possible to place a small catheter for continuous infusion of lidocaine in the intramuscular layers of the incision to render the incision anesthetic. This simple maneuver may significantly improve a patient's pulmonary function. Wound closure in the patient with COPD should emphasize a secure closure with minimal postoperative pain, such as a subcuticular closure. Pain control, such as the use of an epidural catheter, is a significant improvement. In the absence of a postoperative epidural catheter, patient-controlled analgesic devices result in fewer respiratory complications. A gastrostomy (rather than a nasogastric) tube is useful in patients with COPD, as multiple studies have shown that a nasogastric tube in the postoperative period is the one clinical factor associated with a statistically increased incidence of respiratory complications.

Cardiac Disease

The most obvious example of cardiac disease complicating postoperative respiratory function is congestive heart failure with accompanying pulmonary edema. Patients with jugular venous distention, a third heart sound, or previous history of pulmonary edema are most likely to develop this complication. Patients with significant cardiac dysfunction and surgical patients who receive large amounts of fluids during their resuscitation should be observed closely for the development of pulmonary edema in the postoperative period.

Atelectasis

Atelectasis, the collapse of alveoli with ongoing perfusion, is the result of changes in the normal dynamics of pulmonary function resulting from anesthesia, diaphragmatic dysfunction, postoperative incisional pain, and patient positioning. Emphasis should be on prevention rather than treatment. Atelectasis results in a perceptible increase in shunt fraction. Once collapsed, the alveolus is difficult to rerecruit. This may be due to the loss of surfactant but also is a physical property because of the surface tension considerations of the pulmonary parenchyma. Secretions may accumulate in the collapsed alveolus, with potential bacterial overgrowth.

Lung inflation in the postoperative period prevents and reverses atelectasis. The most frequently used techniques include coughing and deep breathing (CDB), chest percussion and postural drainage (CPPD), incentive spirometry, intermittent positive pressure breathing (IPPB), and continuous positive airway pressure (CPAP). Each technique employs a different method to achieve the same goal of lung inflation. Various studies support the use of any of these techniques as superior to no postoperative therapy. The techniques of coughing, deep breathing, and incentive spirometry are inexpensive and not labor-intensive. CPPD, IPPB, and CPAP require significant labor, machinery, or a combination of both. Patients who are at low risk for the development of respiratory complications, such as those undergoing a lower abdominal incision or extremity surgery, probably do not require specific therapeutic interventions. For patients who have moderate risk of developing perioperative respiratory complications, coughing and deep breathing or the use of incentive spirometry usually will suffice.

Three groups of medications have been applied to the prophylaxis and therapy of atelectasis: (1) expectorants, to provide more liquid and less viscous secretions, (2) detergents and mucolytic solutions, to alter the surface tension of secretions and render their elimination more likely, and (3) bronchodilators, used primarily by inhalation, to increase the size of the tracheobronchial tree and eliminate bronchospasm. The mucolytic agents, such as Mucomist or Alevaire, are indicated because inhaled air with a relative humidity lower than 70 percent inhibits ciliary activity and tends to desiccate secretions.

Pneumonitis

Pneumonitis is a nosocomial infection seen with increasing incidence on surgical services. While pneumonitis is the third most common nosocomial infection (after wound and urinary tract infections), it is associated with the highest morbidity and mortality. The organisms involved are powerful pathogens and include *Pseudomonas*, *Serratia*, *Klebsiella*, *Proteus*, *Enterobacter*, and *Streptococcus*. There is an emerging predominance of gram-negative organisms, particularly in patients in intensive care units. This may be a reflection of the widespread use of H_2 -receptor antagonist therapy. Use of these agents results in breakdown of the acid barrier, allowing overgrowth and colonization of the stomach by intestinal flora. This situation is further aggravated by the placement of a nasogastric tube and the use of supine positioning in the postoperative period. Fungal pneumonia is uncommon, but with the increasing use of ever broader spectrum antibiotic regimens, the emergence of this pathogen in the future is likely.

Clinical Manifestations

Patients with pneumonia manifest fever, productive cough, dyspnea, pleuritic chest pain, and a purulent sputum. Bloodstained sputum is rare but may be exacerbated by repeated suctioning attempts. Moderate hypoxemia is common, but severe hypoxemia is unusual unless the pneumonia is severe and widespread. The presence of hypotension usually indicates a gram-negative pneumonia. Auscultation reveals bronchial breathing, areas of dullness to percussion, and the presence of rales.

Management

Management depends on correctly identifying the responsible organism. The proper technique for obtaining an adequate respiratory specimen for the diagnosis of pneumonia is controversial. In the intubated patient, there is increasing emphasis on obtaining a bronchoscopic-guided alveolar lavage specimen or the use of a protected-brush catheter technique. Multiple studies in patients who are intubated have demonstrated that cultures obtained via routine endotracheal suctioning have little predictive benefit in correctly identifying the pathogen responsible for nosocomial pneumonia. Given the increasing incidence of gram-negative nosocomial infections in the intensive care setting, antibiotic therapy with an aminoglycoside and an antipseudomonal penicillin should be initiated when the diagnosis is made. Antibiotic usage must be evaluated with culture results and modified if necessary.

Aspiration

Aspiration can be a cataclysmic, instantaneously lethal event associated with large amounts of particulate-laden acid contents unless expeditiously managed by suction, lavage of the respiratory tree, protection of the airway with an endotracheal tube, and continued pulmonary toilet until all particulate matter has been removed from the tracheobronchial tree. The use of steroids to ameliorate the progression of the clinical syndrome of aspiration has been demonstrated to be effective only when they have been given before the aspiration event. The most likely setting of massive aspiration is during the emergency induction of anesthesia, particularly in patients with gastroesophageal reflux or a hiatal hernia. It is commonly assumed that a nasogastric tube prevents aspiration, but this is not always the case. If a nasogastric tube is improperly positioned or maintained, its presence may facilitate rather than prevent aspiration.

Clinical Manifestations

The clinical sequelae of aspiration usually are not subtle, with the presence of gastric contents in the mouth followed by wheezing, hypoxia, bronchorrhea, and cyanosis. In the conscious patient, cough productive of particulate matter may be present. In the unconscious patient, aspiration may present as a major airway obstruction. Suctioning reveals gastric aspirate in the oropharynx and trachea. If aspiration is untreated, or if it is significant in volume, the results resemble that of a pulmonary burn, with edema, wheezing, cyanosis, and tachycardia. Chest radiographs demonstrate progression of local damage and infiltration. Acute respiratory failure results. In over 50 percent of patients who suffer aspiration, the initial chemical pneumonitis results in bacterial colonization with subsequent development of pneumonia.

Management

The only effective treatment of aspiration is prevention by emptying the stomach and neutralization of gastric contents. Evidence has suggested that neutralization strategies that use histamine H_2 -receptor antagonists or proton pump inhibitors elevate gastric pH to a point at which bacterial overgrowth may occur. Treatment of the early phase of aspiration includes removal of debris and lavage of the upper airway. Endotracheal intubation usually is necessary to initiate treatment and to complete clearance of the tracheobronchial tree. Bronchoscopic clearance of the airway is useful to clear all particulate debris. Bronchodilating agents may help in relieving obstruction in those patients with audible wheezing from reactive airway response. Positive-pressure ventilation (PPV) and *positive end-expiratory pressure (PEEP)* are often necessary, and a pulmonary artery catheter is useful in determining volume status.

Pulmonary Edema

Pulmonary edema results when pulmonary-capillary hydrostatic pressure exceeds plasma oncotic pressure. The result of this imbalance is fluid transudation into the alveolus. The most common causes of pulmonary edema in the surgical patient are fluid overload or myocardial insufficiency secondary to myocardial infarction/ischemia. Additional causes of pulmonary edema include sepsis, valvular dysfunction, neurogenic stimulation, and hepatic failure.

Increased capillary permeability also can result in a transudation of fluid into the alveolus. Common causes of increased capillary permeability include sepsis, *acute respiratory distress syndrome (ARDS)*, and acute pancreatitis.

Clinical Manifestations

There are two peak phases of occurrence of pulmonary edema in the surgical patient. The first occurs during resuscitation. If resuscitation is too aggressive or overreplaces intravascular volume, pulmonary edema may result. The second peak incidence of pulmonary edema is in the postoperative period when fluid mobilization occurs. If the patient's cardiovascular and renal systems do not maintain an adequate pace to off- load the mobilized fluid, pulmonary edema may result, particularly in the elderly patient. When volume status is in doubt, placement of a pulmonary artery catheter is valuable because it allows for adequate estimation of vascular volume and of end points of resuscitation, and it aids in the phase of fluid mobilization.

The patient with pulmonary edema manifests dyspnea at rest, tachypnea, and air hunger. In the elderly or immunocompromised patient, changes in mental status, including lethargy and disorientation, may occur. Wheezing and signs of bronchospasm may be audible. In addition, rales that often are up to the clavicles on posterior auscultation, distended neck veins, cyanosis, and peripheral pitting edema may be present. Chest radiographs may reveal progression of pulmonary edema, vascular prominence, septal lines (Kerley's B lines), and peribronchial and perivascular cuffing.

Management

Management depends on the inciting cause. For patients with a volume overload, simple therapy including oxygen and digitalization can significantly improve the clinical condition. In most instances, the placement of a pulmonary artery catheter significantly aids in the diagnosis and management. The initial findings reveal an elevated pulmonary artery occlusion pressure in the range of 18 to 25 mmHg. Cardiac index is normally decreased, with a concomitant elevation of peripheral vascular resistance. The observation of a low or normal pulmonary artery occlusion pressure (8 to 15 mmHg) suggests an alternative cause, such as acute respiratory distress syndrome or sepsis. An ECG should be obtained to evaluate the presence of pump failure as a result of myocardial infarction. In the setting of an abnormal ECG, cardiac enzymes should be drawn for confirmation by evaluation of MB fraction.

Additional therapeutic measures include oxygen and positioning the patient in the upright position. Diuretics, such as furosemide, are used to promote an off-loading of volume. Intravenous nitroglycerin can promote an increase in venous capacitance and subsequently decrease preload. Low-dose dopamine (2 to 5 mg/kg/min) may also be used to promote diuresis. Inotropic agents, such as dobutamine or amrinone, may improve cardiac output. If these maneuvers fail to produce a sufficient cardiac index, the use of afterload reduction agents, such as sodium nitroprusside, should be considered. Pulmonary embolism is another potential source of pulmonary edema. In this setting, a ventilation-perfusion scan may not be accurate, and if there is sufficient suspicion for the presence of pulmonary embolism, an angiogram must be performed. (See Chap. 21.)

Fat Embolism Syndrome

Fat embolism is an extremely common pathologic finding after trauma. In an autopsy series of 300 accident victims, the incidence rate ranged from 80 to 100 percent, with the higher incidence occurring in patients who survived for 12 h or more after injury. In view of the high volume of fat in long bones, it is not surprising that fat embolism is common after bony trauma. The incidence of fat embolism ranged from 26 percent in patients with a single fracture to 44 percent in patients with multiple fractures.

The fat embolism syndrome of pulmonary dysfunction, coagulopathy, and neurologic disturbances associated with increased circulating fat globules is uncommon. Chan and associates, in a prospective series of 80 patients with tibial and femoral fractures, reported an incidence of 8.75 percent. Studying a larger series of 172 patients, ten Duis and associates identified the fat embolism syndrome in only 3.5 percent of patients. The fat embolism syndrome most commonly follows orthopaedic injuries but also has been reported to occur after prosthetic joint replacement, closed-chest cardiac massage, blast concussion, liver trauma, burns, extracorporeal circulation, rapid high- altitude decompression, bone marrow transplantation, and liposuction. The syndrome has also been reported after acute hemorrhagic pancreatitis and carbon tetrachloride poisoning.

Pathophysiology

Long-bone fractures in animal models suggest that the cause of fat embolism syndrome is the release of marrow fat into the circulation with subsequent lodging in the lungs. The classic presentation of this syndrome is in the patient with multiple long-bone fractures after a traumatic event; it becomes more prominent if the patient has subsequent reaming or rodding of these fractures in the early posttrauma phase. The release of marrow substance and fat from the damaged marrow allows the intravascular passage of these substances to the pulmonary-capillary bed. Fat emboli recovered from the lungs of patients who died with fat embolism presented a lipid profile similar to that of fat in bone marrow. Posttraumatic lipemia, the coalescence of chylomicra, and other metabolic derangements are also considered causes of the fat embolism syndrome.

Large emboli may cause mechanical obstruction of the major and secondary pulmonary vessels. Modalities that increase the activity of lipoprotein lipase, releasing free fatty acids, which are thought to be a toxin, cause a more explosive and damaging syndrome. The pathophysiologic agent is probably a substance such as oleic acid, which has served as the classic model for the production of acute respiratory distress syndrome in the laboratory. Other researchers have suggested that once fat emboli are lodged in the pulmonary vasculature, they are coated with platelets that subsequently lyse, releasing kinin-like substances and vasoactive substances, such as serotonin.

It is more difficult to explain the findings such as petechia and lesions in the brain in these patients given the filtering function of the pulmonary- capillary bed. Other explanations to reconcile these findings include coalescence of the chylomicra that give rise to the fat embolism syndrome, or bypassing the pulmonary filter in precapillary shunts that have opened because of increased pulmonary artery pressure. Since the histologic features of the cerebral lesions consist of petechial hemorrhages of the cortical white matter, brainstem, and spinal cord, these will be self-limited and are reversible provided the patient can be supported during this period.

Clinical Manifestations

Up to 75 percent of patients with fat embolism syndrome manifest some degree of respiratory insufficiency. This usually occurs soon after the injury but occasionally as long as 48 to 72 h afterward. Chest radiographic findings include characteristic bilateral alveolar infiltrates. The syndrome may evolve into acute respiratory distress syndrome, and a minority of patients require intubation and respiratory support. Central nervous system (CNS) involvement occurs in the majority (as many as 86 percent) of these patients but does not develop in the absence of pulmonary abnormalities. Neurologic impairment may precede the pulmonary findings by 6 to 12 h. The most common neurologic presenting symptoms include confusion and disorientation with eventual progression to coma. Hypoxemia may exacerbate the confusion and disorientation, but oxygen does not reverse these CNS findings. Focal neurologic findings are uncommon. The characteristic petechial rash occurs in the axillae, neck, and skin folds. This same rash also may occur in the oral mucosa or conjunctiva. The rash tends to be transient, is usually present between 12 to 24 h, and rapidly disappears. Fever and tachycardia are common, with the fever out of proportion to injury.

The examination of urine for the presence of fat globules is not specific. A great number of patients have fat globules present in their urine after a traumatic event, but only a few of these patients develop the fat embolism syndrome. Associated clinical findings in fat embolism syndrome include an unexplained drop in hematocrit level, thrombocytopenia, hypocalcemia, and hypoalbuminemia. Hypoxemia is noted on arterial blood gases analysis. Serum lipase levels may be elevated in patients with the fat embolism syndrome. This finding might be a result of the escape of lipoprotein lipase and does not represent pancreatic lipase.

Management

Patients with long-bone fractures tend to be most prone to the development of fat embolism syndrome. Any patient with hypoxemia, fever, unexplained confusion, or tachypnea should have the fracture immobilized. Multiple studies have demonstrated that early surgical immobilization and fixation significantly decrease the incidence of pulmonary complications of the fat embolism syndrome in the posttrauma population. Adequate fluid resuscitation, transfusion, and, according to some, administration of TPN are associated with a decreased incidence of both encephalopathy and fat embolism syndrome. Encephalopathy is treated by oxygenation and supportive measures. There is not much support for the routine use of steroids in this disease. Heparin has been reported by some to increase lipase activity and thereby increase the clearance of fat. Other investigators have questioned the use of heparin because lipase actually may increase the toxicity of this syndrome by releasing oleic acid.

Other suggested therapeutic modalities include the use of low-molecular- weight dextran (40,000 MW), which is thought to act by decreasing blood viscosity, reducing platelet adhesion, providing partial reversal of thrombocytopenia, and reducing red cell aggregation. The use of ethyl alcohol has been advocated because of its ability to reduce lipase activity and decrease the production of free fatty acids, but this is unproved. Supportive modalities include ventilatory support as necessary and adequate fluid resuscitation. Death as a result of the fat embolism syndrome in the properly supported patient occurs infrequently.

Acute Respiratory Distress Syndrome (ARDS)

By definition, acute respiratory failure is the clinical situation in which the patient is incapable of maintaining adequate oxygenation, adequate ventilation, adequate tissue delivery, or some combination of these defects. The cause of this failure may be single and identifiable, such as pneumonia, decompensation of preexisting chronic obstructive pulmonary disease, or traumatic flail chest. Alternatively, it may represent the end point of a poorly understood pathway with a common final denominator of lung damage and subsequent decompensation of oxygenation and ventilation. An example of this is acute respiratory distress syndrome.

Ashbaugh and Petty are credited with the first description of ARDS. They described a syndrome characterized by atelectasis, reduced pulmonary compliance, and refractory hypoxemia. Estimates have suggested that the incidence of ARDS is about 100,000 cases per year. In 1992 a joint American-European conference on ARDS was convened with the goal of developing a working definition of ARDS. As part of this process, “*adult respiratory distress syndrome*” was changed to “*acute respiratory distress syndrome*” in recognition of the fact that pediatric patients also develop this disease process. The most widely accepted definition of ARDS is the syndrome that includes (1) lung injury, acute in nature, (2) bilateral infiltrates on frontal chest radiograph, (3) Pa O₂/FIO₂ less than 200, and (4) pulmonary-capillary wedge pressure less than 19 mmHg with no evidence of congestive heart failure. These same findings associated with a Pa O₂/FIO₂ less than 300 are defined as “acute lung injury” (ALI).

Etiology and Pathophysiology

Attention has focused on the concept of an abnormal cytokine response to injury. What is not established is whether the extent or components of this response are abnormal. Important components of this abnormal response include some activation of the complement cascade, activation of the thromboxane-leukotriene pathway, disorders in nitric oxide production, degranulation of neutrophils, and production of increased permeability factors by macrophages. All of these various factors have been implicated in the resultant transudation of fluid and reactive materials that are the hallmark of the alveolar flooding that characterizes ARDS.

The signature of ARDS is a ventilation/perfusion mismatch. Alveolar hypoventilation occurs because of collapse, expansion of the alveolar membrane, or presence of exudate and fluid within the alveolar spaces that are still available for perfusion. This “alveolar block,” when combined with changes in perfusion relationships, results in the increased hypoxemia manifested as a shunt as well as increased dead space. Shunt fraction, a reflection of the magnitude of ventilation/perfusion abnormality, is calculated by the formula Cc - Ca/Cc - Cv, where Cc is pulmonary capillary O₂ content, Ca is arterial O₂ content, and Cv is mixed venous O₂ content. Under normal circumstances, less than 5 percent of the blood flow across the pulmonary bed is a shunt fraction. In severe cases of ARDS, this shunt fraction can exceed 40 percent.

The classic radiographic appearance of “whiteout” on chest radiograph implies a uniform lung injury in ARDS. Computed tomography (CT) scans have demonstrated that this concept is misleading. CT scans of a patient with significant ARDS characteristically demonstrate regional changes in lung function and normal areas of lung interspersed with markedly diseased portions of lung. Dependent lung regions suffer the most significant consolidation, while the nondependent regions remain air-filled. The suggestion is that in some areas regional lung compliance is not reduced during ARDS but that lung volume is drastically diminished.

A newly described concept of ventilator lung injury has been termed “volutrauma.” Volutrauma is different from barotrauma and refers to the maldistribution of inspired tidal volume secondary to positive-pressure ventilation and the heterogeneous nature of lung injury in ARDS. Barotrauma is simply extra alveolar air. Volutrauma does not result in dissection of air from the alveolus but rather is characterized by direct tissue damage at the alveolar/capillary interface.

The mechanism of injury in volutrauma is thought to be overdistention or “stretching” of the alveolus beyond its normal maximum. This overdistention results in capillary fracture and parenchymal inflammation. This initial overstretching may be the primary insult, which results in a cascade of injury leading to increased capillary permeability and culminating in hypoxemia. The traditional therapy for ARDS may lead to a clinical syndrome that actually resembles ARDS. The heterogeneous nature of ARDS promotes the maldistribution of delivered tidal volume such that the majority of ventilation and pressure is transmitted to “normal” alveolar units rather than to the diseased areas of the lung. Based on the relationship of normal lung volume and transpulmonary pressure, the maximum alveolar pressure should remain less than 35 cmH₂O.

Management

Current mechanical ventilation strategies have emphasized the need to reduce volutrauma. These include: (1) early use of PEEP adjusted to the inflection point, (2) pressure-limited ventilation with plateau pressures less than 35 cmH₂O, (3) permissive hypercapnia (P_{CO₂} up to 90 mmHg, pH > 7.20, tidal volume 4–8 mL/kg), and (4) use of inhalational nitric oxide.

PEEP has remained the mainstay of treatment of ARDS for the past 30 years. End points based on Pa_{O₂}/Sa_{O₂}, intrapulmonary shunt, pulmonary compliance, oxygen delivery, and functional residual capacity have been suggested as defining “optimum PEEP.” PEEP is important not only as a method of recruiting collapsed alveolar units but also as a means of attenuating lung injury associated with positive-pressure ventilation. A pressure-volume curve is constructed to determine the point at which the pressure-volume relationship of the lung results in a rapid rise in the slope of this curve. PEEP is then set at a level equal to or just above the inflection point. Early in ARDS this value typically is 10 to 15 cmH₂O, with values of up to 20 cmH₂O necessary in patients with stiff chest-wall compliance. This use of PEEP may prevent loss of functional residual capacity and prevent alveolar collapse at end-expiration.

Positive-pressure ventilation is delivered predominantly as a volume- controlled breath. In this instance, the desired tidal volume is set on the ventilator, and that volume is delivered regardless of other variables. Peak airway pressures vary inversely with pulmonary impedance during volume- controlled ventilation. Monitoring of the peak airway pressure is used to evaluate the progression of ARDS. Pressure-controlled ventilation has been reported to improve oxygenation while maintaining lower peak airway pressures. Pressure-controlled ventilation is characterized by a square waveform of pressure and a decelerating waveform of flow. The rapid rise in flow reduces patient/ventilator dyssynchrony and reduces the work of breathing. The rapid rise in pressure allows peak airway pressure to be applied throughout inspiration, increasing mean airway pressure, enhancing ventilation-perfusion relationships, and allowing for improved distribution of inspired gases. The cumulative effect of these changes results in a more favorable ventilatory pattern while reducing volutrauma. Current practice is to use pressure- controlled ventilation in patients requiring PEEP greater than 10 cmH₂O, patients with elevated airway pressures (peak inspiratory pressure greater than 45 cmH₂O), and patients with hypoxemia despite adequate PEEP.

Permissive hypercapnia is not a therapeutic maneuver but rather a strategy of ventilatory support. Use of permissive hypercapnia includes the appropriate application of PEEP and the implementation of pressure- controlled ventilation, but the typical end points for acid-base balance are drastically altered in this strategy. Permissive hypercapnia relies on intentional hypoventilation and hypercapnia in an attempt to limit potentially detrimental effects of increased peak airway pressures. Permissive hypercapnia also limits the number of breaths necessary per minute, which reduces the risk of barotrauma and volutrauma. Appropriate initiation of permissive hypercapnia allows a gradual increase in Pa_{CO₂} over a period of 10 days as renal compensation maintains pH above 7.20. Permissive hypercapnia is a strategy that must be adopted early in the treatment of ARDS. It has little value when applied late in the course of ARDS, when volutrauma already has occurred. The lower level of acceptable pH is open to debate. Reports of pH as low as 7.0 with no adverse cardiovascular or neurologic effects have been published. Well- controlled prospective randomized trials comparing the morbidity, mortality, ventilator days, and length of stay in the intensive care unit for patients managed with permissive hypercapnia versus traditional strategies in ARDS have provided suggestive, but not unequivocal, evidence of its benefits.

In the weaning process, the first priority is to reduce the FI_{O₂} to less than 0.5 to avoid maintaining the collapse of the alveoli. Next, the number of intermittent mandatory ventilation (IMV) breaths should be decreased to a level that permits a normal pH and a Pa_{CO₂} of 35 to 45 mmHg at a respiratory rate of less than 30 per min. This is continued until only two mechanical breaths per minute are required. PEEP is lowered in increments of 2 to 3 cmH₂O/min while monitoring the Pa_{O₂}. When adequate oxygenation is maintained with a PEEP of 5 cmH₂O, the IMV is 0, the continuous positive airway pressure (CPAP) is 5cmH₂O, and the criteria of the second column of Table 11-14 are met, the patient generally no longer requires ventilatory support.

Newer Modalities

Inhalation of nitric oxide at small doses (0.1 to 20 parts per million) has reduced pulmonary hypertension and improved oxygenation in a variety of patients. Initial experience with the use of nitric oxide in ARDS has suggested a response rate of 60 to 70 percent. Partial liquid ventilation (PLV) or perfluorocarbon-assisted gas exchange (PAGE) has been applied. Perflubron, a perfluorocarbon with twice the density of saline that has an oxygen-carrying capacity of 50 mL/100 mL of perflubron, has been used. PAGE refers to the combination of PLV and traditional gaseous ventilation. The functional residual capacity is filled with perflubron (30 mL/kg), and mechanical ventilation is initiated. This strategy is sometimes referred to as liquid PEEP. Early limited studies with PLV have shown: (1) limited distribution of gas to the dependent regions of the lung, (2) more uniform ventilation with PLV, (3) improved gas exchange, and (4) reduced histologic evidence of lung injury with PLV. Because perflubron is immiscible with most substances, it facilitates removal of cellular debris and mucus.

CARDIAC COMPLICATIONS

Myocardial Infarction

Perioperative myocardial infarction (MI) probably is the leading cause of death in the elderly after noncardiac surgery. Mortality from perioperative MI ranges from 54 percent to 89 percent; 80 percent of the deaths occur within 48 h of operation. This is surprising, considering that the mortality rate for acute MI without shock, unassociated with operation, is approximately 12 percent.

The presence of coronary artery disease increases the incidence of perioperative MI from the control level of 0.1 to 0.7 percent to 1.1 percent after operation. In patients over 40 years of age, with or without coronary artery disease, the infarction rate is 1.8 percent. In patients with previous MI, the reinfarction rate ranges from 5 to 8 percent. The most important variable in a patient with a previous MI is the time that has elapsed since that MI. For patients who are operated on within 3 months the reinfarction rate is 27 percent, between 3 to 6 months the rate is 11 percent, and after 6 months the reinfarction rate stabilizes at 5 percent.

Identification of the Patient at Risk

The most widely used criteria and computation for the multifactorial index score to estimate cardiac risk in noncardiac surgery is that originally published by Goldman (see Table 11-1). Indications on physical examination include jugular-venous distention and an S3 gallop, more than 5/min premature ventricular beats, rhythm other than sinus, age over 70 years, and transmural or subendocardial infarction in the previous 6 months. Emergency operation, intrathoracic, intraperitoneal, or aortic sites of surgery, evidence for important valvular aortic stenosis, and “poor general medical condition” also are indicators. On the basis of the computational score, patients with more than 25 points (Class IV, the highest-risk class) have a mortality rate from cardiac causes of 56 percent and a morbidity rate of 22 percent with life-threatening, nonfatal cardiac complications.

The history is important in evaluating the risk of myocardial infarction. A history of dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, peripheral edema, and particularly angina pectoris (especially at rest) should lead the surgeon to obtain a more detailed history and a cardiac evaluation. A preoperative ejection fraction of less than 0.35 determined by radionuclide imaging and ventriculography is associated with a 75 to 85 percent incidence of perioperative MI, compared to a 20 percent incidence in patients with an ejection fraction greater than 0.35.

Clinical Manifestations

Most cases of perioperative MI occur on the operative day or during the first 3 postoperative days. Although infarction has been associated with all anesthetics, the incidence is higher after general anesthesia for abdominal or pelvic surgical treatment. The most important precipitating factor is shock, either during the operation or in the early postoperative phase. The more prolonged the shock, the greater the risk of coronary thrombosis and myocardial ischemia. The ECG may show ST depression and T-wave flattening with the loss of as little as 500 mL of blood in patients with previous coronary occlusion.

Diagnosis can be difficult because chest pain often is absent or obscured by narcotics. Chest pain occurs as a primary manifestation in only 27 percent of patients, which is less than the 97 percent generally reported in patients in whom a coronary occlusion is not related to surgery. It is appropriate to consider routinely monitoring patients with previous infarction in an intensive care unit. The sudden appearance of shock, dyspnea, cyanosis, tachycardia, arrhythmia, or congestive failure should be an indication of the diagnosis. Dyspnea, cyanosis, and arterial hypotension require a differential diagnosis between cardiac and respiratory problems. The ECG may provide the diagnosis with a characteristic infarction pattern, but this is not an unequivocal finding. In older patients, ST-segment and T- wave changes may be associated with myocardial ischemia, and the same changes may be observed with postoperative shock. A study of arterial gases may provide a differential diagnosis of respiratory problems. Left ventricular failure with pulmonary edema generally is not accompanied by carbon dioxide retention, and, in contrast to airway obstruction and alveolar hypoventilation, there usually is a reduction in arterial CO₂ tension and respiratory alkalosis when cardiac failure accompanies MI. The CPK- MB isoenzyme is the most precise method for detection of myocardial necrosis after operation. If MI is suspected, serial studies, including ECG and measurements of aspartate transaminase (SGOT) and CPK-MB, should be done daily. Isotope scanning of the myocardium using technetium pyrophosphate may detect a recent acute infarction.

Management

Preoperative preparation of patients with signs of cardiac insufficiency should include digitalization for patients with enlarged hearts or histories of previous cardiac failure. Routine digitalization is not indicated. Anemia, if present, requires treatment, and attention should be directed toward the regulation of fluid and electrolyte balance and hypovolemia. Patients on propranolol should continue to receive the drug until the morning of the operation. Operation is contraindicated for a period of at least 3 months, and preferably 6 months, after myocardial ischemia or infarction, except in an emergency. During the operation, a broad array of factors precipitating MI should be avoided. These include hypoxia,

hypotension, hemorrhage, dehydration, electrolyte disturbance, and arrhythmias. The regulation of blood pressure during anesthesia probably is the most important measure in the prevention of myocardial ischemia and infarction. When blood pressure falls significantly in the absence of blood loss, the prompt correction of hypoxia by adequate ventilation with oxygen and the administration of vasopressors is indicated. Digitalization may be required when shock is combined with heart failure. The administration of blood or fluid is indicated to maintain blood volume.

Treatment of MI itself consists of relief of pain and anxiety using morphine and sedation. Relief of hypoxia is accomplished with 33 to 50 percent oxygen delivered via a mask or nasal catheter. Suctioning of the tracheobronchial tree may be required to clear obstructing secretions. Critically ill patients are best managed in an intensive care setting with invasive monitoring using arterial lines and a pulmonary artery catheter. Shock is treated by vasopressor agents. Promptness in instituting vasopressor therapy increases the chance of its effectiveness. Rapid digitalization is applicable in the treatment of shock when the myocardial insufficiency may be responsible for the severe hypotension. Digitalization also is indicated for the treatment of heart failure, which is a frequent manifestation of postoperative MI. In addition to digitalization, parenteral diuretic therapy may be used in the treatment of cardiac failure. Some have advocated the use of anticoagulant therapy after the danger of excessive bleeding from an operative site has passed. When acute MI is detected, early emergency cardiac catheterization, angioplasty, or stenting may reverse an evolving MI. Rarely, emergency coronary artery bypass surgery may be indicated.

Arrhythmias

If arrhythmia is defined as a sequence of abnormal beats sustained for more than 30 s, an overall incidence of 73 percent of intraoperative cardiac arrhythmias has been reported in one series and 62 percent in another. The incidence was higher in intubated patients and in patients who had undergone neurosurgical and thoracic procedures. Twenty-one percent were ventricular in origin. In another study, 84 percent of patients experienced significant arrhythmias. The majority were associated with the intubation and extubation phase of anesthesia. Of these, 43 percent were ventricular arrhythmias. Once anesthesia is over, the incidence of arrhythmias in noncardiac surgery is approximately 2.4 percent, and the majority of patients are asymptomatic.

Sinus tachycardia, not an arrhythmia, is by far the most common disturbance in rhythm, followed by premature ventricular contractions and sinoatrial arrhythmia, which can be a normal variant. Bradycardia and trigeminy also have been reported in a significant number of patients.

With cardiac procedures, the incidence of arrhythmias is approximately 50 percent, while thoracic procedures have an incidence of 20 to 30 percent. Pneumonectomy has been associated with an arrhythmia rate of 30 to 40 percent, leading to the practice of digitalizing the patient before pneumonectomy. In one report, the incidence of supraventricular tachycardias, including supraventricular tachycardia, atrial flutter, and fibrillation, after pneumonectomy was 22 percent. Of these, more than half occurred within the first 72 h of operation, and one-third occurred on the first postoperative day.

Etiology

The causes of arrhythmia include intrinsic cardiac disease, perioperative release of catecholamines because of stress or pain, and organ manipulation that stimulates a reflex response.

Electrolyte Abnormalities and Metabolic Disturbances

Hypokalemia is associated with paroxysmal atrial contractions and ventricular contractions or, in rare cases, ventricular fibrillation. Hyperkalemia, especially when severe, results in conduction abnormalities and, when potassium levels reach 6.5 to 7.5 mEq/L, conduction defects resulting in asystole. Hypocalcemia increases the QT interval and can cause ventricular arrhythmias. Hypercalcemia causes bradycardia and heart block. Hypomagnesemia can cause ischemic heart disease and increase ventricular irritability, and it may make the heart prone to the dysrhythmic effects of hypoxia and other disturbances.

Cardiac Medications

Digitalis may predispose surgical patients to serious dysrhythmias, and digitalis toxicity can result in supraventricular-atrial flutter with varying block, premature ventricular contractions, and ventricular tachycardia or fibrillation. Some of the common antihypertensive medications or beta blockers such as propranolol, reserpine, methyldopa, and quinidine may cause sinus bradycardia or induction block.

Anesthetic Agents

While no longer used, cyclopropane and, less commonly, halothane may result in ventricular dysrhythmias. Parasympathetic stimulation, such as the use of neostigmine, physostigmine, and the relaxant succinylcholine, may cause bradycardia. Atropine is administered simultaneously to prevent bradycardia.

Other Factors

Hypercapnia suppresses the intrinsic pacemaker activity and, at times, sinoatrial node function. It also may lead to ectopic pacemaker or aberrant reentry mechanisms, resulting in atrial or ventricular arrhythmias. Thyrotoxicosis commonly results in atrial dysrhythmias, the most common of which is atrial fibrillation. Pheochromocytoma, with its elevated plasma catecholamines, also can cause a variety of arrhythmias.

Management of Preexisting Arrhythmias

Approximately 33 percent of patients with preoperative arrhythmias undergoing peripheral vascular surgery develop cardiac complications, as compared with 9 percent of the patients with normal sinus rhythm. When the preoperative evaluation is accomplished with ECG, rhythm strip, and, if necessary, 24-h continuous Holter monitoring, the preexisting arrhythmia should be controlled. Digoxin (Lanoxin) and other cardiac glycosides can be used to control the ventricular rate in patients with supraventricular tachycardia, taking care not to push the patient into digitalis toxicity.

Multifocal premature ventricular contractions or runs of ventricular tachycardia should be treated aggressively, especially in elderly patients with coronary artery disease or congestive heart failure. Reversible causes, such as electrolyte disturbances, drug toxicity, hypoxia, etc., should be controlled. Intravenous lidocaine should be given. For significant conduction defects, cardiac pacing should be considered. In third-degree AV block, secondary to Mobitz II block and sick sinus syndrome, a permanent pacer should be implanted before elective surgery. Percutaneous pacing might be indicated in patients with new-onset ischemia if operation cannot be delayed. In patients with ischemic development of left fascicular block, hemodynamic monitoring with a pulmonary artery catheter is essential.

Management of New-onset Arrhythmias

A 12-lead ECG and a rhythm strip should be obtained. Carotid sinus pressure may slow the rhythm sufficiently so that the critical issue, which is whether P waves are present and, if so, what their morphology is, can be detected. The presence of P waves implies a supraventricular origin. The variable morphology of the P waves may suggest an ectopic focus, a multifocal atrial tachycardia or supraventricular tachycardia. Absence of P waves indicates atrial fibrillation. A small sine wave usually is evident. The QRS response indicates whether there is an abnormality in ventricular function. A narrow and normal-appearing QRS complex suggests that the arrhythmia is supraventricular. Wide, aberrant QRS responses indicate a ventricular origin or a supraventricular rhythm with aberrant conduction. AV conduction block rhythms also result in a wide QRS complex.

The management of new-onset arrhythmias essentially consists of determining (1) the hemodynamic stability of the patient, (2) the ventricular rate (rapid or slow), (3) the site of origin (atrial or ventricular) of the arrhythmia, (4) the need for cardioversion, and (5) identifying and correcting the underlying cause of the arrhythmia. In hypotensive patients with an acute tachyarrhythmia, cardioversion should be performed. The initial impulse should be at 100 joules (J), and if the arrhythmia is not eliminated, cardioversion should be repeated with the voltage rapidly increased to 360 J.

The rapidity with which therapy is attempted, and what is attempted, is directly dependent on the ventricular rate, which is critical. The ventricular rate may be too fast or too slow. In bradycardia, defined as a heart rate of less than 60 beats/min, chest pain, dyspnea, altered mental status, evidence of myocardial ischemia, or ventricular asystole demands rapid treatment with 0.5 mg of atropine intravenously. If bradycardia persists, atropine is given every 5 min to the maximum dose of 0.04 mg/kg. If a single dose of atropine does not result in the rapid reversal of bradycardia, a transcutaneous or, preferably, a temporary transvenous pacemaker should be inserted promptly. If the ventricular response rate is too great (a tachyarrhythmia is defined as a heart rate of more than 100 beats/min), hemodynamic instability may result, especially when ventricular response rates of 130 to 140 beats/min are achieved.

Sinus Tachycardia

Sinus tachycardia is not a dysrhythmia but may be mistaken for one and can cause alarm when the heart rate is markedly elevated. Sinus tachycardia usually suggests sympathetic stimulation by a variety of conditions, including pain, hypovolemia, hypoxia, acidosis, sepsis, congestive heart failure, hypoperfusion, or hypercapnia. While thyrotoxicosis may cause sinus tachycardia, particularly in thyroid storm, an atrial dysrhythmia is more common. Treatment should include 2 to 4 liters of oxygen/min and is directed at identification and correction of the underlying cause.

Paroxysmal Supraventricular Tachycardia

The paroxysmal supraventricular tachycardia dysrhythmias, which are reentry in nature, have a ventricular rate between 150 and 250 beats/min. They may be caused by hypoxia, myocardial ischemia or infarction, congestive heart failure, or thyrotoxicosis. With a rapid ventricular response, synchronized direct-current countershock is indicated. Carotid sinus massage or Valsalva maneuver usually is unsuccessful. Primary treatment is adenosine 6 mg intravenously, which may be repeated after 1 to 2 min with 12 mg; this should be infused slowly to prevent the hypotension that may be associated with the medication. If the arrhythmia persists, verapamil 2 to 5 mg intravenously is given as an initial dose, with a second dose given after 15 to 30 min. Verapamil should be used with caution in the elderly because hypotension may result in patients with poor ventricular function.

Atrial Fibrillation

Atrial fibrillation can be troublesome because the lack of the “atrial kick” can result in a 10 to 15 percent diminution in cardiac output, which may be poorly tolerated in certain elderly patients. Causes include thyrotoxicosis, valvular heart disease, hypertension, coronary artery disease, pulmonary embolism, and myocardial ischemia. Atrial fibrillation is very common after pulmonary resection, particularly pneumonectomy. Direct-current cardioversion is indicated when patients are hemodynamically unstable. However, if the atrial fibrillation is long-standing, there may be a clot in the atrial appendage, and the patient should undergo anticoagulation therapy. Verapamil is the drug of choice once the initial treatment controls cardiac rate, and digitalis glycoside is used to maintain control once the heart rate is decreased. When atrial fibrillation supervenes in a patient on digitalis glycosides, quinidine or procainamide usually is successful in converting fibrillation to a sinus rhythm. Part of the success of the conversion depends on the size of the atrium; if the atrium is more than 4 cm in diameter, atrial fibrillation may be refractory to conversion.

Sustained Supraventricular Tachycardias

Atrial tachycardias and atrial flutter, especially multifocal or ectopic atrial tachycardias with 2:1 or 3:1 block, may be a result of digitalis toxicity. Serum levels of potassium and digoxin should be obtained promptly, and digoxin discontinued temporarily. Potassium should be supplemented if serum level is low, and procainamide and quinidine might be necessary.

Atrial Flutter

The ventricular rate in atrial flutter is sustained and high, but it is regular. Ventricular response varies with the degree of AV conduction and usually determines the patient's hemodynamic stability. Atrial flutter can be associated with mitral or tricuspid valve disease, sustained pulmonary hypertension, or cor pulmonale. If the patient is hemodynamically unstable, synchronized direct-current countershock should be applied. Once the heart rate is controlled, digitalis is used to maintain it. In patients who have had previous digitalis therapy, quinidine or procainamide may be effective.

Ventricular Tachycardia

Ventricular tachycardias are the most dangerous arrhythmias. A sustained ventricular tachycardia cannot be tolerated. The underlying cause usually is intrinsic disease of the heart, including cardiomyopathy, coronary artery disease, or mitral valve prolapse. Hypoxia and cardiac glycoside toxicity are rare causes. The rhythm is variable, and it may be regular or irregular. The critical diagnostic feature is a wide, bizarre QRS complex with a rate varying between 100 and 225 beats/min. The patient may be pulseless, in which case a precordial thump and immediate defibrillation at 200 J should be performed while cardiopulmonary resuscitation is attempted. Treatment is the same as that of ventricular fibrillation. If a pulse is present, lidocaine 1 mg/kg is given, followed by a second dose of 0.5 mg/kg and a lidocaine drip 2 to 4 mg/ min. Bretylium may be used in refractory cases at a dose of 5 to 10 mg/kg and may be repeated every 15 min to a dose of 30 mg/kg.

Ventricular Fibrillation

Ventricular fibrillation usually is fatal. Its underlying causes include ischemia, hypoxia, digitalis toxicity, or hypokalemia. No P waves or normal QRS complexes are seen on the ECG but rather a fine or coarse fibrillation. There is no pulse or cardiac output. Cardiopulmonary resuscitation is initiated and direct-current countershock repeated up to three times. Epinephrine is given intravenously, and, if it is effective, cardiopulmonary resuscitation may maintain some aspect of the circulation. Lidocaine 1 mg/kg is given, followed by a second dose of 0.5 mg/kg and a continuous infusion of 2 to 4 mg/min. Bretylium may be given as well in a dose of 5 to 10 mg/kg and can be repeated at 15-min intervals to a maximum dose of 30 mg/kg. Administration of epinephrine may be repeated every 3 to 5 min, followed by defibrillation. The patient usually will become acidotic, and in addition to intubation and hypocapnia to control the acidosis, bicarbonate should be used. Arterial blood gases analysis should be used to guide the resuscitation.

Hypertension

Approximately 40 percent of the population, at one time or another, has a systolic blood pressure of more than 140/90 mmHg. There is controversy about whether this is dangerous preoperatively. Long-term hypertension causes arterial medial hypertrophy, accelerated atherosclerosis, increased left ventricular work, and cardiac hypertrophy. Untreated hypertension leads to diminished renal blood flow and premature renal failure. The pathophysiology of very wide swings in blood pressure, and particularly in peripheral vascular resistance in the postanesthetic period because of sympathetic stimulation as a result of pain, anesthesia, or hypovolemia, is the result of vascular smooth muscle hypertrophy and wall thickening. Diminution of intravascular diameter associated with hypertension exaggerates changes in vascular resistance brought about by the inevitable sympathetic discharge that occurs after an operation. The central nervous systems of the elderly are vulnerable under these circumstances because the autoregulation of blood flow is diminished with the thickening of the arterial media, resulting in an increased risk of ischemic strokes.

Preoperative Hypertension

It is not clear that patients with preoperative hypertension are at risk for increased cardiac morbidity and mortality. For those patients whose diastolic blood pressure is lower than 110 mmHg, it appears that there is no increased perioperative risk of MI or sudden cardiac death, although there may be a slight increase of intraoperative hypotension and myocardial ischemia. Preoperative hypertension that is untreated or poorly controlled does increase the risk of perioperative blood pressure lability, which may result in an increased incidence of stroke, transient neurologic event, arrhythmias, postoperative myocardial ischemia, and possibly postoperative renal failure. Whether *systolic* hypertension is a critical issue is unclear, but evidence suggests that it is not. In the event of previous hypertension with a *diastolic* pressure higher than 110 mmHg, new-onset hypertension, sudden increases in hypertension, or recent deterioration in critical end- organ status (renal failure, eye, or heart), elective operation should be postponed until the hypertension is controlled.

In patients with uncontrolled new-onset hypertension or poorly controlled preexistent hypertension, operation should be delayed until adequate blood pressure control is achieved. In patients with mild to moderate hypertension, the following factors call for delay of an operative procedure:

- (1) Electrocardiographic changes of myocardial ischemia or infarction
- (2) New-onset dysrhythmias
- (3) Emergence of left ventricular hypertrophy on ECG
- (4) New-onset or unstable angina pectoris
- (5) Congestive heart failure, whether established or new
- (6) A recent neurologic deficit
- (7) New onset of high-grade hypertensive retinopathy

Antihypertensive medications should be continued until the operation. Although beta blocking agents, which previously were used for the treatment of angina or hypertension, may complicate intra- and perioperative hemodynamic monitoring, abrupt stoppage of these medications has resulted in ventricular tachycardia, myocardial infarction, unstable angina, and sudden death. Preoperative discontinuation of quinidine can result in anxiety, tremors, diaphoresis, malaise, and tachycardia.

Postoperative Hypertension

Approximately 25 percent of patients with vascular disease and previously established hypertension who are operated on experience postoperative hypertension. Postoperative hypertension develops in over 50 percent of patients after abdominal aortic aneurysm and 20 percent of patients after carotid endarterectomy. This is important because systolic blood pressures higher than 200 mmHg result in bleeding from the suture line, hemorrhagic cerebral infarction, myocardial ischemia or infarction, and acute renal failure. If such hypertension complicates a carotid endarterectomy operation, the elevated blood pressure results in a statistically significant increase in neurologic deficits. Similarly, cardiac operations in which cardiopulmonary bypass is used are commonly followed by hypertensive episodes, which may jeopardize the integrity of vascular anastomoses. Patients with uncontrolled hypertension undergoing plastic surgical procedures experience an increased incidence of hematomas.

If hypertension develops during anesthetic induction or emergence, the adequacy of ventilation, hydration, and fluid status should be established. The anesthesiologist should be prepared to use sodium nitroprusside or nitroglycerin if the increase in pressure cannot be otherwise controlled. Nearly 80 percent of postoperative hypertensive episodes occur within the first 3 h of emergence from anesthesia. Obvious factors include the presence of an endotracheal tube in a patient who is awake and agitated, inadequate analgesia, acute bladder distention, and fluid overload. More subtle causes of postoperative hypertension include tracheal stimulation, hypothermia, hypercapnia, and hypoxemia. Diuretic therapy may be required to diminish the intravascular volume and hypoxemia. The efficacy and adequacy of ventilation and oxygenation should be evaluated. If the blood pressure is uncontrollable, sodium nitroprusside or labetalol is given. Effective management of postoperative hypertension includes intravenous or sublingual nitroglycerin or nifedipine. Other antihypertensive agents, such as methyl dopa or hydralazine, can be used in less emergent situations.

Hypertension occurring later in the postoperative course usually is related to hypervolemia secondary to fluid mobilization into the intravascular space, inadequate analgesia, or failure to resume previous antihypertensive medications. If fluid overload is mild, fluid restriction may be sufficient. Occasionally, diuretic therapy may be necessary. Sufficient doses of analgesics should be provided and preoperative medications resumed as soon as feasible.

HYPERCOAGULABLE STATES

Acquired Hypercoagulable States

Lupus Anticoagulant Factor (Anticardiolipin Syndrome)

Lupus anticoagulant factors are antibodies that interfere with the in vitro partial thromboplastin time (PTT) by prolonging phospholipid-dependent clotting factors and also interfere with heparin monitoring. The presence of these antibodies is associated with an increased risk of arterial and venous thrombosis. A positive history of thrombotic events is obtained in many patients. Several specific assays are available to detect the presence of lupus anticoagulants.

A problem with the treatment of acute venous thromboembolism is the distortion of the activated partial thromboplastin time (APTT). The patients normally do not require anticoagulation therapy. Patients undergoing major surgical procedures should receive prophylactic anticoagulation therapy and mechanical prophylaxis, such as sequential compression boots, against venous thromboembolism.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia is a form of consumptive platelet activation. It is idiosyncratic in that the effect of heparin is not dose- dependent, and very small quantities of heparin can elicit the syndrome. Porcine heparin may be less likely to induce thrombocytopenia. The mechanism is thought to be autoantibody formation directed toward heparin and platelet surface antigens. Platelets are then activated and the clot consumed.

Mild transient thrombocytopenia occurs 2 to 4 days after heparin exposure; it may occur earlier if the patient has been exposed to heparin in the past. A more severe syndrome includes marked severe hyperthrombocytopenia 6 to 12 days after heparin exposure and is associated with thrombosis. Arterial thrombosis is common and includes aortic and lower extremity vascular bypass grafts, femoral arteries, coronary arteries, and cerebral arteries. Thrombosis of the vena cava and the feeding branches of the iliofemoral and femoral veins also have been reported.

Mortality is significant, and phlegmasia cerulea dolens results in an amputation rate of up to 30 percent. While arterial thrombosis may be effectively managed by surgical thrombectomy, ultimately antithrombotic agents, such as dextran and warfarin, must be used. Venous thrombosis is treated by mechanical interruption of the vena cava, such as by Greenfield filter, and by warfarin therapy when platelet levels are adequate.

The diagnosis is based on clinical suspicion and elimination of other causes of thrombocytopenia. It is possible to perform platelet aggregation studies using donor platelets and the patient's serum, plasma, and in vitro heparin. Discontinuation of the heparin results in lower morbidity and mortality, especially if the syndrome is detected early.

Inherited Thrombotic Disorders

The surgeon occasionally is required to treat patients who have known inherited thrombotic disorders. More often, the patient gives a history of unexplained venous thromboses without a clear family history. It is useful to investigate these patients in order to prevent the occurrence of thrombosis after operation. Indications are spontaneous venous thrombosis, especially in unusual sites such as the mesenteric or the cerebral veins, a family history of thrombotic problems, and recurrent thrombosis with no apparent precipitating factor. Arterial thrombosis is notably absent, except as complicating mesenteric venous thrombosis where venous thrombosis could lead to bowel necrosis. Heparinization is indicated until the dose of warfarin sodium is adjusted. Prophylactic anticoagulation should occur before any type of surgical procedure.

Antithrombin-III Deficiency

Perhaps the most important inhibitor of coagulation is antithrombin III. In addition to acting on thrombin, antithrombin III inactivates factors Xa, IXa, XIa, plasmin, kallikrein, and factor XIIa. The physiologic range of antithrombin III is narrow. Its deficiency, an autosomal-dominant inherited trait, with resultant moderate decreases in concentration may have significant clinical impact in the form of thrombosis. Recurrent thrombosis occurs in approximately 60 percent of patients, and pulmonary embolism occurs in up to 40 percent. Antithrombin-III deficiency can be confused with several acquired conditions that include estrogen therapy, oral contraceptives, heparin, l-asparaginase, cirrhosis, nephrotic syndrome, and disseminated intravascular clotting. Treatment is with heparin. Patients undergoing operation should be given fresh-frozen plasma to raise their level of antithrombin III. Warfarin is effective.

Protein C Deficiency

Protein C is a vitamin K–dependent inhibitor of the procoagulant system. It forms in the liver and causes its inhibitory action by inactivating factors V and VII:C. Its inhibitory action is greatly facilitated by protein S (see below). Approximately 4 to 5 percent of patients under the age of 45 years with unexplained venous thrombosis have this diagnosis, but evidence suggests that it might be as important as antithrombin III deficiency. It is an autosomal-dominant gene disorder of which two types of deficiency are known: patients in whom there is an absence of protein (CRM-) and those who have a dysfunctional protein (CRM+). Thrombosis occurs when serum activity falls to less than 70 percent. Since the levels are affected by warfarin, anticoagulation therapy with warfarin is sufficient.

Protein S Deficiency

Protein S is a vitamin K–dependent protein that is produced by hepatocytes and megakaryocytes. Its primary role is to function as a cofactor in protein C's inhibitory actions on factors V and VIII. Protein C deficiency occurs as an autosomal-dominant disorder, but protein S deficiency can occur in the heterozygous and homozygous forms; the homozygous form generates symptoms earlier in life. As in protein C deficiency, there is a quantitative and qualitative subgrouping for protein S–deficient patients. Thrombosis occurs when serum activity falls below 60 percent of normal. Patients may acquire protein S deficiency in acute thrombotic disease and in disseminated intravascular clotting.

POSTOPERATIVE PAROTITIS

Postoperative parotitis is a serious complication that is associated with a high mortality related mainly to the primary disease. Studies indicate a recrudescence in occurrence, probably related to the increasing age of the surgical population. The right and left glands are involved equally, and the disease presents bilaterally in 10 to 15 percent of cases. Seventy-five percent of patients are 70 years of age or older, and the majority have associated diseases. Patients who undergo major abdominal operations or who have a fractured hip, debilitating disease, or severe injury are among the most commonly afflicted.

Causes include poor oral hygiene, dehydration, and the use of anticholinergic drugs. In one large series, one-third of the patients with acute suppurative parotitis had carcinoma, and one- half had preexisting major infection elsewhere in the body. In only one-third of the cases in this series did the acute suppurative process develop in the postoperative period.

The majority of infections are from staphylococci, and the pathogenesis is thought to be a transductal inoculation of the parotid gland. Poor oral hygiene and lack of oral intake to stimulate parotid secretions predisposes to bacterial invasion of Stensen's duct. The inflammatory lesions of early parotitis are confined to an accumulation of cells within the larger ducts. The parenchyma of the smaller ducts are initially spared, but once penetration of the parenchyma occurs, multiple abscesses form and later coalesce. If the process continues, the purulent material penetrates the capsule and invades the surrounding tissue along one of three routes: downward into the deep fascial planes of the neck, backward into the external auditory canal, or outward into the skin of the face.

Clinical Manifestations

The interval between operation and the onset of parotitis varies from a few hours to many weeks. The patient initially presents with pain in the parotid region that is usually unilateral but may become bilateral in a short time. Initially the gland is slightly swollen and exquisitely tender. Because of the septate anatomy of the gland, fluctuance rarely is demonstrable. The course of postoperative parotitis is rapid and fulminating with severe cellulitis on the affected side of the face and neck. The temperature and leukocyte count may be extremely high. Obstruction of the airway might necessitate tracheostomy, and the abscess can rupture into adjacent structures of the ear, mastoid process, pharynx, or anterior and posterior triangles of the neck. Parotitis is differentiated from benign postoperative swelling of the parotid glands that occurs more frequently in black patients and may be related to straining or to the administration of atropine or neuromuscular depolarizing drugs.

Management

Prophylaxis includes adequate hydration and good oral hygiene, which is aided by allowing the patient to take ice chips and hard candy to stimulate salivary flow. Prophylactic antibiotics have no apparent value.

When considering the diagnosis, pus should be expressed from Stensen's duct and culture and sensitivity tests performed. While awaiting results, a broad-spectrum antibiotic is begun that acts against staphylococci. In one series of 66 glands cultured, 64 contained staphylococci. Some cases were combined with streptococci, gram-negative bacilli, and pneumococci. If there is considerable pain and the disease is less than 48 h old, irradiation of the gland in small doses is indicated. Irradiation may provide symptomatic relief by reducing the secretions of the obstructed gland, but this type of therapy does not affect the course of the disease as much as antibiotics or surgical drainage.

Frequent observation of the patient is essential. If the disease persists or progresses, drainage should be considered as early as the third day. If there is moderate improvement, drainage may be delayed for a day or two, but it should not be delayed beyond the fifth day. An incision is made anterior to the ear, extending down to the angle of the mandible, and flaps are reflected to expose the gland. A hemostat is inserted through the capsule and opened in the direction of the course of the branches of the facial nerve, establishing multiple drainage sites; the wound is packed lightly open. Deferring drainage until fluctuation is apparent is unwise. Stimulation of the salivary flow by massage of the gland or other means is contraindicated once the inflammatory process is established.

Prognosis

In one series, the mortality rate approximated 20 percent, but this was frequently related to the patient's basic disease. Thirty-six percent of the patients who died demonstrated active parotitis. In 80 percent of patients treated with incision and drainage, the parotitis was palliated or cured.

COMPLICATIONS OF SURGERY OF THE GASTROINTESTINAL TRACT

Ileus and Partial Small-Bowel Obstruction

Ileus is defined as nonmechanical obstruction that prevents normal postoperative progression of the return of bowel function, food intake, and discharge. Some of the complications that are called ileus probably include partial mechanical obstructions that are difficult to differentiate from nonmechanical obstruction. Ileus is thought to arise from a neural inhibition that interferes with coordinated intrinsic bowel wall motor activity and effective propulsive peristalsis. It is believed that the small bowel normally does not manifest ileus postoperatively, because the small bowel continues to function throughout and after operation; tube feedings into the small bowel can begin almost immediately after operation. When inflammation is adjacent or there are several anastomoses in the small bowel, a 24-h ileus might be experienced. If adjacent inflammation continues, the ileus may be prolonged. Gastric ileus can persist from 24 to 48 h, and sometimes longer. Colonic ileus lasts from 3 to 5 days. The end of colonic ileus is signaled by the passage of flatus.

Ileus increases with increased manipulation, inflammation, peritonitis, and large amounts of blood left in the peritoneal cavity because of inadequate hemostasis or deficient coagulation factors. Blood in the retroperitoneum often produces ileus. Hypokalemia, hypocalcemia, hyponatremia, and hypomagnesemia prolong postoperative ileus. Opiates and phenothiazines, especially when given in large doses and in patients who are habituated, contribute to a delay in the resolution of ileus.

While in the United States water-soluble dyes such as diatrizoate (Hypaque) are used for radiologic examinations, enteroclysis with thin barium is used in other countries where there is less fear of barium accumulating in an intestine that may be obstructed. Failure to pass contrast past a fixed point is pathognomonic of intestinal obstruction.

If ileus persists postoperatively, a long tube (Kaslow or Miller-Abbott) may be effective in reversing intestinal obstruction without operation. The serum albumin should be measured, because patients who are very hypoalbuminemic can experience a prolonged ileus. Infusion of 12.5 g of albumin every 8 or 12 h to raise the serum albumin level above 3.0 mg/dL often results in the passage of flatus and a return of bowel function. The treatment of ileus is purely supportive. Rarely, if ileus is prolonged and it is not mechanical obstruction, TPN may be required to support nutrition until the ileus resolves.

Ileus and mechanical obstruction may be difficult to distinguish. Postoperative mechanical obstruction, particularly in carcinomatosis, can be difficult to distinguish from a prolonged ileus. Radiographic examinations, particularly enteroclysis, might be helpful. Long-tube decompression may be helpful for postoperative obstruction.

Anastomotic Leaks and Fistulas

General Considerations

There are a number of features that are essential for normal, complication- free healing of gastrointestinal tract anastomoses:

- (1) The two ends of bowel or the two hollow viscera being anastomosed should have adequate blood supply without ischemia and should bleed freely.
- (2) The orientation of the bowel and its mobilization should result in an anastomosis that lies well and is free of tension.
- (3) Meticulous technique should be used in anastomosing bowel. The sutures should be appropriate for the anastomosis —small, fine, nonabsorbable sutures for the serosa and a variety of sutures in the mucosa. A single-layer anastomosis with excellent apposition of the serosa can be expected to undergo normal healing.
- (4) Preparation of the large bowel, including antibiotics and especially a mechanical (cathartic) preparation, is critical.
- (5) Hemostasis should be meticulous, especially in and around the anastomosis. Hematomas at the suture line should be avoided.
- (6) No contaminated material, fibrin, etc. should be left in the immediate vicinity of the anastomosis.
- (7) If possible, the anastomosis should be reinforced with a serosal patch or omentum onlay.
- (8) Nutritional preparation of patients, when the operation is not an emergency, should be optimal. Patients who are at risk nutritionally for disrupted anastomoses include those with an albumin level in the hydrated state of less than 3.0 mg/dL and weight loss of more than 10 to 15 percent in the previous 3 to 4 months. Confirmatory findings include the inability to perform tasks previously done, anergy to injected skin test antigens, and a true transferrin level of less than 200 mg/dL. Hand dynamometry and other tests of physiologic capacity also are confirmatory.

Factors that increase the likelihood of anastomotic leakage include emergency procedures, poorly prepared patients, inadequately resuscitated patients, prolonged intraoperative hypotension, and hypothermia. Three etiologic factors are: (1) poor surgical technique; (2) distal obstruction; and (3) inadequate proximal decompression.

Duodenal Stump Blowout

Duodenal stump blowout remains a disastrous complication with a high mortality. A review of gastrectomies performed at the Mayo Clinic in 1956 revealed that 4.5 percent of patients subjected to the procedure for gastric ulcer had some evidence of leakage, and 5.6 percent of patients in whom the same procedure was performed for duodenal ulcer revealed similar evidence. In that study, drains were inserted into the stump region, and in many patients increased drainage represented the evidence of a leak. Edmunds and associates reported a 1.1 percent incidence of dehiscence of the stump with a mortality of 0.6 percent.

Duodenal stump leakage occurs most commonly after operation for a duodenal ulcer and frequently when gastrectomy is performed as an emergency procedure to stop hemorrhage. In a majority of cases, the leak is a result of technical error and failure of the suture line. A scarred and edematous duodenum, obstruction of the afferent loop, and local pancreatitis predispose to leakage. Complications of duodenal leakage include peritonitis, subhepatic abscess, pancreatitis, sepsis, establishment of an external fistula with fluid, and electrolyte abnormalities.

Specific measures can be taken to avoid this complication. With marked inflammatory disease in the duodenal region, vagotomy and gastroenterostomy represent safer procedures. When resection has been undertaken and duodenal closure is difficult, catheter duodenostomy may be used as an adjunct. Rodkey and Welch reported that in 51 cases with difficult duodenal stump closures in planned duodenostomy, there was one death, and in five patients drainage from the fistula continued for more than 48 h after the catheter was removed. As a compromise between primary closure and planned duodenostomy, some surgeons advise drainage of the right upper quadrant, with the drain placed in the region of the duodenal stump so that if perforation occurs, the contents discharge along the tract. This does not provide the safety factor of planned duodenostomy because the drain tract may wall off from the stump before the perforation becomes established.

Duodenal blowout is most likely to occur between the second and the seventh postoperative days, manifested by sudden pain, elevation in temperature and pulse rate, and general deterioration of the patient's condition. Adequate drainage must be instituted immediately, which is best accomplished by an incision below the right costal margin and insertion of a large sump catheter that is passed down to the duodenal stump area with constant suction applied. Attention must be directed toward fluid and electrolyte therapy, and TPN should be instituted. Fistula closure can be anticipated within 2 to 3 weeks.

Intestinal Leaks and Fistulas

Leakage of intestinal anastomoses usually is manifest by fever, leukocytosis, unexplained ileus in the absence of intestinal obstruction, and a complicated postoperative course. There may be localized swelling of the abdominal wall and point tenderness. CT scanning usually is diagnostic. Percutaneous drainage often is effective in reversing the sepsis.

If the leak is small or if previous drains were placed to the area of the anastomosis, the patient is not deteriorating, the sepsis is contained, and the patient is not jeopardized, nasogastric suction, broad-spectrum antibiotics, total parenteral nutrition, and adequate drainage may result in containing the leakage without further need for operative intervention. If the patient is in jeopardy, the sepsis is uncontrolled, and there is no effective drainage, the patient's abdomen should be reexplored. Under no circumstances should the anastomosis be resutured; it will almost always leak again for the same reason it leaked initially. The anastomosis must be completely resected and redone. If contamination is not massive, the blood supply is adequate, and the patient is not hypotensive, a redone anastomosis will most likely heal. If there is gross contamination and purulence, the patient is hypotensive, septic, or hemodynamically unstable, then separation of the two ends of the bowel and diversion should be performed. When the patient has stabilized and the area of sepsis is resolved, reanastomosis may be attempted.

A fistula represents an anastomotic leak that has developed a pathway to the skin. The typical presentation of a patient with an enterocutaneous fistula is characterized by fever, ileus, leukocytosis, malaise, and some manifestation of sepsis. On the fourth or fifth postoperative day, increased wound pain and redness lead to drainage of purulent material from the wound. This usually is followed within 24 h by leakage of intestinal contents through the wound. Postoperative fistulas usually result from operations involving inflammatory bowel disease, cancer, or lysis of adhesions.

The treatment plan for patients with enterocutaneous fistulas is to allow the fistula to close spontaneously; it is more likely to do so without operative intervention in the absence of distal obstruction. Operative intervention in patients with fistulas is dangerous; the mortality in patients with enterocutaneous fistulas from all causes is 10 to 20 percent.

Therapy of an Established Fistula

The treatment of patients with gastrointestinal-cutaneous fistulas can be divided into five phases: (1) stabilization, (2) identification and diagnosis, (3) decision, (4) operation, and (5) healing.

Stabilization

The typical presentation is a wound that developed an infection and was drained, subsequently followed by the appearance of enteral contents. Another situation occasionally occurs in which there is localized swelling and redness, an abscess from a disrupted anastomosis that points to the skin. Before drainage, a fistulogram should be obtained with water-soluble dye. Once the fistula is defined, rapid and complete resuscitation should take place. The patient has probably not eaten for about a week, there are 3–4 liters of electrolyte-rich solution in the gut, the serum albumin level is probably decreased, and the patient is most likely anemic because of sepsis. Resuscitation should take place using crystalloid, red blood cells when appropriate, and, if there is no capillary leakage syndrome, albumin to raise the albumin level to 3.0 mg/dL. The patient is largely given nothing by mouth, so that intestinal secretion is avoided. Hard candy can be used to stimulate salivary flow to avoid parotitis. Nasogastric tubes are unnecessary unless the patient has an obstruction, in which case the passage of a long Miller-Abbott or Kaslow tube in the early postoperative period should be considered. Antibiotics are not used unless the patient is septic. A sump-type drain is placed around the skin, and the skin and skin edges are protected with Stomadhesive and ion exchange paste to keep the pH of the skin acidic and prevent activation of the pancreatic enzymes that require a basic pH.

Nutritional support is delayed only if there is anticipated drainage of abscesses because hematogenous spread, while rare, may occur and result in seeding the TPN catheter. TPN is initiated with a 5 or 6 percent amino acid solution, 15 to 25 percent dextrose, and 20 percent of the caloric content as fat. It is started at 40 mL/h and advanced rapidly until the patient's metabolic needs are met. The adequacy of nutritional support can be monitored with short-turnover proteins, such as retinol-binding protein, thyroxin-binding prealbumin, and transferrin, or by indirect calorimetry.

Enteral nutrition also is effective, but in all series the rate of closure using enteral nutrition is decreased slightly when compared to parenteral nutrition. Enteral nutrition, while it temporarily increases the drainage from the fistula, results in increased hepatic protein synthesis, decreased contamination, decreased translocation, and other beneficial metabolic effects. It might not be possible to meet the patient's entire metabolic needs with enteral feedings. It is estimated that as little as 20 percent of the caloric needs supplied enterally provide all of the benefits usually associated with enteral feedings. A combination of enteral and parenteral feedings may be more effective than total parenteral nutrition alone.

If enteral nutrition is used, 4 feet (1.2 m) of small bowel must be present to absorb the feeding. If the material is given into the duodenum, or beyond the ligament of Treitz, which is best from the standpoint of safety in order to avoid aspiration, it should not be given at full strength but started at isosmolar or slightly below isosmolar levels and the rate increased to 125 mL/h. The osmolality is increased to the point where it may be 400 to 500 mOsm, but not greater. Many patients will not tolerate osmolalities greater than 300 to 400 mOsm when feedings are given into the small bowel. If the material must be given into the stomach, hypertonic material can be given initially. The osmolality may be increased, and when 600 mOsm is reached, the rate can then be increased. When hyperosmolar material is given into the stomach, peristalsis stops, and the stomach ceases emptying and secretes fluid until the material is diluted to isosmolar. Peristalsis then returns and the material is transferred in 2- to 4- mL aliquots every 30 seconds across the pylorus.

Identification and Diagnosis

After the patient is stabilized, the fistula controlled, and the skin protected, the characteristics of the fistula are defined in order to determine whether or not the fistula is likely to close spontaneously, or whether operation is required. The most important exercise in making that decision is a fistulogram. The prognostic indicators that should be obtained from the fistulogram include the degree of bowel continuity, the size and depth of the defect, whether there is distal obstruction, the nature of the bowel adjacent to the fistula, and whether there is a large abscess adjacent to the fistula (Fig. 11-5). The location of the fistula also is important. Ileal fistulas, gastric fistulas, and fistulas at the ligament of Treitz close less frequently than fistulas in the area of the jejunum, esophagus, pancreas, biliary tree, or colon. The fistula should be inspected to make certain that it is not a mature fistula, i.e., intestinal epithelium that has grown up to the skin. Fistulas that have matured as an enterostomy never close and always require operation to resect the area and

perform an anastomosis.

Spontaneous closure usually occurs within 5 weeks of adequate nutritional support, enteral or parenteral, in a patient who is sepsis-free. Duodenal and esophageal fistulas may close within 3 weeks. While remote sepsis (e.g., urosepsis, pneumonitis) may not interfere with spontaneous closure, local sepsis almost always prevents spontaneous closure. If the patient is systemically septic, spontaneous closure will not occur.

Decision

If spontaneous closure is to occur, the drainage of the fistula usually decreases. Somatostatin has been used to promote closure. Somatostatin will not close a fistula that is anatomically unfavorable for closure. Randomized prospective trials suggest that somatostatin is not effective in speeding up closure but might be useful in pancreatic and biliary fistulas as well as duodenal fistulas.

The critical decision in the management of these patients is *whether* operation is indicated, and if so, *when*. If spontaneous closure has not occurred during 5 weeks of sepsis-free parenteral nutrition and drainage has not decreased dramatically, it is unlikely that the fistula will close. The timing of operation is important. It is best performed when the skin around the fistula is in a good state and the patient has shown no recent improvement. This is a judgment that can be made readily with the use of laboratory data. If the short-turnover protein levels are increasing, the serum albumin concentration is approaching 3.0 g/dL, and the patient is maintaining the albumin level without infusions of exogenous albumin, operation can take place. A rise in the level of serum transferrin at the onset of the treatment or after 3 weeks is predictive of spontaneous closure. A rise in levels of transferrin, retinol-binding protein, and thyroxin-binding prealbumin predict survival, but failure to maintain or increase these is indicative of mortality.

If the patient is to be operated on, careful preparation should be undertaken. The skin should be washed with chlorhexidine gluconate (Hibiclens) for 2 or 3 days before surgery, and a sump should be positioned with Stomadhesive to protect the skin. Fistula or abscess drainage should be cultured and appropriate antibiotics covering aerobes and anaerobes given just before the start of the incision. If yeast is present, prophylaxis by fluconazole (Diflucan) is appropriate. Formal bowel preparation, neomycin enemas, and irrigation to the colon may be useful adjuncts.

Operation

A significant mortality exists in patients with enterocutaneous fistulas. Mortality is approximately 10 to 11 percent if patients are reoperated on during the first 10 days or after 4 months, but a mortality of 20 percent is expected if operation is performed between 10 days and 4 months after the fistula appears. All adhesions must be taken down and all abscesses drained. Resection and end-to-end anastomosis yields the lowest incidence of failure and the lowest incidence of complications. Bypasses or intentionally staged procedures lead to higher rates of complications and may result in total failure of closure of the fistula. The authors do not recommend using stapled anastomoses under these circumstances. An exception to the dictum that fistulas should be excised with end-to-end anastomoses is the duodenal fistula. If a duodenal fistula does not close, it is suggested that a vagotomy and gastrojejunostomy be performed, a feeding jejunostomy and a gastrostomy be placed, and the area of the fistula be drained, which usually closes.

Ancillary procedures at the time of resection and operation include the placement of gastrostomy and a feeding jejunostomy, which is essential. A No. 12 latex Robinson nephrostomy catheter is preferred, as it allows greater flexibility with respect to the tube feedings. The anastomoses should be protected where appropriate by omentum onlay. If the colonic anastomosis is unsatisfactory or suspect, it should be protected by colostomy or ileostomy.

A chronic pancreatic fistula that communicates with the duct may be dealt with by excising the fistula down to the pancreas, identifying the leak, and performing a distal pancreatectomy and splenectomy if the spleen cannot be spared. A Roux-en-Y anastomosis can be used to provide internal drainage for the pancreatic fistula. Alternatively, the fistula tract can be dissected free starting at the skin and anastomosed to a Roux-en-Y.

Healing

After the procedure has been performed successfully and there are no or few perioperative complications, feeding is delayed 7 to 10 days postoperatively, particularly if the anastomoses are tenuous. Many of these patients will have difficulty in eating because they have not eaten for some time. Some patients lack taste sensation; zinc sulfate or lactate given once a day often restores taste within 10 to 14 days. It may be necessary to allow the patient alcohol to induce eating, and families can bring home-cooked meals that may be more palatable than hospital food. After a prolonged period of time without food, most patients require cycling of their enteral or parenteral nutrition at night to enable them to eat during the day.

Colocutaneous Fistulas

Colocutaneous fistulas are generally the result of colonic anastomotic leaks or unrecognized trauma to the colon during operation. Creation of an anastomosis in the presence of infection or fecal contamination, such as for acute diverticulitis or traumatic colon injuries, increases the likelihood of fistula formation. In contrast to enterocutaneous fistulas, fluid and electrolyte abnormalities and skin digestion are rare, but infectious complications are significant, with abscess formation and wound infections.

Nutritional status is maintained by using low-residue elemental enteral diets. Localized infection is controlled with percutaneous drainage of intraabdominal abscesses and local care of wound infections. Antibiotics are used as indicated. Spontaneous closure of colocutaneous fistulas is very likely, with rates approaching 75 percent. The presence of sepsis involving the fistula, distal obstruction, anastomotic dehiscence, Crohn's disease, or carcinoma are associated with persistence of the fistula. Earlier operative intervention is indicated if peritonitis or septicemia is present. The lack of spontaneous closure by 5 weeks is an indication for surgical repair. Definitive operation involves resection of the fistula and affected colonic segment with primary anastomosis and temporary diversion of the fecal stream by colostomy if necessary. The success rate of surgical repair of colocutaneous fistulas is 70 to 80 percent.

Postgastrectomy Syndromes

Dumping

Dumping is the result of the loss of the pyloric valve that normally is the mechanism by which hyperosmolar material is prevented from entering the duodenum and small bowel. This function is lost as a consequence of pyloroplasty, pyloromyotomy, gastrojejunostomy, gastric resection, and Billroth I or Billroth II anastomosis after which hyperosmolar material enters the small bowel. This results in physiologic changes including the release of vasoactive substances, such as serotonin, bradykinin, substance P, and peptides including vasoactive intestinal peptide, possibly pancreatic polypeptide, insulin, glucagon, neurotensin, and enteroglucagon. There also is a loss of plasma volume as the small intestine secretes actively to dilute the hyperosmolar contents, resulting in a decrease in plasma volume and hence hypotension. Rapid absorption of glucose, secretion of insulin, and the rapid entry of glucose and potassium in the cell results in hypokalemia, which may also be responsible for some of the symptoms.

Symptoms of dumping consist of early postprandial bloating, borborygmus, cramps, sensation of light-headedness, palpitations, sweating, and hypotension. Most patients admit to dumping immediately after gastric procedures, but most usually improve so that at the end of 4 to 5 months there are few patients who remain seriously symptomatic. Separating solids and liquids (eating the solids at the meal and drinking the liquids afterward) diminishes the symptoms. Carbohydrate-rich foods are more likely to provoke dumping; these include milk shakes, cereal with significant sugar content, etc., all of which should be avoided. Acquired lactase deficiency also may be present. In time, most dumping subsides or is minimized as the patient adapts. In more severe cases, long-acting octreotide may oppose some of the actions of the released peptides and ameliorate the symptoms. If the patient remains severely symptomatic, the anastomosis may be converted from a Billroth II to a Billroth I. The duodenum seems more resistant to an osmotic load and, because it contains any number of polypeptides, may provide an antagonist to dumping. If this strategy fails, a 6-cm reverse loop of jejunum may slow the transit of hypertonic solution in the small bowel sufficiently to ameliorate the symptoms of dumping.

Postvagotomy Diarrhea

Most patients have increased bowel movements or softer stools after truncal vagotomy. Between 5 and 20 percent of patients have diarrhea that is troublesome, and 1 to 2 percent of patients with truncal vagotomy have severe, disabling diarrhea. The latter may take two forms: diarrhea that is present every day, or a poorly explained episodic diarrhea occurring about every 7 to 10 days and lasting about 3 days. This does not respond to opiates, and it subsides spontaneously.

Many factors have been blamed for postvagotomy diarrhea, including stasis and overgrowth of bacteria, malabsorption of fat, and increased and incoordinate bile flow into the small bowel. The cause is not clear but is ascribed to the denervation of the celiac plexus, resulting in a dysmotility or dysfunction of small bowel motility.

Treatment is difficult. Episodic postvagotomy diarrhea is almost impossible to correct. Neomycin or tetracycline to sterilize a blind loop syndrome and cholestyramine to bind bile salts have been tried with little success. In patients who are incapacitated, a 10-cm reversed jejunal loop 100 cm distal to the ligament of Treitz has been advocated. A difficulty with the reverse loop is that although it initially may be effective, it ultimately enlarges and elongates and becomes obstructive, requiring shortening. A shorter reverse loop might be more appropriate (Fig. 11-6).

Afferent Loop Syndrome

This complication is a mechanical problem peculiar to the gastroenterostomy reconstruction after gastrectomy. Optimal function of this arrangement requires free flow of material from the duodenum (afferent loop) to the intestine draining the gastric pouch (efferent limb). The afferent loop syndrome can be acute or chronic. In its classic form, the syndrome almost always occurs when the afferent loop is anastomosed to the greater curve after a Billroth II gastrectomy. Obstruction of the afferent loop can result from adhesions, kinking, intussusception, volvulus of the afferent loop, stomal ulcer, or obstruction of the efferent limb. In the chronic form, as the afferent loop becomes obstructed, bile, pancreatic juice, and duodenal secretions accumulating in the afferent loop are suddenly regurgitated into the stomach. In the acute form, as the secretion increases, hemorrhagic pancreatitis (a Pfeffer loop) or perforation can occur. The ligament of Treitz may be located too close to the midline, resulting in kinking when the afferent limb is anastomosed to the greater curve. In these circumstances, this type of anastomosis should be avoided.

The clinical history is distinctive and often diagnostic. Patients experience a classical syndrome in which eating is regularly followed by right upper quadrant epigastric distention and pain, borborygmus, and cramps, all of which are suddenly relieved by an almost projectile vomitus of clear bile that is never mixed with food.

The diagnosis can be made on the basis of history, endoscopy, and, in some cases, by an upper gastrointestinal series showing a massively distended afferent loop. Operation is required for the relief of these symptoms; in most instances the afferent loop is anastomosed into a Roux-en-Y efferent loop approximately 60 cm downstream to prevent the reflux of bile into the stomach. A vagotomy is necessary because bile and pancreatic juice are diverted from the gastroenterostomy, increasing the propensity for a marginal ulcer.

Alkaline Reflux Gastritis

In alkaline reflux gastritis, also called bilious vomiting, the stomach is sensitive to bile, patients complain of severe continual burning epigastric pain, and eating is associated with

pain rather than relief of pain. Vomiting may be present. The vomitus may be bilious and may contain food. Endoscopy reveals large amounts of bile emanating from the afferent loop, and there is a beefy-red gastritis with an abrupt cutoff of the gastritis to normal jejunal mucosa at the anastomosis. Ritchie and associates demonstrated increased bile salts in bile gastritis. Biopsy analysis reveals acute and chronic inflammation, evidence of a decrease in parietal cells, an increase in mucus-secreting cells, and intestinalization of the gastric glands.

The most effective treatment is the combination of cholestyramine and sucralfate. Histamine H₂-receptor antagonists or omeprazole often make the syndrome worse. Aluminum-containing antacids and metoclopramide have variable effects. Cranberry juice may afford some relief. If the diagnosis is made and the pain is intractable, and relief by medication is unattainable, a Tanner-19 procedure with a vagotomy and a long bile- containing loop anastomosed 60 cm downstream is our preference, though some prefer a Roux-en-Y. The advantage of the Tanner- 19 is the absence of the Roux-en-Y syndrome, and if the diagnosis is actually efferent loop obstruction, a Tanner-19 type of operation will correct the obstruction.

Nutritional Complications

Late complications of the postgastrectomy syndrome include cases in which patients become “nutritional cripples,” with weight loss of 10 to 30 pounds resulting from excision of the majority of the stomach. While fat absorption may be near normal (fecal fat excretion of less than 5 g/24 h) after a Billroth I procedure, fat excretion averages approximately 9 g/24 h in most patients with a Billroth II anastomosis. This fat malabsorption may be accompanied by chronic nutritional deficiency, failure of absorption of fat- soluble vitamins, and chronic bile salt diarrhea. Iron and calcium also are absorbed primarily in the duodenum. After a Billroth II procedure, many patients are persistently hypocalcemic, and iron-deficiency anemia may be present. The loss of intrinsic factor after partial gastrectomy necessitates monthly injections of vitamin B₁₂; otherwise a megaloblastic anemia might result. If iron, calcium, or fat malabsorption is crippling, conversion from a Billroth II to a Billroth I anastomosis can be considered. After conversion to a Billroth I anastomosis, the mixing of food with bile and pancreatic juice may be restored to near normal, and fat absorption may improve. Weight gain and the reversal of malabsorption of fat-soluble vitamins results.

Stomal Complications

Planning, siting, and dialogue with the patient and an enterostomal therapist help to avoid patient dissatisfaction with a stoma. An enterostomal therapist is an essential member of the team. Some patients will have difficulty obtaining a satisfactory stoma. These include patients who are obese, in whom the thickness of the abdominal wall prevents sufficient mobilization of the colon or, especially, the ileum to obtain a well-functioning stoma without compromising blood supply. Patients with numerous abdominal scars, especially concave scars, and patients with many fat folds on the abdomen also present difficult stomal problems.

The stoma should be placed through the rectus muscle, splitting the muscle in a longitudinal fashion so that it can be closed easily, e.g., ileostomy accompanying a ileal pouch/anal anastomosis procedure, or a temporary colostomy with a coloanal type of anastomosis. Stomas work best when they are on a convexity of the abdomen when the patient is upright. Five centimeters of flat, unscarred, nonconcave abdominal wall for the stoma appliance to seal is optimal. The stoma should be a sufficient distance from the umbilicus and the anterior superior iliac spine, whether in the right or left lower quadrant. There should be no tension on the bowel as it is brought up through the fascia, and the bowel should be fixed to the fascia with fine nonabsorbable sutures to prevent it from falling back into the abdomen. The fascial opening should be adequate; two fingersbreadth is reasonable in a normal-sized patient. The stoma should not be placed in a skin crease or at the belt line, where care of the stoma would be difficult.

Recurrence of Disease

The incidence of complications for ileostomies is about 4 percent for patients with ulcerative colitis and up to 30 percent in patients with Crohn's disease. Crohn's disease at the stoma may take the form of recurrence in the bowel, in which case granulomatous, ulcerated, swelling, and ultimately fibrotic bowel develops at the stoma. Crohn's disease may also result in peristomal fistulas at a distance or immediately adjacent to the stoma. A combination of ciprofloxacin and metronidazole should be initiated. There is little advantage in resiting the stoma, because whatever led to the recurrence of Crohn's disease usually leads to recurrence in the new site as well. Recurrence of Crohn's disease in the peristomal skin results in a sharply punched out, but undermined, violaceous ulceration that is difficult to treat.

Stomal Necrosis and Retraction

Inadequate vascularization of the stoma can lead to ischemia or necrosis in the immediate postoperative period. The development of duskiness or frank necrosis of the stoma should prompt an evaluation to determine the extent of involvement. A good light and a lubricated glass or plastic test tube inserted into the stoma can help in ascertaining the level of viability. If the necrosis is superficial to the fascia, no immediate action is required; the necrotic tissue will slough or require debridement. Stricture formation usually results. If the necrosis extends below the fascia, immediate laparotomy and reconstruction of the stoma is indicated to prevent the development of peritonitis.

Inadequate mobilization of the mesentery or poor fixation of the stoma to the skin or fascia can result in retraction of the stoma, usually during the early postoperative period. Retraction below the level of the fascia requires immediate laparotomy to prevent further fecal contamination of the peritoneal cavity. Retraction above the fascia does not require intervention, but it usually results in poor fitting of the appliance and leakage because of loss of the spigot configuration.

Skin Complications

Skin complications are usually a result of siting and the inability to obtain an appropriate seal around the stoma. To avoid this complication, the stoma should be one-quarter inch above the skin level so that a satisfactory fit of the appliance is obtained. In difficult situations, flexible appliances especially fitted for a particular patient, may be appropriate. Once the skin breaks down, it is difficult to heal, and the intervention of an ostomy nurse is invaluable.

The critical issue for healing of peristomal skin problems is the placement of a Stomadhesive that can be left in place for 5 to 7 days. Medication can be applied under the Stomadhesive on the skin to effect healing. Caraya powder, ion-exchange paste (to keep the pH of the intestinal contents at acidic rather than basic pH, preventing activation of enzymes), and, when yeast is present in the effluent, nystatin powder and systemic fluconazole are helpful in solving peristomal problems. Cellulitis of the surrounding skin requires antibiotic therapy. Appropriate cultures should be taken to rule out unusual pathogens. Any tendency to high ileostomy output, such as in short-bowel syndrome, should be treated with opioids, thickening agents such as Kaopectate, and, if necessary, codeine. Bulk formers, such as Metamucil or fiber tablets, also thicken ileostomy contents so that they will be more manageable. When breakdown is severe and the situation uncontrollable, the patient may need to be admitted to the hospital for placement of a sump tube within the ileostomy. Parenteral nutrition may be necessary to decrease ileostomy output.

Stomal Stricture
