Although stomal stricture is a late complication, it is caused by the development of serositis in the immediate postoperative period. Primary maturation by approximating the intestinal mucosa to the skin at the time of stoma construction has drastically reduced the development of serositis. The most common cause of stomal stricture is necrosis or retraction, resulting in mucocutaneous separation, exposure of the serosa, and subsequent serositis.

A superficial stricture of the stoma can sometimes be dilated, but a minor procedure is often indicated. Under local anesthesia, the stoma is separated from the skin, the skin opening is enlarged, and a new maturation is performed. If the stricture is at the fascial level, the fascial opening is enlarged and the bowel fixed to the newly enlarged opening. It rarely is necessary to reexplore the abdomen and to free the fascial stricture from within the abdomen.

Peristomal Hernias and Prolapse

Peristomal hernias and prolapse may be coincidental. Stomal prolapse occurs when there is vigorous peristalsis and insufficient fixation of the bowel to the underside of the anterior abdominal wall. There usually is some component of a peristomal hernia; a local procedure (resecting the stomal prolapse and fixing it again in place) results in recurrence. In a good percentage of cases the entire stoma must be repositioned. If the stoma is temporary, accelerated closing of the stoma is appropriate; it is often much easier to eliminate an ostomy rather than fix a stomal prolapse. In the event of a peristomal hernia, it is necessary to site the stoma in a new area. The fascial defect of the peristomal hernia should be closed in the usual fashion, making certain that a good hernia repair can be obtained.

METABOLIC COMPLICATIONS

Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH)

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is perhaps the most common metabolic complication after surgery and is especially frequent in the elderly. It usually is easily managed but if not promptly recognized and treated may result in central nervous system damage, seizures, and even death. The basis for the inappropriate secretion of *ADH* is that when the various receptors perceive that the volume within the vascular system is not adequate, ADH and aldosterone are secreted. In the case of inappropriate ADH secretion, the secretion of ADH is more prolonged or more intense than after normal operative procedures. The development of this syndrome is augmented by the tendency to overhydrate patients postoperatively, especially with hypotonic solutions.

If the extent of the inappropriate secretion of ADH causes slight edema and a serum sodium concentration that is below the range of 125 to 130 mEq/L, fluid restriction is all that is necessary because the syndrome ultimately will correct itself. If, however, the serum sodium is more significantly reduced and the patient, especially an elderly patient, manifests central nervous system symptoms such as confusion and somnolence, medical therapy is necessary. If the symptoms are not severe, mannitol may be given slowly. This provokes a diuresis of excess water secreted with a minimum of sodium, adjusting the tonicity. Small doses of furosemide can be added if sodium is given intravenously or orally. If the situation is acute and there has been a seizure brought on by hyponatremia, administration of 3% saline solution is the therapy of choice. Three percent saline should be given in small increments of 50 to 100 mL over 3 to 4 h, provoking a diuresis of excess water and restoring the serum tonicity toward normal. This must be done slowly because permanent central nervous system damage may result from too rapid correction of the hyponatremia.

This syndrome is far better prevented than treated. Patients postoperatively should be appropriately resuscitated, but not overresuscitated. Free water in the form of 5% dextrose in water should be minimized. In the normal course of postoperative recovery, a certain amount of proteolysis and lysis of fat normally takes place, which generates between 500 and 800 mL of electrolyte-free water per day.

Disorders of Thyroid Metabolism

Thyroid Storm

While not as common as in the past, thyroid disorders, especially in patients with undiagnosed latent hyperthyroidism, can be very dangerous. Thyroid storm is the most common and the most dangerous. It occurs in patients with existing thyrotoxicosis that is unrecognized or uncontrolled. The abrupt administration of iodides without the protection of antithyroid drugs may also precipitate a thyroid storm. Any traumatic event, such as surgery, infection, or embolism, may complicate thyrotoxicosis and provoke thyroid storm.

Tachycardia, high fever, and mental status changes are the most prominent early symptoms. Patients are intensely irritable and manifest confusion, delirium, or perhaps coma. Tachycardia is initially sinus, but if thyroid storm persists, high-output cardiac congestive failure may result in tachyarrhythmias. Once hypotension supervenes, it is a preterminal event. Irreversible cardiac failure usually is the mode of death. In other patients, gastrointestinal side effects, such as diarrhea, nausea, vomiting, and abdominal pain also may be present, but these symptoms are secondary.

Treatment of thyroid storm, which has a mortality of 10 to 20 percent, involves control of the catecholamine-induced cardiac symptoms. Propranolol or other beta blockers are given 1 mg/min intravenously to a maximum of 10 mg to control the tachycardia and stabilize the cardiovascular system. Inotropic agents that do not promote tachycardia, such as dobutamine, may be necessary. Diuretics can be helpful, but if furosemide is given, care should be taken to replace the potassium. Propylthiouracil 200 mg and potassium iodide 5 to 10 drops are given to decrease triiodothyronine (T₃) and thyroxine (T₄) release. Hydrocortisone 200 mg intravenously as an initial dose and 100 mg every 8 h thereafter diminishes thyroid hormone release.

Myxedema Coma

An even rarer form of thyroid dysfunction that may result in a fatality is myxedema coma. The principal patients at risk are those with chronic hypothyroidism that is unrecognized or inadequately controlled and whose hypothyroidism is provoked by the stress of operation. Any number of inciting factors may provoke myxedema coma, including trauma, infection, gastrointestinal bleeding, surgery, and the administration of narcotics and phenothiazines. In these patients, there are signs of a metabolic slowdown, including hypothermia, hypoventilation, bradycardia, obtundation, psychotic behavior, seizures, or coma. Once the situation is suspected, serum levels of T₄, thyroid-stimulating hormone (TSH), and serum cortisol should be drawn and therapy initiated before the return of the laboratory values. Supportive care includes warming, hydration, and assisted ventilation. L-thyroxine 300 to 500 mg is given intravenously, followed by a maintenance dose of 50 to 100 mg/ day. Serum cortisol level should be measured and care should be taken to make certain that the patient is not hypoadrenal; 100 mg cortisol is sufficient to ensure that hypoadrenalism is not a problem.

Adrenal Insufficiency

Adrenal insufficiency occurs because of suppression of the pituitary-adrenal axis by previous administration of steroids or the destruction or exhaustion of the adrenal glands. In the former, postoperative adrenal insufficiency, particularly in a very stressful situation, may occur within 1 year of discontinuing steroids despite the absence of any symptoms indicating adrenal insufficiency.

Adrenal insufficiency complicating other forms of severe illness, such as sepsis, hypovolemia, shock, or trauma, can result in unexplained hypotension that will end fatally unless diagnosed and treated. In patients with carcinoma, unsuspected bilateral adrenal metastases may occur, but this has become less common with the frequent use of computed tomography and magnetic resonance imaging.

Acute adrenal insufficiency is manifested by unexplained hypotension, fever, abdominal pain, light-headedness, weakness, palpitations, mental status changes, nausea, and vomiting. Confirmatory laboratory findings include hypoglycemia, hyponatremia, and occasionally hyperkalemia. If the diagnosis is suspected, serum cortisol level is measured and treatment initiated. The mortality and morbidity associated with hypoadrenalism are significant because of prolonged hypotension and hypoglycemia resulting in central nervous system damage.

Treatment consists of 200 mg hydrocortisone given intravenously. Hypotension should resolve within 1 or 2 h if the diagnosis is correct. A solution of 5% dextrose in saline should also help to correct the hypotension. If not, 400 mg hydrocortisone in divided doses over 24 h should be given and can rapidly be tapered to a maintenance dose.

Liver Failure

The most common cause of liver failure is preexisting liver disease. Patients with cirrhosis, alcoholic hepatitis, or fatty infiltration secondary to alcoholism requiring surgical intervention are prone to the development of liver failure postoperatively. In patients with established liver disease such as cirrhosis, general anesthesia should be avoided if possible; in cirrhosis, the portal vein's contribution to hepatic perfusion of the liver is diminished, and the hepatic artery supplies at least 50 percent of hepatic blood flow. Since the hepatic artery is a splanchnic artery, general anesthesia, hypotension, shock, blood loss, and hypovolemia result in splanchnic vasoconstriction and hepatic ischemia as portal flow and hepatic artery flow are markedly decreased. A regional or epidural anesthetic is preferred in patients with liver disease.

Any stress, even in the absence of infection, may result in liver failure beginning on the third to fifth postoperative day. Somnolence, jaundice, diminished urine output, and ascites are manifestations of incipient hepatic failure. Liver function tests reveal an elevated bilirubin level, usually of the indirect fraction, some minor elevation of transaminase level, a decreased albumin level, and a lengthening of prothrombin time. Treatable reversible causes include hypovolemia, hypokalemia, hypomagnesemia, gastrointestinal bleeding, constipation, and remote infection. Spontaneous bacterial peritonitis must be ruled out by paracentesis, culture, and Gram stain. Other infections must be promptly treated.

Treatment of postoperative liver failure includes the correction of electrolyte abnormalities (especially hypokalemic alkalosis), the administration of neomycin, cathartics, or lactulose orally or by enema, and provision of nutritional support. Nutritional support is best carried out enterally if the patient tolerates tube feedings or by total parenteral nutrition. A modified, low aromatic, high branched-chain amino acid formulation is appropriate, preferably with 15 to 25% dextrose and less than 20% of the caloric requirements as fat.

Hemodynamic parameters and urinary output should be carefully monitored. A high-cardiac-output, low-peripheral-resistance hemodynamic state usually complicates hepatic failure. The cardiac index is elevated above 4 L/min/m². Systemic vascular resistance usually is low, with systemic hypotension and warm, well-perfused skin and extremities. Urinary output is decreased, and urinary sodium concentration is less than 10 mEq/ L. The BUN level rises out of proportion to that of creatinine, suggesting the Type II hepatorenal syndrome. Hemodynamic support can be initiated with dopamine and alpha-adrenergic agents to restore peripheral resistance. If the liver does not recover postoperatively, renal and high-output cardiac failure result in death.

PSYCHIATRIC COMPLICATIONS

There is an increased incidence of postoperative psychiatric complications in older patients. In most instances there is nothing more than disorientation in the evening, known as "sundowning." In such cases, setting the patient up in front of a television set or providing other external stimuli, such as a newspaper or music in the background, can help to reorient the patient. Delirium is diagnosed in 20 percent, depression in 9 percent, dementia in 3 percent, and a functional psychosis in 2 percent of elderly postoperative patients.

The first account of postoperative psychiatric disturbance presented by a surgeon was that of Dupuytren who wrote in 1834 that "the brain itself may be overcome by pain, terror, or even joy and reason leaves the patient at the instant when it is most necessary to his welfare that he should remain calm and undisturbed." In 1910, Da Costa indicated that the anticipated frequency for such complications is as high as 1 in 250 laparotomies, while Lewis suggested an incidence of 1 in 1500. Scott described 11 cases in 2000 surgical procedures.

Titchener and associates evaluated 200 patients admitted to the surgical service of the Cincinnati General Hospital using interviews and the Minnesota Multiphasic Personality Inventory to substantiate a psychiatric diagnosis. Although the patients in the study represented a lower socioeconomic status group, 86 percent of the sample had distressing psychologic symptoms, disabling patterns of behavior, or both; 21 percent were found to have neuroses, 11 percent psychophysiologic reactions, 14 percent psychoses, 34 percent character behavior disorders, and 3 percent chronic brain syndrome.

General Considerations

"Postoperative psychosis" cannot be considered a distinct clinical entity. No single factor has been shown to be responsible, and the physical illness and operative procedure may merely reveal a latent psychotic tendency. Illness, particularly when prolonged, and surgical procedures represent threats to the integrity of the organism on somatic and psychologic grounds. In nearly every person informed of the need for a surgical procedure, some degree of anxiety arises. There may be fear of loss of life or loss of body part or function, including, e.g., fear of castration in pelvic and hernia operations. The psychodynamic processes at work during the preoperative, postoperative, and convalescent periods may be classified as involving (1) psychophysiologic factors, (2) somatopsychic factors, or (3) psychosocial factors. Psychophysiologic factors represent processes originating from psychologic stress that act along neurogenic or humoral pathways to modify the healing process. A poorly functioning gastroenterostomy or marginal ulcer in a patient with emotional stress is an example. The somatopsychic factors have to do with the psychologic adaptation involved when the surgical procedure imposes a somatic defect, such as an ileostomy or colostomy. The psychosocial factors refer to patients' concern with the effects of their physical illness or surgical procedure on their position in society. All these may interplay and contribute to anxiety, neurotic symptoms, severe depression, and frank psychosis.

Clinical Manifestations

The occurrence of psychiatric derangement during illness is variable, and the duration of latent interval between surgical treatment and the psychologic disturbance may be days to weeks. Winkelstein and associates reported that, in the recovery room, patients who were subjected to surgical procedures under general anesthesia exhibited a lack of concern about the operation and an absence of affective response, despite the fact that they were sufficiently oriented to be interviewed. After 24 h, however, the patients responded with the concerns and emotions that had been so conspicuously absent in the immediate postoperative period. Both psychologic and pharmacologic factors are implicated in this response, since patients under spinal anesthesia exhibit immediate and overt emotional reaction.

The manifestations are extremely variable. Fear can be accompanied by depression or elation and overactivity. Clinical presentation may disclose acute delirium with confusion and disorientation or merely a vague alteration in perception and mood. The manic reaction may incorporate psychomotor excitement, delirium, delusions, visual or auditory hallucinations, agitated depression, and feelings of persecution. The psychotic reactions observed in 44 of 200 patients in the Cincinnati series are indistinguishable from the range of psychoses observed under other circumstances. The acute brain syndrome, or delirium, was manifest in 20 patients.

Delirium may begin with an inappropriate remark or a dramatic agitated outburst and is frequently the first sign of continued mental deterioration leading to a chronic brain syndrome, particularly in an elderly patient. Delirium must be regarded as a potentially dangerous situation. It occurs most commonly in elderly patients who have lost the closeness and support of family or friends and in patients who are immobilized for long periods.

Depressive reactions represented the second most important psychosis in the Cincinnati series, occurring in 4.5 percent of the sample. The patient is characteristically uncooperative in an active way or recovery may be impeded by listlessness, anorexia, and disinterest. The depressive reaction may be accompanied by physiologic changes. For example, Moore and associates demonstrated effects of emotion on the pituitary-adrenal axis during the immediate and postoperative period. Suicide is a major risk in patients with depressive reaction.

Another category includes the paranoid psychotic disorder. Although it is not rare for schizophrenic reaction to have its onset in the surgical patient, no acute breaks of the

schizophrenic type were noted among the 200 patients studied by Titchener and associates. There is no contraindication to operations for patients with schizophrenia. Manic excitement is a particularly difficult problem in the management of surgical patients and requires close cooperation of psychiatrist, surgeon, and anesthesiologist.

Knox indicated that the incidence of postoperative psychosis is not related to the duration of preoperative hospital stay. The duration of illness, particularly when prolonged, does determine the patient's psychologic reaction to surgical experience. By contrast, emergency operation often results in reactions marked by acute anxiety, nightmares, insomnia, irritability, and protective withdrawal from all stimuli. Age is an important factor, the highest incidence occurring in children under the age of two and in elderly patients. Knox presented evidence of constitutional predisposition, and although 17 percent of his patients had had previous surgical treatment uncomplicated by psychiatric disturbances, 11 percent had a previous psychiatric illness. Twenty- two percent of patients had a family history of mental illness of serious proportion. There is an increasing incidence of delirium in response to anesthesia and surgical treatment in patients who are alcoholic, while patients suffering from extensive trauma may have organic psychosis. Acidosis, acetonuria, hyperglycemia, hypercalcemia, hypomagnesemia, and hepatic insufficiency can all cause postoperative mental aberrations, and cerebral hypoxia frequently results in behavioral changes. Medications such as barbiturates, anticholinergics, and cortisone also have been implicated.

Management

There is a need to integrate psychologic treatment with the management of the surgical problem. As Titchener and Levine emphasize, it is not necessary, possible, or advisable for the management of psychologic problems to be turned over to psychiatrists, and it is frequently preferable that the measures be initiated by the surgeon in charge. Verbal communication between the surgeon and the patient is the best means of overcoming emotional or mental difficulty. The anesthesiologist is regarded as an impersonal figure who performs a task without emotional impact on the patient. The surgeon should be aware of the patient's feelings, attitudes, and needs for specific information on diagnostic procedures, operating approach, postoperative possibilities, and the like. Discussion of expected feelings and sensations may have a direct effect on the adequacy of adjustment. Also, changes in treatment to increase the patient's positive adaptation to the illness should be constantly considered. The incidence of significant postoperative disturbance suggests the need for a "mental check" to be incorporated into the usual postoperative surgical rounds. Efforts should be directed at removing toxic causes of the acute brain syndrome, removing unnecessary stimuli without isolating the patient, and providing psychologic or pharmacologic tranquilization.

The physician's psychologic approach should include repeated explanation and inquiries about the patient's concerns. In some instances, specific counseling and directive treatment, which may require direct intervention in the patient's personal or family affairs and the assistance of the social services department, is indicated.

The provocative patient who emits anger or attempts to irritate others as a mechanism for covering fear or relieving guilt needs understanding and an attitude of firmness rather than anger from the physician. A patient's attempting to sign out of the hospital against advice is a mechanism of expressing anger or fear and should be handled by the surgeon in a way that allows the patient to change his or her mind without embarrassment.

Consultation with a psychiatrist is indicated in the case of any acute and severe emotional disturbance. The referral should be candidly discussed between the surgeon and the patient. Patients must come to the conclusion that they require help to resolve their problems. Referral also is indicated for long-standing disturbances discovered during hospitalization and is frequently appropriate in patients with psychosomatic illness. Browning and Houseworth, in a study of patients with peptic ulcer, demonstrated that the removal of symptoms without altering the psychosomatic disorders led to the formation of a new set of symptoms. The surgeon should be prepared to differentiate organic from functional disorders, psychosis, and depressive states, because psychiatric consultation may not be available or may be refused by the patient. Specific drugs may be prescribed. Most postoperative traumatic neuroses, manifested by anxiety and reliving the operative experience, can be managed with minor tranquilizers such as diazepam or lorazepam or hypnotics such as flurazepam. Psychoses, such as schizophrenia, mania, and depression, may respond to a phenothiazine derivative. Benzodiazepine derivatives are preferable for nonpsychotic anxiety. Tricyclic antidepressants have an effect that is often delayed 1 to 3 weeks, and they are associated with acute cholinergic side effects and changes in cardiac conduction. These drugs are rarely used in the postoperative period. The newer class of S1 antagonists are rapid acting but may have significant side effects, including dyspepsia and other gastrointestinal complaints.

Delirium Tremens and Other Forms of Delirium

As drug and alcohol abuse become more prevalent, the surgeon must be aware that a relatively normal-appearing patient may undergo withdrawal from alcohol, benzodiazepines, or narcotics in the postoperative period. It may be difficult to distinguish between withdrawal from one type of medication and another.

Delirium is defined as a transient disorder with an impairment of cognitive functions and widespread disturbances in cerebral and entire body metabolism. It is a potentially fatal complication if not corrected. Delirium usually follows operation within 48 h but may be delayed. There usually is a lucid interval postoperatively while withdrawal from the agent is progressing. The patient typically is hyperactive with irritability, delusions, hallucinations, restlessness, and agitation and is noncooperative with treatment. There is a rare hypoactive variant in which the patient is apathetic or somnolent. Speech ranges from the incoherent to the rambling and irrelevant. There may be urinary and stool incontinence, and a loss of motor coordination may be noted.

The cause is multifactorial (Table [11-15](#)). Certain features, such as rapid- onset nystagmus, may indicate withdrawal of psychoactive medications such as sedatives or tranquilizers. Hypoxia, disorders in calcium metabolism, acidosis, and other endocrinopathies should also be ruled out by obtaining "confusion chemistries." A toxicology screening should be ordered to assure that drug withdrawal is not an issue.

Haloperidol 2 to 15 mg orally twice a day or 1 to 5 mg intravenously followed by 5 to 10 mg/h may help agitation, but an occasional patient, particularly among the elderly, may have a paradoxical response. Extrapyrimal symptoms that sometimes complicate the use of haloperidol are relieved with parenteral bntzropine mesylate. In patients with atropine-type psychosis, hepatic failure, or alcohol or drug withdrawal, a neuroleptic agent is not the drug of choice. If benzodiazepine or promethazine hydrochloride (Phenergan) drug abuse is suspected, a small dose of Phenergan with gradual tapering may prevent the emergence of full- blown withdrawal. Prophylactic medication with lorazepam should be administered in the perioperative period to patients with severe alcoholic histories who are candidates for delirium tremens.

Depression

Postoperative depression is not uncommon. It characteristically occurs rather late in the postoperative period. Major manifestations are inability to sleep, anorexia, loss of energy, and a reversal of the day-night rhythm. There may be agitation, but apathy and withdrawal are more common. There is decreased communication and movement. Suicidal tendencies may be present.

A peculiar form of depression occurs in patients in whom life-threatening situations have occurred, such as fistulas, chronic sepsis, major surgical catastrophes, etc. In these patients, depression usually does not occur until the acute syndrome has passed. It is as if these patients hold themselves together until it is clear to them that they will survive. At this point they allow themselves the "luxury" of emotional disintegration.

The use of the newer class of S1 antagonists and second- generation S1 antagonists are useful, although they may have gastrointestinal side effects. A minimal daily dose of 20 mg of paroxetine hydrochloride (Paxil) or 50 mg of sertraline hydrochloride (Zoloft) may not be sufficient, and Paxil may be required at a dose of 40 mg/day and Zoloft at 100 mg/day. Psychiatric consultation can be useful. As the patient understands the cause and leaves the hospital, the depression usually reverses and the medications are discontinued.

Special Surgical Situations

Very young and old patients are particularly vulnerable to the development of psychiatric complications after surgical treatment. Psychotic disturbances have been found in 2 to 3 percent of patients after cataract extraction. The combination of surgical procedure and awareness of the implications of the illness is critical in the patient with cancer. Special consideration is indicated for patients undergoing mastectomy and gynecologic procedures, cardiac surgical treatment, dialysis and transplantation, and prolonged periods in an intensive care unit. The management of drug addicts is assuming greater importance.

Pediatric Surgery

In children, severe anxiety states may be precipitated by the shock of operation. Levy reported that of a group of 124 children who had operations, 20 percent showed residual emotional disturbances. This occurred most frequently in the 1- to 2-year-old group; after the age of three there was a sharp decrease. The age distribution was attributed to a greater dependence on home and mother, and Levy suggested postponement of elective surgical treatment until the child could comprehend the situation. Postoperative reactions consisted of negativism, disobedience, tantrums, defiance, destructive behavior, and dependency manifested by clinging to the mother or attendant. The responses have been related to a feeling of betrayal and the consequent desire for revenge and rebellion. When a child is suffering from fears engendered by an operation, a second operation usually intensifies the earlier fears.

Prophylactic therapy is important. The maturity of the child's emotional adaptation is more a factor in the response than the operation per se. Parental absence frequently is associated with emotional difficulty. Prugh and associates compared two groups, one treated without organized consideration for emotional needs and another in which these needs were considered and ample opportunity for play was provided. Moderate or severe anxiety reactions immediately after leaving the hospital were observed in 92 percent of the control group and in 68 percent of the "treated" group, with a peak incidence in children under the age of three. Three months after discharge, the incidence of persisting anxiety had fallen to 58 percent for the control group and 44 percent for the "treated" group. The younger children reacted more severely, with apprehension, feeding disturbances, and depression. The pattern for the 4- to 6-year-old group was a tendency toward obsessive worries, phobias, and accentuated aches and pains. The 6- to 10-year-olds manifested conversion symptoms, compulsive behavior, and restlessness.

Surgery in the Aged

Elderly patients are more prone to becoming emotionally disturbed when confronted with new situations, especially if they have inadequate comprehension and a generalized feeling of insecurity. The operative procedure also presents an obvious physical threat to the integrity of the nervous system. Titchener and associates reported a 25 percent incidence of significant, and in some cases irreversible, change in cerebral function in the Cincinnati study patients over the age of 65 years. Some degree of depression was observed in 90 percent of the older patients and was disabling in about 50 percent. The indifference of family, friends, and society contributed to the evolution of a paranoid cycle. Efforts should be made to familiarize the patients with the hospital and personnel, and visitors should be encouraged to maintain human contact and prevent withdrawal. Collaboration with a social worker frequently is indicated for long-term rehabilitation.

Gynecologic and Breast Surgery

Removal of the breast and a variety of gynecologic procedures are highly represented in most series on postoperative psychosis. Maquire and associates found that 1 year after mastectomy the women reported a 20 percent incidence of depression, a 10 percent incidence of anxiety, and a 38 percent incidence of sexual difficulties. Contact with other

mastectomy patients expedites psychologic rehabilitation. Routine counseling lowers the postoperative psychiatric morbidity from 38 to 12 percent. Hysterectomy is associated with emotional disturbance more frequently than other gynecologic operations. The more the procedure antedates menopause, the greater the likelihood of associated psychologic disturbance. The loss of menstrual function is perceived by the woman as a blow to normal feminine esteem. Hollender reported that of 203 women admitted to psychiatric hospital, nine had pelvic surgical treatment as a precipitating event, compared to a total of five women admitted after operations of other kinds. Lindemann noted that the relative frequency of restlessness, insomnia, agitation, and preoccupation with depressive thoughts was greater after pelvic operations than after cholecystectomy.

Cancer Surgery

Cancer patients are exposed to two major threats—disease and extensive surgical treatment. They are concerned with death or injury during operation and with disruption of their pattern of living as a result of the effects of cancer or the surgical procedure. Anorexia, insomnia, tachycardia, fear, and panic may occur. Acute depression with suicidal tendencies has been reported in patients anticipating surgical procedures. Postoperatively, depression is related to an anticipated interference with valued activities. Sutherland and associates demonstrated that colostomy imposed on almost all patients a new order of living, and the patients were motivated to avoid social rejection. A rigid life arose from the fearful expectation of rejection because of the colostomy, combined with the fear of death from cancer. There is a tendency toward seclusion, withdrawal, and nonparticipation. Periods of depression are frequent. The study reported that loss of an important bodily part or function is more depressing than the fear or expectation of death. The management of patients with carcinoma must be based on an appreciation of their frequently suffering a sense of isolation, guilt, and abandonment.

Cardiac Surgery

Serious psychiatric disturbances have been observed to occur with considerable frequency after mitral valvulotomy and open-heart surgery. Studies have reported incidences of 16 to 19 percent of serious emotional disturbance after mitral valve surgery. Bolton and Bailey, however, in an evaluation of 1500 consecutive patients, noted an incidence of psychosis in 3 percent with no relation to age, sex, severity of heart disease, duration of failure, or complications of surgical treatment. Egerton and Kay noted delirium in 25 of 60 adults after open-heart surgery.

Manifestations generally occur after an initial lucid interval of 3 to 5 days and resolve shortly after the patient is transferred from an intensive care unit to a standard hospital ward. Postoperative incapacitation and increased time on the heart-lung machine apparently are factors increasing the likelihood of delirium, and incidence is unrelated to age and sex. Zaks has suggested that cardiac operation may produce organic brain damage, sensitizing patients and increasing the incidence of postoperative psychologic symptoms. A prediction equation was successful in differentiating reactors from nonreactors. Using the ego strength variable of the Minnesota Multiphasic Personality Inventory, a significant inverse correlation was found between the reaction and the incidence of acute psychotic episodes after cardiac operation. The incidence of psychosis is greater in males, older patients, and those expressing minimal preoperative anxiety. A preoperative psychiatric interview reduces the incidence of postoperative psychosis by 50 percent.

After operations on the heart, patients with emotional disturbances have been found to manifest perceptual distortion, visual and auditory hallucinations, disorientation, and paranoia. Egerton and Kay reported that 28 percent of adult patients who underwent open-heart surgery had delirious states ranging in duration from several nights to several weeks, averaging 5 days. The delirious patients had no psychologic sequelae, and no relation was established between the incidence of delirium and the duration of cardiac bypass, but open-heart procedures were more likely to produce delirium than other intrathoracic operations. Precipitating factors for delirium included dehydration, hyponatremia, and the performance of a tracheostomy, and predisposing factors included a familial history of psychosis, previous brain damage, overwhelming personal problems, and the presence of a rheumatic valvular lesion. Other psychiatric disturbances noted in patients after open-heart surgery were disabling anxiety state, conversion hysteria, tension headaches, and exacerbation of peptic ulcer. The almost total absence of delirium and other emotional disorders in children is particularly interesting and may be related to the fact that the concept of death as a permanent biologic process usually does not develop until the age of nine.

Dialysis and Transplantation

The suicide rate is 300 times greater in dialysis and transplantation patients than in a comparable healthy population. Uremia, debilitating disease, and the undergoing of repeated procedures are contributing factors. Wright and associates followed 11 patients on chronic dialysis and noted several stresses affecting them, such as unpredictability of well-being, tensions arising in marital relations from guilt and anger, effects of separation on the families, and financial anxiety. After each episode of dialysis, the main response was relief. Cramond and associates noted that their patients first denied their illness but later realized the loss of health and independence and the uncertainty of their future. This has been referred to as a “mourning reaction.” At times, the patients wished to be dead. They felt that life dependent on chronic dialysis was not worth living. Some patients passed from the “mourning reaction” to a state of active depression.

All patients undergoing dialysis become extremely dependent and emotionally attached to the staff and often react emotionally with a sense of loss when any replacement of staff occurs. During the course of the dialysis program, regression occurs relatively frequently, and the patient becomes withdrawn and pretends to sleep. Insomnia and frightening dreams also occur, and the frequency of emotional disturbances suggests that psychiatric assistance has an important role in a dialysis program.

CHAPTER 12 - Physiologic Monitoring of the Surgical Patient

Albert J. Varon
Orlando C. Kirton
Joseph M. Civetta

The primary reason for the surgeon's involvement in bedside critical care is the opportunity to understand and enhance the patient's physiologic response and to recognize and correct the pathophysiologic challenges. To do this effectively, the surgeon must understand physiologic monitoring. Without a thorough knowledge of the physics and methods of monitoring, ensuring the quality of numbers obtained, perceiving their importance, and using measurements as a guide for therapy, selection of proper therapy would be difficult, without foundation, rote, or naive. Thus there are many stimuli to obtain a fundamental knowledge of physiologic monitoring. This chapter is designed to initiate a lifelong process, one that extends the capabilities of the surgeon, improves patient outcome, and advances surgical science.

HEMODYNAMIC MONITORING

The traditional clinical evaluation, usually the initial assessment tool, is often unreliable in critically ill patients, since there may be major changes in cardiovascular function that are not accompanied by obvious clinical findings. Invasive hemodynamic monitoring at the bedside provides information about cardiorespiratory performance and guides therapy on a rational physiologic basis.

Arterial Catheterization

Indications

Arterial catheterization is indicated whenever there is a need for continuous monitoring of blood pressure and/or frequent sampling of arterial blood. States in which precise and continuous blood pressure data are necessary include shock of any etiology, acute hypertensive crisis, use of potent vasoactive or inotropic drugs, high levels of respiratory support (high intrathoracic pressure), high-risk patients undergoing extensive operations, controlled hypotensive anesthesia, and any situation in which any of the factors affecting cardiac function is rapidly changing. This is particularly true in patients with shock, because indirect measurement of blood pressure by a cuff has been proved inaccurate. Sequential analyses of blood gas tensions and pH are necessary in any acute illness involving cardiovascular or respiratory dysfunction or when hyperventilation is instituted in patients with central nervous system injuries. An indwelling arterial catheter also can provide ready access for other blood samples necessary to chart the progression of multisystemic illness.

Inserting arterial lines is a relatively safe and inexpensive procedure. There are no absolute contraindications to arterial catheterization per se, although bleeding diathesis and anticoagulant therapy may increase the risk of hemorrhagic complications. Severe occlusive arterial disease with distal ischemia, the presence of a vascular prosthesis, and local infection are contraindications to specific sites of catheterization.

Clinical Utility

With an indwelling arterial catheter and monitoring system, the systolic blood pressure (SBP), diastolic blood pressure (DBP), and *mean arterial pressure (MAP)* can be displayed continuously. The pulse rate can be calculated from the arterial tracing when the electrocardiogram (ECG) is not available (e.g., during electrocautery use in surgery).

Direct measurements of arterial pressure correlate rather poorly with indirect measurements. The disparities are due in part to physiologic considerations but are largely conditioned by the frequency response of the monitoring systems. Because blood pressure trends are probably more important than absolute values, the most important aspect of direct arterial pressure monitoring is that it constantly reminds the clinician to pay attention to the patient, to think about what is happening, and to reason why changes are occurring.

To obtain accurate data when measuring any pressure within the vascular system, the clinician must understand the monitoring system and methods of calibration. Minor details such as the use of long tubing and the presence of air bubbles or blood clots in the system can make the measurements unreliable.

Observation of the arterial pressure waveform obtained with an arterial catheter and monitoring system may permit a qualitative assessment of the patient's cardiovascular status. The shape of the arterial pressure tracing represents a particular stroke volume ejected at a particular state of myocardial contractility. Qualitative interpretation can be made in a hypovolemic patient with a small stroke volume that will create a smaller pressure wave. As intravascular volume is replenished, the stroke volume increases, and the arterial pressure tracing will increase in size until it attains normal shape. If myocardial contractility is diminished, the rate of increase in aortic pressure will diminish, and the upslope of the arterial pressure tracing will become less vertical and assume a more tangential trajectory with the apex moved to the right.

Although quantitation of stroke volume has been attempted using computers to solve the equations necessary to relate the shape of the peripheral arterial pressure tracing to actual stroke volume ejected, critical illness introduces too many variables for this measurement to be reliable. The location of the dicrotic notch on the arterial waveform also has been advocated as an indicator of the systemic vascular resistance; however, Gerber and associates were unable to demonstrate any statistically significant correlation.

Analysis of the SBP variation during mechanical ventilation may offer important information about the nature of low-flow states. The normal decrease in SBP after a mechanical breath is more pronounced during hypovolemia but practically nonexistent during congestive heart failure.

Sites of Catheterization

Many anatomic sites have been used to access the arterial circulation for continuous monitoring. The superficial temporal, axillary, brachial, radial, ulnar, femoral, and dorsalis pedis arteries have all been used. Although the selection of anatomic site for arterial catheterization usually has an institutional bias, specific advantages and disadvantages should be considered.

The dual blood supply to the hand and the superficial location of the vessel make the radial artery the most commonly used site for arterial catheterization. Cannulation is technically easy, as is securing the catheter in place, and there is a low incidence of complications. The mean and end-diastolic radial pressures are usually accurate estimates of the corresponding aortic pressures; however, the systolic pressure at the radial artery is often much higher than that of the aorta due to overshoot caused by the resonant behavior of the radial artery. This exaggeration is accentuated in stiff, arteriosclerotic radial arteries.

Most authors recommend assessing the adequacy of collateral circulation before cannulation of the radial artery. The most commonly used test is the modified Allen test. The patient is instructed to elevate one hand, make a fist, and clench it firmly, thus squeezing the blood from the vessels of the hand. After the examiner compresses at the same time both the radial and ulnar arteries, the patient lowers and opens the hand in a relaxed fashion (carefully so as not to overextend it). The examiner then releases the pressure over the ulnar artery, and the time for return of color is noted. It is considered normal if the capillary blush of the hand is complete within 6 s. Other methods such as ultrasonic Doppler technique, plethysmography, and pulse oximetry also have been used to assess the adequacy of the collateral arterial supply.

The axillary artery has been recommended as suitable for long-term direct arterial pressure monitoring. Its use has been associated with relatively few complications and no reported permanent sequelae. The major advantages include its larger size, freedom for the patient's hand, and close proximity to the aorta so that there is better representation of the aortic pressure waveform and minimal systolic pressure overshoot. Pulsation and pressure are maintained even in the presence of shock with marked peripheral vasoconstriction. Also, because of the extensive collateral circulation that exists between the thyrocervical trunk of the subclavian artery and the subscapular artery (which is a branch of the distal axillary artery), thrombosis of the axillary artery will not lead to compromised flow in the distal arm. Major disadvantages are its rather deep location and mobility, which increase the technical difficulty for insertion, and its location within the neurovascular sheath, which may increase the possibility of neurologic compromise if hematoma occurs.

The femoral artery also has been used for continuous blood pressure monitoring. Major advantages are its superficial location and large size, allowing easier localization and cannulation when the pulses over more distal vessels are absent. The major disadvantages are the presence of atherosclerotic occlusive disease in older patients and the problems associated with maintaining a clean dressing in the presence of draining abdominal wounds and ostomies in surgical patients. Furthermore, bleeding at this site may be difficult to control or may occur in an occult manner into the abdomen or thigh. Despite these potential disadvantages, studies have failed to demonstrate a higher complication rate in patients with femoral artery catheters.

The dorsalis pedis artery has no significant cannulation hazards if collateral flow can be demonstrated to the remainder of the foot through the posterior tibial artery. This can be done by occluding the dorsalis pedis artery, blanching the great toe by compressing the toenail for several seconds, and then releasing while observing return of color. A Doppler technique also can be used. Major disadvantages are its relatively small size (which makes it more difficult to cannulate) and overestimation of systolic pressure at this level.

The superficial temporal artery has been used extensively in infants and in some adults for continuous pressure monitoring. Because of its small size and tortuosity, however, surgical exposure is required for cannulation. Furthermore, a very small but worrisome incidence of neurologic complications due to cerebral embolization has been reported in infants.

The brachial artery is not used often because of the high complication rate associated with its use for cardiac catheterization. Although this artery has been used successfully for short-term monitoring, there are little data to support the use of prolonged brachial artery monitoring. If collateral circulation is inadequate, obstruction of the brachial artery may be catastrophic, leading to loss of the forearm and hand. Other problems include the difficulty in maintaining the site in awake, active patients and the possibility of hematoma formation in anticoagulated patients. The latter may lead to median nerve compression neuropathy and Volkmann's contracture.

Complications

Common problems associated with arterial catheterization are failure to cannulate, hematoma formation, and disconnection from the monitoring system with bleeding. The majority of reports that describe the complications following radial artery cannulation have stressed the high incidence of early radial artery occlusion and the rarity of late ischemic damage. Recannulation of the occluded artery generally occurs but may take several weeks. The incidence of radial artery thrombosis has declined progressively as a result of the understanding of the effects of different catheter sizes (smaller is better) and materials (Teflon is better) and of the use of continuous heparin flow instead of intermittent flushing. Factors associated with an increased risk of radial artery occlusion include female gender, low cardiac output states, use of vasoconstrictor drugs, severe peripheral vascular disease, small wrist circumference, insertion by surgical cut-down, multiple puncture attempts, hematoma formation, and increased duration of cannulation.

Infections related to arterial catheterization also can occur. Factors associated with an increased risk of infection include placement of the catheter for more than 4 days, insertion by surgical cut-down rather than percutaneously, and local inflammation. The rate of catheter-related infection varies from 0 to over 9 percent, but the risk of catheter-related septicemia is very low.

Other possible complications include retrograde cerebral embolization (when flushing catheters), arteriovenous fistulas, and pseudoaneurysm formation. Finally, inadvertent injection of vasoactive drugs or other agents into an artery can cause severe pain, distal ischemia, and tissue necrosis.

Central Venous Catheterization

Indications

The most common indications for central venous catheterization are to secure access for fluid therapy, drug infusions, or parenteral nutrition and for *central venous pressure (CVP)* monitoring. Central venous catheters also have been used to aspirate air in case of embolism during neurosurgical procedures in the sitting position, for placement of cardiac pacemakers or inferior vena cava filters, and for hemodialysis access.

There are no absolute contraindications for CVP catheter placement, although bleeding diatheses may increase the risk of hemorrhagic complications. Vessel thrombosis, local infection or inflammation, and distortion by trauma or previous surgery are considered contraindications to specific sites of catheterization.

Clinical Utility

While central venous lines are placed primarily for venous access, useful information occasionally can be obtained by measuring the CVP. The CVP may be useful in a hypotensive trauma patient to differentiate a pericardial tamponade from hypovolemia. Analysis of the CVP tracing also may be helpful in the differential diagnosis of certain cardiac arrhythmias (a waves are absent in atrial fibrillation) and in the diagnosis of tricuspid insufficiency (prominent v waves).

A properly placed catheter can be used to measure right atrial pressure, which, in the absence of tricuspid valve disease, will reflect the right ventricular end-diastolic pressure. CVP, therefore, can give information about the relationship between intravascular volume and *right* ventricular function but cannot be used to assess either of these factors independently. CVP cannot be used to assess left ventricular function in critically ill patients because ventricular disparity and independence of right and left atrial pressures have been confirmed repeatedly in these patients. Furthermore, CVP is only a single parameter, in contradistinction to the more complete information concerning pressures, flow, and venous gas measurements available with pulmonary artery catheters.

When monitoring CVP, the catheter should be attached to a pressure transducer for electronic measurement rather than to a water manometer. Water manometry does not permit visualization of the pressure tracing and cannot provide reliable measurements because of the frequency-response limitations of a fluid-filled column that cannot respond to the full range of pressure variations.

Sites of Catheterization

There are many anatomic routes to obtain access to the central venous circulation. The most commonly chosen sites include the subclavian, internal jugular, external jugular, femoral, and brachiocephalic veins. The patient's anatomy and the operator's experience are the major factors influencing site selection.

The subclavian vein can be cannulated with a high rate of success and may be the easiest to cannulate in situations of profound volume depletion. Another advantage of this approach is the ease with which the catheter and the dressings can be secured. Disadvantages include the higher risk of pneumothorax and the inability to compress the vessel if bleeding occurs.

The internal jugular vein has been cannulated with success rates similar to those of the subclavian approach. The major advantages of internal jugular vein catheterization are the lower risk of pneumothorax and the ability to compress the insertion site if bleeding occurs. In addition, the right internal jugular vein provides a straight path to the superior vena cava, facilitating placement of catheters and pacemakers. The internal jugular vein, however, may be more difficult to cannulate in patients with volume depletion or shock. Fixation and dressing of catheters are also more difficult.

Cannulation of the external jugular vein has a lower incidence of complications but a higher incidence of failure. Since catheters inserted through the neck are more difficult to fix and dress than those in other sites, this approach is not suitable for prolonged central venous access.

Although some authors have reported no higher incidence of complications from femoral cannulation than from subclavian or internal jugular sites, concerns over the risk of infection and thrombosis continue to limit general acceptance of long-term femoral cannulation in critically ill patients. Other peripheral veins, such as those in the antecubital fossa, have been used for central venous access, but the high incidence of thrombophlebitis and the fact that many catheters cannot be passed into the central venous circulation make these routes undesirable in critically ill patients.

Complications

Complications can be divided into technical or mechanical complications, usually occurring during catheter placement, and long-term complications related to the length of time that the catheter remains in place. The list of technical and mechanical complications is truly impressive: catheter malposition, dysrhythmias, embolization (air or catheter fragments), vascular injury (hematoma, vessel laceration, false aneurysm, or arteriovenous fistula), cardiac injury (atrial or ventricular perforation or cardiac tamponade), pleural injury (pneumothorax, hemothorax, or hydrothorax), mediastinal injury (hydromediastinum or hemomediastinum), neurologic injury (phrenic nerve, brachial plexus, or recurrent laryngeal nerve), and injury to other structures (trachea, thyroid, or thoracic duct). Pneumothorax is the most frequently reported immediate complication of subclavian vein catheterization, and arterial puncture is the most common immediate complication of internal jugular vein cannulation. The literature suggests that serious mechanical complications of central venous catheterization, although extremely rare, are associated with a high mortality rate.

Long-term complications related to the length of time the catheter is in place are due to infection or thrombosis. Norwood and associates studied triple-lumen catheter infections in septic and nonseptic critically ill surgical patients. They found no catheter-related infections or instances of septicemia in the nonseptic patients, but the incidence of catheter-related infection in the septic group was 26.3 percent, with a 9.6 percent incidence of septicemia. The catheter infection rate per 100 days, however, was only 0.9 for both septic and nonseptic patients combined, which is very similar to rates previously published for single-lumen catheters. Surface-modified central venous catheters have been developed to reduce catheter-related infection. Catheters impregnated with silver sulfadiazine and chlorhexidine resist bacterial adherence and biofilm formation. These catheters have been reported to have a significantly lower proportion of catheter-related infection compared with standard catheters.

At least three types of thrombi can develop in patients with central venous catheters: mural thrombus, catheter thrombus, and “fibrin sleeve” or sleeve thrombus. Any of these thrombi may break loose spontaneously or may be set loose when the catheter is removed. Generally, however, symptoms or clinical consequences do not occur. Superior vena cava syndrome does occur, especially in long-term patients who have had many catheters placed.

Pulmonary Artery Catheterization

Indications

Several studies in critically ill patients have shown that the clinical assessment is inaccurate in predicting cardiac output, pulmonary artery occlusion pressure, and systemic vascular resistance and that the information obtained from pulmonary artery catheterization prompts a change in therapy in 40 to 60 percent of patients. Although the pulmonary artery catheter permits a more accurate hemodynamic assessment and therapy may be modified as a result, this does not prove that knowledge of these data and alteration of the therapy improve overall patient outcome. Some studies indicate that preoperative invasive hemodynamic monitoring and cardiac function optimization in high-risk patients are associated with reduced intraoperative and postoperative cardiac complications and decreased mortality. While there are not enough carefully designed studies to definitely establish the benefit of hemodynamic monitoring to the individual patient, it is reasonable to assume that more precise bedside knowledge of fundamental cardiovascular parameters would facilitate earlier diagnosis and guide therapy. Whether morbidity can be decreased and overall survival can be improved also depend on the patient's overall response, not just on improved cardiovascular function, and thus should not be considered a necessary requirement for initiating invasive monitoring.

In general, a pulmonary artery catheter is indicated whenever the data obtained will improve therapeutic decision making without unnecessary risk. Table [12-1](#) represents the indications most often noted in the medical literature. Variables that are particularly important in assessing benefit versus risk of perioperative use of a pulmonary artery catheter include disease severity, magnitude of anticipated surgery and fluid shifts, and practice setting. There are no specific contraindications to pulmonary artery catheterization, but the same cautions as those attached to central venous access apply.

Clinical Utility

The pulmonary artery catheter has provided a “quantum leap” in the physiologic information available for the management of critically ill patients. The information that can be obtained includes CVP, *pulmonary artery diastolic pressure (PADP)*, pulmonary arterial systolic pressure (PASP), *mean pulmonary artery pressure (MPAP)*, *pulmonary artery occlusion (“wedge ”) pressure (PAOP)*, *cardiac output (CO)* by thermodilution, mixed venous blood gases by intermittent sampling, and continuous mixed venous oximetry. On the basis of this information, a multitude of derived parameters also can be obtained (see below).

When the pulmonary artery catheter balloon is inflated (1.5 mL), the blood flow in a distal segment of the pulmonary artery is occluded, creating a conduit through which left atrial pressure (LAP) can be measured (Fig. [12-1 A](#)). In a tubular system, flow can only be created if there is a pressure differential at both extremes. If there is no pressure differential, flow cannot be present. Using this principle in reverse, a stagnant system in which no forward flow is present would permit an accurate measurement of a distal pressure from a proximal location (see Fig. [12-1 B](#)). In fact, simultaneous PAOP and LAP measurements in patients have validated this principle. The PAOP is a reliable index of the LAP even in the presence of elevated pulmonary vascular resistance. Although the PADP also has been used as an index of LAP, it is not as reliable as the PAOP, particularly if there is tachycardia or increased pulmonary vascular resistance.

The PAOP represents the LAP as long as the column of blood distal to the pulmonary artery catheter tip is patent to the left atrium. This may not be so if the catheter is positioned in an area of the lung where the alveolar pressure exceeds pulmonary venous pressure (zone 2, as described by West) (Fig. [12-2](#)) or both pulmonary artery and venous pressures (West's zone 1), causing intermittent or continuous collapse of the pulmonary capillaries. The PAOP may then reflect alveolar pressure and not LAP. This is particularly important if patients have low pulmonary vascular pressures (i.e., hypovolemia) and/or are treated with high levels of *positive end- expiratory pressure (PEEP)*. Fortunately, since the pulmonary artery catheter is flow-directed, it is most likely to pass into dependent areas of the lung where blood flow is high and both pulmonary artery and venous pressures exceed alveolar pressure (West's zone 3). In this location, the continuous column of blood between the distal lumen of the catheter and the left atrium will remain patent, and the PAOP will reflect LAP. Another factor favoring appropriate catheter position is that when the patient is supine, the volume of lung located above the heart and the hydrostatic gradient favoring the formation of zones 1 and 2 are decreased. If there is any doubt, a lateral chest x-ray can be used to determine the location of the catheter tip in relation to the left atrium. If the tip of the catheter is below this chamber, zone 3 conditions will exist even if high levels of PEEP are used.

In the absence of mitral valve disease or premature mitral valve closure due to aortic regurgitation, the LAP reflects the *left ventricular end-diastolic pressure (LVEDP)*. If there are no alterations in left ventricular compliance (the relationship between pressure and volume), LVEDP will reflect *left ventricular end-diastolic volume (LVEDV)*. In the intact ventricle, LVEDV reflects the end-diastolic stretch of the muscle fiber, which represents the true preload (discussed later).

Raising intrathoracic pressure introduces an artifact that affects all intrathoracic vascular pressures to an extent that depends on the state of pulmonary compliance. In patients with acute respiratory insufficiency, compliance is often diminished, and the “stiff” lungs do not transmit alveolar pressure as readily to the pulmonary circulation. In these patients, the PEEP artifact on the PAOP measurement usually should not exceed 1 mmHg for every 5 cmH₂O of PEEP applied. A greater discrepancy can be seen if the patient is hypovolemic or if the catheter is malpositioned as described above. Another method of evaluating the effects of PEEP on the PAOP measurement is to observe the decrement in PAOP when PEEP is briefly removed. Presumably, this decrement remains relatively constant and can be subtracted from subsequent pressure measurements. Although removal of PEEP may decrease arterial oxygen tension and increase physiologic shunt, these changes are rapidly reversible. If a physician believes that the PAOP should be measured off PEEP, this probably should be done when PEEP is discontinued for other reasons (suctioning or changing breathing circuits), and increased concentrations of oxygen should be given before and after PEEP is stopped. Patients who are receiving very high levels of PEEP or whose condition deteriorates when PEEP is discontinued (such as immediate bradycardia) should not have PEEP removed for the exclusive purpose of measuring PAOP.

Since intravascular pressure measurements are affected by the intrathoracic pressure changes during respiration, they should be performed at end-expiration and obtained from a calibrated strip-chart recorder or oscilloscope rather than from a digital display. Most digital displays are inaccurate because the unselective nature of time-based electrical sampling and averaging includes positive and negative breathing artifacts. The digital average then contains the very respiratory variations that can be excluded by visualizing the tracing and selecting the appropriate value.

The cardiac output is measured by the thermodilution technique, which correlates well with both the Fick and the dye dilution methods. Thermodilution represents an application of the indicator dilution principle in which a change in the heat content of the blood is induced at one point in the circulation, and the resulting change in temperature is detected at a point downstream. This change is produced by a rapid injection of a known volume of fluid at a known temperature (colder than the body) into the right atrium via the proximal port of the pulmonary artery catheter. The change in temperature is registered by a thermistor located 4 cm from the catheter tip. This lowered temperature decreases the electrical resistance of the thermistor and results in a thermodilution curve.

The measurement of CO is based on a modification of the Stewart- Hamilton equation:

CLICK HERE FOR EQUATION

The variables in the formula are essentially fixed before injection, except for the denominator. The denominator of the equation is the thermodilution curve produced by injection of the indicator. A computer integrates the area under this curve, and the resulting calculation is displayed as the cardiac output in liters per minute. The area under the curve is inversely proportional to the CO; that is, the larger the area under the curve, the lower is the CO. In actuality, right ventricular output is being measured: In the absence of intracardiac shunting, right and left ventricular cardiac outputs are equivalent.

The injectate solution can be either 5% dextrose in water or normal saline. A volume of 10 mL of iced or room-temperature injectate is recommended. The injection should be smooth, completed within 4 s, and timed with a specific phase of the respiratory cycle—i.e., injecting at peak inspiration or end-exhalation—rather than randomly. The measurement protocol should be consistent, and three measurements should be averaged, since a single measurement is not reliable. If for any reason the fluid bolus cannot be injected through the atrial port of the catheter (e.g., obstructed lumen), it can be administered through the venous infusion port, the right ventricular port, or the introducer side port.

Pitfalls in cardiac output measurement include injectate temperature different from the temperature used to determine the computer constant or that of the fluid being monitored by the reference probe, delivered volume less than the one entered in the computation constant, incorrect computer constant, rapid infusion of intravenous fluids during measurements, electrical noise created by electrocautery, faulty catheter lumens, improperly positioned catheter (e.g., if the catheter is in the wedge position or if the proximal lumen is above the atrium or within the introducer sheath), and presence of intracardiac shunts or tricuspid regurgitation.

A continuous thermodilution technique is now available for measuring CO. Pulmonary artery catheters are modified to locate a 10-cm thermal filament in the right ventricle during use. Without using any fluid injectate, the thermal filament continually transfers a safe level of heat directly into the blood in a random on-off fashion. The resulting temperature changes are detected at the distal thermistor located in the pulmonary artery. These data are collected by a computer, which then applies a complex formula to cross-correlate the temperature changes with the heat-input sequence to produce the familiar thermodilution curve. CO is then computed from the area under the curve by using an equation similar to the one used for standard bolus thermodilution. The continuous CO monitoring technique has been reported to be accurate and safe in critically ill patients.

Pulmonary artery catheters equipped with rapid-response thermistors and ECG electrodes have permitted the measurement of right ventricular ejection fraction at the bedside; however, the clinical utility of these systems remains unclear.

Catheter Insertion

The most commonly used pulmonary artery catheter is a 7 Fr 110-cm catheter with a distal pulmonary artery lumen, a proximal lumen 30 cm from the tip, a lumen for inflation of the balloon located at the catheter tip, and a thermistor for measurement of cardiac output by the thermodilution method (Fig. 12-3). Newer catheters may contain an additional lumen for fluid administration or for passing a pacing electrode, fiberoptic bundles for continuous measurement of the oxygen saturation of mixed venous hemoglobin (SV O₂), or a rapid-response thermistor to measure right ventricular ejection fraction.

Preparation of the electronic monitoring equipment and testing of the catheter components before insertion are essential because the displayed tracing is used to localize the position of the catheter tip during insertion. The pressure transducer must be calibrated and zeroed to the level of the left atrium. The catheter should be tested before insertion by (1) flushing the proximal and distal lumens to ensure that they are patent, (2) inflating the balloon (1.5 mL) to detect asymmetry or leaks, (3) testing the thermistor by connecting it to the cardiac output computer, and (4) shaking the catheter tip to verify that a tracing can be obtained on the oscilloscope.

Access to the central venous circulation for insertion of a pulmonary artery catheter is the same as for placement of a CVP catheter. Once an introducer sheath is in place, the pulmonary artery catheter is inserted and advanced until the tip reaches an intrathoracic vein (as evidenced by respiratory variations on the pressure tracing). The balloon is then inflated with 1.5 mL of air and the catheter advanced while the operator observes both the pressure waveform and the ECG tracing. After the right atrium is entered, the catheter is advanced through the right ventricle and into the pulmonary artery until a PAOP tracing is obtained (Fig. 12-4). Maneuvers often used to facilitate passage through the pulmonary valve include elevation of the head of the bed, turning the patient into the right lateral decubitus position, performance of the Valsalva maneuver, and increasing ventricular ejection in low-output states by the administration of inotropic drugs. To determine if the catheter is in the wedge position, the waveform needs to be inspected. The mean PAOP should be lower than the MPAP and lower than or equal to the PADP. In the wedged position, arterialized blood can be aspirated, or SV O₂ will increase to systemic arterial levels or above if an oximetric pulmonary artery catheter is used. The latter is not an absolute criterion because incomplete arterialization of the sample can occur if the tip of the pulmonary artery catheter lies wedged in a low ventilation- perfusion region.

Complications

There are risks to pulmonary artery catheterization, although they are typically infrequent and not usually life-threatening. In addition to the complications attributed to central venous cannulation, complications can occur during passage or after the catheter is in place.

The most common complication during passage of the pulmonary artery catheter is the development of dysrhythmias. They can occur in up to 50 percent of patients, but less than 1 percent of these are serious. The incidence of malignant dysrhythmias during catheterization seems to be lower when patients are in the head-up and right lateral tilt position. Transient right bundle branch block (RBBB) has been reported in 3 to 6 percent of catheterizations. Because of the rare but grave consequences of RBBB in patients with preexisting left bundle branch block, the use of standby external pacemakers and equipment for transvenous pacemaker insertion has been recommended in these patients during catheterization. Coiling, looping, or knotting in the right ventricle can occur during catheter insertion. This can be avoided if no more than 10 cm of catheter is inserted after a ventricular tracing is visualized and before a pulmonary artery tracing appears. Aberrant catheter location, such as pleural, pericardial, peritoneal, aortic, vertebral artery, renal vein, and inferior vena cava, also have been reported.

Complications that can occur after the catheter is in place include infections, thromboembolism, and rupture of the pulmonary artery. Infections from pulmonary artery catheters are directly related to the length and severity of illness. The incidence of microbial colonization of the catheter has been reported to be between 5.9 and 29.1 percent, but only 0 to 4.6 percent of catheters produce catheter-related bacteremia. Asymptomatic thrombotic complications are frequent, but symptomatic complications attributable to such thrombi are rare. Pulmonary infarction can occur due to emboli, distal migration of the pulmonary artery catheter tip, or prolonged balloon inflation occluding distal blood flow in the pulmonary artery. Pulmonary artery rupture and hemorrhage are the most serious of all the pulmonary artery catheter complications and are more likely in patients with pulmonary hypertension and in the elderly. Recurrent hemorrhage from a pulmonary artery pseudoaneurysm secondary to pulmonary artery catheter-induced perforation also can occur. Complications related to the peripheral migration of the catheter tip can be limited by continuous monitoring of the pulmonary artery tracing, avoiding prolonged balloon inflation, ensuring proximal catheter placement by review of daily x-rays, and the use of continuous heparin flush systems. Whenever the balloon is inflated, the tracing must be observed. Inflation must be stopped instantly when the waveform changes. If the catheter tip has drifted distally and is in a smaller artery, inflation with the usual 1.5 mL of air may be too much and may rupture the thin-walled pulmonary artery. Other complications that can occur after the catheter is in place include thrombocytopenia, cardiac valve injuries, catheter fracture, and balloon rupture.

In addition to the complications associated with catheter insertion and use, complications can result from delays in treatment due to time-consuming insertion problems and from inappropriate treatment based on erroneous information or erroneous data interpretation. Complications of pulmonary artery catheterization can be minimized by meticulous attention to detail and by careful evaluation of the data obtained.

Derived Hemodynamic Parameters

In addition to the information directly provided by arterial and pulmonary artery catheterization, many parameters can be calculated. The derived hemodynamic parameters (Table 12-2) aid the clinician by quantitating the relationships among heart rate, filling pressures, resistance, contractility, and cardiac output.

Cardiac output (CO) is the sum of all stroke volumes ejected in a given time. It is usually represented as the product of average stroke volume and heart rate (beats per minute),

where stroke volume is the amount of blood ejected by the heart with each contraction. The primary determinants of stroke volume are the ventricular preload, afterload, and contractility.

Preload is the passive load that establishes the initial muscle length of the cardiac fibers before contraction and therefore is not usually measured directly in critically ill patients. On the basis of the work by Otto Frank and others, Starling described the relationship between the resting fiber length of the myocardium and ventricular work. As resting fiber length increases, there is an increase in work performed on subsequent contraction. Beyond a certain point, however, further increases in fiber length will not increase external mechanical work, and work may decrease—a description of cardiac failure. The end-diastolic fiber length is proportional to the end-diastolic volume. If there is no change in ventricular compliance (the relationship between pressure and volume), LVEDV is proportional to LVEDP. Because in most clinical circumstances the PAOP provides a reliable measure of LVEDP, changes in PAOP frequently are used as an estimate of changes in left ventricular preload. In critically ill patients, however, changes in ventricular compliance may affect the relationship between LVEDP and LVEDV. Therefore, caution should be taken in interpretation of the PAOP as the sole measure of left ventricular preload. In clinical practice, judgments concerning preload adequacy are often best made empirically, by observing the responses of PAOP and indices of cardiac performance to a rapid alteration of intravascular volume.

The second determinant of stroke volume is afterload. Afterload is the sum of all the loads against which the myocardial fibers must shorten during systole, including the aortic impedance, the arterial wall resistance, the peripheral vascular resistance, the mass of blood in the aorta and great arteries, the viscosity of the blood, and the end-diastolic volume of the ventricle. In the clinical setting, the most commonly used measure of ventricular afterload is the peripheral or systemic vascular resistance (SVR). Changes in SVR usually reflect either altered blood viscosity or a change in the radius of the vascular circuit. SVR, however, does not necessarily reflect left ventricular loading conditions, since the true measure of ventricular afterload must consider the interaction of factors internal and external to the myocardium. Although it is not physiologically correct to speak of afterload in terms of SVR, it is clinically useful to relate changes in SVR to changes in ventricular afterload. Since sympathetic control of the circulation mediated by peripheral baroreceptors is designed to maintain blood pressure within relatively narrow limits, cardiac output is inversely proportional to SVR whenever this control is functioning. In the human circulatory system, however, additional factors are so often present that this relationship should not be assumed to be a substitute for direct measurements and repeated calculations.

Contractility, the final determinant of stroke volume, may be estimated in the laboratory by the maximum velocity of contraction of the cardiac muscle fibers. At the bedside, we only have inferences based on the stroke work performed by the ventricle as filling pressure (“preload”) changes. Plotting the work done by the ventricle for each beat—the left ventricular stroke work index (LVSWI) or right ventricular stroke work index (RVSWI)—against an estimate of preload and comparing that point with a normal range may be a useful means of assessing overall ventricular function (Fig. 12-5). An upward shift to the left has been interpreted as an improvement in ventricular performance. A shift downward and to the right has been considered as a declining ventricular performance. The “ventricular function curves” are influenced by changes in ventricular afterload and compliance and therefore do not reflect true contractility. At present, the method for assessing myocardial contractility most widely considered load-independent is the end-systolic pressure-volume relationship (ESPVR). The logistical difficulty of obtaining frequent ventricular volume measurements in the intensive care unit (ICU) limits the clinical usefulness of this method. Thus plotting PAOP and stroke work against normal curves is an appropriate use of data currently available in the ICU, but the underlying physiology is often better understood if it is considered in terms of the ventricular pressure-volume relation.

An appreciation of the determinants of stroke volume provides a rational approach in the management of patients with low-perfusion states. The first and most common intervention used to increase stroke volume is to increase preload by augmentation of intravascular volume. The level of PAOP that corresponds to optimal left ventricular preload can be determined only by sequentially assessing the effects of acute hemodynamic interventions on cardiac function and may vary over time in any particular patient. Fluid can be administered rapidly in predetermined increments while changes in PAOP and in the indices of cardiac performance are monitored. A major increase in PAOP during infusion suggests poor ventricular compliance, exhausted preload reserve, and increased risk of pulmonary edema with further volume loading. If the PAOP rises modestly, if indices of cardiac performance improve, and if PAOP returns to within several millimeters of mercury of the original value within 10 min of stopping the infusion, additional fluid can be given without high risk of exacerbating pulmonary venous congestion. After a brief observation period, this sequence can be repeated until the hemodynamic parameters are adequate or the PAOP shows an unacceptable rise. If tissue perfusion remains inadequate after volume optimization, augmentation of stroke volume may be accomplished by increasing myocardial contractility with inotropic drugs and/or decreasing ventricular afterload with vasodilators. Some authors have reported reduced complications and improved survival in perioperative patients when hemodynamic therapy was aimed at augmenting rather than simply normalizing hemodynamic and oxygen-transport parameters. Recent studies, however, found no advantage to the use of supranormal target values in a general population of critically ill patients.

RESPIRATORY MONITORING

Monitoring ventilation and gas exchange in critically ill surgical patients is of particular importance in deciding if mechanical ventilation is indicated, assessing response to therapy, optimizing ventilator management, and deciding if a weaning trial is indicated. In addition, gas monitoring permits an assessment of the adequacy of oxygen transport and calculation of derived parameters.

Ventilation Monitoring

Lung Volumes

Several lung volume measurements are useful for monitoring ventilatory function in the operating room and ICU. These include tidal volume, vital capacity, minute volume, and dead space.

Tidal volume (V_T) is defined as the volume of air moved in or out of the lungs in any single breath. If the tidal volume is depressed, the patient may have difficulty in both oxygenation and ventilation. Rapid, shallow breathing, as reflected by the respiratory frequency (f) to tidal volume ratio ($f/V_T > 100$), is an accurate predictor of failure, and its absence ($f/V_T < 80$) is an accurate predictor of success, in weaning patients from mechanical ventilation. V_T can be measured at the bedside using a hand-held spirometer (Wright respirometer). Because moisture impairs its performance, the instrument is most appropriate for intermittent monitoring. Continuous V_T monitoring is facilitated by the presence of pneumotachometers in the breathing circuit of modern ventilators. In order to obtain accurate V_T measurements, the spirometer must be located between the ventilator Y piece and the endotracheal tube. If the spirometer is instead positioned on the expiratory limb of the breathing circuit, the entire V_T delivered by a ventilator, not that actually received by the patient, is measured. Under conditions of decreased lung compliance or increased airway resistance, the higher peak inspiratory pressure (PIP) would result in an increase of gas volume compressed in the breathing circuit, with correspondingly less delivered to the patient. The product of $PIP\text{ (cmH}_2\text{O)} \times 5\text{ (mL/cmH}_2\text{O)}$ provides an estimate of the compression volume of most circuits.

Vital capacity (VC) is defined as the maximal expiration following a maximal inspiration. It can be readily measured at the bedside in a manner similar to the one used for V_T . The VC is reduced in diseases involving the respiratory muscles or their neural pathways, in obstructive and restrictive ventilatory impairment, and in patients who fail to cooperate fully. VC is normally 65 to 75 mL/kg, and a value of 10 mL/kg or greater is commonly considered a favorable predictor of weaning outcome. This value, however, is quite dependent on patient cooperation, and its predictive power is rather poor.

Minute volume (or total ventilation) ($V_{(dot)E}$) is the total volume of air leaving the lung each minute (product of V_T and f). Many ventilators display $V_{(dot)E}$, or it can be measured with a Wright spirometer. An increase in the minute volume required to maintain a normal arterial blood carbon dioxide tension (Pa_{CO_2}) suggests an increased dead space relative to V_T or an abnormally high carbon dioxide (CO_2) production. A resting $V_{(dot)E}$ of less than 10 L and the ability to double the resting $V_{(dot)E}$ on command have been associated with successful weaning from mechanical ventilation.

The physiologic (or effective, or total) *dead space* (V_D) is the portion of tidal volume that does not participate in gas exchange. Physiologic dead space may be divided into two components: the volume of gas within the conducting airways (the anatomic dead space) and the volume of gas within unperfused alveoli (the alveolar dead space). The ratio of physiologic dead space to tidal volume (V_D/V_T) is calculated from the Enghoff equation (modified from the Bohr equation) as follows:

$$V_D / V_T = Pa_{CO_2} - PE_{CO_2} / Pa_{CO_2}$$

where PE_{CO_2} is the mean partial pressure of exhaled CO_2 in the total exhaled volume of gas after thorough mixing. Normally, exhaled gas is collected in a bag over 3 min and the PE_{CO_2} is measured from the bag. The PE_{CO_2} should not be confused with P_{etCO_2} , the partial pressure of end-tidal CO_2 (discussed later). The V_D/V_T ratio provides a useful expression of the efficiency of ventilation. In healthy subjects, the ratio is between 0.33 and 0.45. The V_D/V_T ratio is increased in a number of disease states associated with regions of the lung possessing high ventilation-perfusion ratios, such as adult respiratory distress syndrome, emphysema, pulmonary embolism, shock with low cardiac output, and the employment of positive-pressure ventilation with high V_T or excessive (more than is needed) PEEP. Patients whose V_D/V_T exceeds 0.6 are usually not weanable from ventilatory support.

By measuring $V_{(dot)E}$ and calculating V_D/V_T , the alveolar (or effective) ventilation ($V_{(dot)A}$) also may be calculated:

$$V_{(dot)A} = V_{(dot)E} - (V_{(dot)E} \times V_D/V_T)$$

Pulmonary Mechanics

Various respiratory mechanical parameters also can be monitored in the operating room and ICU. These include maximal inspiratory pressure, static compliance, dynamic characteristic, and work of breathing.

Inspiratory force is measured as the maximal pressure below atmospheric that a patient can exert against an occluded airway. The measurement requires a connector to an endotracheal or tracheostomy tube and a manometer capable of registering negative pressure. A maximal inspiratory pressure (Pi_{max}) value more negative than -20 to 25 cmH₂O has been used as one of the clinical parameters to confirm recovery from neuromuscular block after general anesthesia. Pi_{max} values more negative than -30 cmH₂O have been used to predict successful weaning from mechanical ventilation. Studies have found that Pi_{max} has limited power in predicting weaning outcome, especially in patients receiving prolonged mechanical ventilation. These findings may be due in part to the fact that Pi_{max} assesses only the strength of the respiratory muscle pump without taking into account the demands placed on it.

Compliance, a measure of the elastic properties of the lung and chest wall, is expressed as a change in volume divided by a change in pressure (DV/DP). In patients receiving mechanical ventilation, a rough measure of total thoracic compliance (both the lungs and chest wall) can be obtained by dividing the delivered V_T by the inflation pressure displayed on the ventilator gauge during conditions of zero gas flow. These can be achieved by using the “inspiratory hold” option on the ventilator, during which period the airway pressure falls to a plateau. If the patient is receiving PEEP, this must be first subtracted from the plateau pressure before calculating static thoracic compliance, that is,

$$\text{Static compliance} = \text{volume delivered} / \text{plateau pressure} - \text{PEEP}$$

The usual range for adult patients receiving mechanical ventilation is 60 to 100 mL/cmH₂O. Decreased values are observed with disorders of the thoracic cage or a reduction in the number of functioning lung units (resection, bronchial intubation, pneumothorax, pneumonia, atelectasis, or pulmonary edema). When the static compliance is less than 25 mL/cmH₂O, as in severe respiratory failure, difficulties in weaning are common because of the increased work of breathing (see below).

The dynamic characteristic is calculated by dividing the volume delivered by the peak (rather than the plateau) airway pressure minus PEEP. It is not correct to call this value *dynamic compliance* because it is actually an impedance measurement and includes compliance and resistance components. The dynamic characteristic is normally about 50 to 80 mL/cmH₂O. It may be decreased by disorders of the airways, lung parenchyma, or chest wall; if it decreases to a greater extent than the static compliance, it suggests an increase in airway resistance (e.g., bronchospasm, mucous plugging, kinking of the endotracheal tube) or an excessive flow rate.

Work of breathing, which relates to the product of the change in pressure and volume, is a measure of the process of overcoming the elastic and frictional forces of the lung and chest wall. The work of breathing in the critically ill patient who requires ventilatory support (WOB_{PI}) can be divided into three components: normal physiologic work (WOB_{Phys}), work to overcome the pathophysiologic changes in the lung and chest wall (WOB_{Dis}), and work to overcome the imposed work of breathing (WOB_{Imp}) created by our methods of ventilatory support. The sum is total work. Physiologic work of breathing consists of three elements: elastic work, flow-resistive work, and inertial work. Elastic work is the work necessary to overcome the elastic forces of the lung and is inversely proportional to the compliance of the lung. If compliance becomes diminished, the work of breathing increases dramatically. The second element of physiologic work is flow-resistive work, or the work that is needed to overcome the resistance of the airways and parenchymal tissues. This may increase the pressure change necessary to inhale the same tidal volume but also adds another component of work during expiration, that necessary to expel the gas from the lungs through the narrow airways. The third component of physiologic work is the inertial work to overcome the tendency of gas volume to remain at rest. This element is negligible in comparison with the elastic and flow- resistive work. When a patient develops respiratory failure, in addition to the normal physiologic work, the patient must overcome the increased work of breathing associated with the disease. This is clinically manifest as a change from a relatively large tidal volume at a slow rate to a small tidal volume at a rapid rate. Finally, the patient must do additional work to breath spontaneously against a breathing apparatus that consists of the ventilator itself, demand valve, tubing, exhalation valves, and most important, the endotracheal tube. Banner and associates showed that the endotracheal tube acts as a resistor in series in the breathing apparatus, thereby causing an increase in work of breathing. Imposed work has been shown to exceed physiologic work of breathing by a factor of 6 under conditions of spontaneous breathing through a narrow-internal-diameter endotracheal tube at a high inspiratory flow rate demand during continuous positive airway pressure. Poor demand system sensitivity, ventilator dyssynchrony, malfunctioning demand valves, and inadequate inspiratory flows are also contributing factors.

The goal of ventilatory support is to carefully titrate the ventilator's contribution to minute ventilation so that the patient's effort remains a nonfatiguing work load. Failure to do so by supplying either too much or too little ventilatory support may result in unsuccessful weaning trials and increase the duration of mechanical ventilation. Normal range for WOB_{PI} is 0.3 to 0.6J/L.

Microprocessor-based respiratory monitors such as the CP-100 Pulmonary Monitor (Biocore Monitoring Systems, Irvine, CA) measure many mechanical ventilation and respiratory muscle parameters, including compliance, airway resistance, strength and endurance, and both patient and ventilator work of breathing. Physiologic data are accrued from a miniature pneumotachograph and airway pressure sensor positioned between the Y piece of the breathing circuit tubing and the endotracheal tube. A catheter with a distally annealed balloon is positioned in the distal esophagus to measure changes in intraesophageal pressure as an estimate of changes in intrathoracic pressure. We have employed this pulmonary monitor to evaluate unexplained tachypnea or respiratory distress, to guide endurance and strength reconditioning, and to avoid iatrogenic ventilator dependency caused by inappropriate ventilator settings in complex long-term ventilated patients.

Incorporation of work-of-breathing analysis into our preextubation trial allowed successful extubation in 97 (of 589) patients who remained on mechanical ventilation because of tachypnea (respiratory rate between 32 and 52 breaths per minute) secondary to excessive imposed work of breathing. Earlier extubation in this group of patients resulted in a projected net savings in excess of \$292,000. Incorporating work-of- breathing strategies also decreased the duration of ventilation in our trauma ICU from 8.8 to 4.2 days.

Gas Monitoring

Blood-Gas Analysis

Blood-gas measurements provide information about the efficiency of gas exchange, the adequacy of alveolar ventilation, and the acid-base status. Blood gas values are usually reported in terms of directly measured partial pressures (P_{O2} or P_{CO2}) and calculated hemoglobin oxygen saturations (S_{O2}). Calculated S_{O2} values are derived from the measured partial pressure and a nomogram of the oxyhemoglobin dissociation curve usually corrected for blood temperature, pH, and perhaps other factors. Because these assumptions may not be accurate in critically ill patients, actual measurements of S_{O2} by cooximetry are preferred. S_{O2} also can be measured continuously by using pulse oximeters or pulmonary artery catheters that incorporate oximetric fibers (see below).

Arterial blood gas tensions are determined by the composition of the alveolar gas and the efficiency of gas transfer between the alveoli and pulmonary capillary blood. Alveolar gas tensions depend on the mixture of inspired gas, ventilation, and blood flow in the lungs; the matching of ventilation and perfusion; and the composition of mixed venous blood gases. Pathophysiologic causes of arterial hypoxemia include ventilation- perfusion inequality or venous admixture from regional alveolar hypoventilation, true intrapulmonary or intracardiac shunt, and decreased mixed venous oxygen content. Although diffusion abnormalities may lead to hypoxemia if pulmonary end-capillary blood fails to equilibrate fully with alveolar gas, such conditions are uncommon. A decreased cardiac output in the presence of a constant oxygen consumption, an increased oxygen consumption in the presence of a constant CO, and a decreased CO and an increased oxygen consumption must all result in a lower mixed venous oxygen content and therefore also can produce arterial hypoxemia. Failure to recognize this nonpulmonary cause of hypoxemia may cause a clinician to falsely attribute a decreasing arterial blood oxygen tension (Pa_{O2}) to deteriorating pulmonary function. Thus pulmonary and cardiac function must be assessed to evaluate any given set of arterial blood gases accurately. A decreasing Pa_{O2} without a change in Pa_{CO2} suggests that blood oxygenation is deteriorating despite constant alveolar ventilation. In the acutely ill patient, this finding is usually attributable to ventilation-perfusion imbalance or intrapulmonary shunting. An important feature of shunting is that as it increases, supplemental oxygen has progressively less effect on Pa_{O2} because shunted blood bypasses ventilated alveoli. Intrapulmonary shunting usually does not result in elevation of the Pa_{CO2} because the central chemoreceptors sense any rise in Pa_{CO2} and respond by increasing ventilation.

The relation of P_{O2} to S_{O2} is described by the oxyhemoglobin dissociation curve (Fig. 12-6). The flat upper portion of the dissociation curve means that even if the P_{O2} in alveolar gas decreases somewhat, loading of oxygen will be little affected. The steep lower part of the curve means that the peripheral tissues can withdraw large amounts of oxygen for only a small decrease in capillary P_{O2}. The curve shifts as the affinity of hemoglobin for oxygen changes. A shift to the right (decreased affinity for oxygen) helps release oxygen into the tissue. A shift to the left (increased affinity for oxygen) causes less oxygen to be available to tissue. The curve can be shifted to the right by *increased* erythrocyte 2,3-diphosphoglycerate concentration, temperature, P_{CO2}, and concentration of hydrogen ion (decreased pH). Opposite changes shift it to the left. Other conditions such as carboxyhemoglobinemia and methemoglobinemia also can shift the oxyhemoglobin dissociation curve to the left and therefore interfere with peripheral oxygen unloading. The position of the oxyhemoglobin dissociation curve is defined by the P₅₀, that is, the P_{O2} at which hemoglobin is 50 percent saturated. Normal hemoglobin has a P₅₀ of 26.5 mmHg. When it is greater than this value, the curve is shifted to the right; when it is lower, the curve is shifted to the left. Despite a considerable amount of information, there is little evidence that shifts of the oxyhemoglobin dissociation curve are clinically significant in the majority of patients. Individuals with limited circulatory reserve, however, who cannot augment oxygen delivery by the usual compensatory mechanisms of increased cardiac output and organ blood flow, may develop local tissue hypoxia when an increased hemoglobin-oxygen affinity state (i.e., alkalemia) exists.

The Pa_{CO2} directly reflects the adequacy with which alveolar ventilation meets metabolic demands for CO₂ excretion. The relationship between Pa_{CO2}, CO₂ production (V_{(dot) CO2}), and alveolar ventilation (V_{(dot) A}) in normal lungs is given by the equation

$$Pa_{CO2} = V_{(dot) CO2} / V_{(dot) A} \times K$$

where K is a constant. In diseased lungs, the denominator V_{(dot) A} in this equation is less than the ventilation going to the alveoli because of alveolar dead space, that is, unperfused alveoli or those with high ventilation- perfusion ratios. For this reason, the denominator is sometimes referred to as the *effective alveolar ventilation*.

An increased Pa_{CO2} (hypercapnia) reflects the failure of the ventilatory system to eliminate the CO₂ produced during metabolism. This “ventilatory failure” is traditionally described as respiratory acidosis. Hypercapnia can occur because of hypoventilation (i.e., CNS depression), increased CO₂ production (e.g., hyperthermia, hyperthyroidism), or increased physiologic dead space resulting in inadequate alveolar ventilation. The mechanisms of hypocapnia are the reverse of those which produce hypercapnia, the most common being hyperventilation (respiratory alkalosis).

The oxygen tension of mixed venous blood (PV_{O2}) and the oxygen saturation of mixed venous hemoglobin (SV_{O2}) provide valuable diagnostic information and are necessary for the calculation of various parameters, such as arteriovenous oxygen content difference, intrapulmonary shunt, and oxygen consumption. Mixed venous blood is the mixture of all blood that has traversed the capillary beds capable of extracting oxygen. This venous effluent is thoroughly mixed, so its oxygen content is a flow- weighted representation of all the end-capillary contents of the body and as such will reflect the *total body balance* between oxygen delivery and oxygen consumption of *perfused* tissues. The mixed venous oxygen content (and therefore SV_{O2}) is determined by the variables in the Fick equation (see section on Continuous Mixed Venous Oximetry). The PV_{O2} is determined by the same factors and the position of the oxyhemoglobin dissociation curve.

In critically ill patients, sampling of mixed venous blood can be performed accurately only in the pulmonary artery. Sampling technique is important; blood should be withdrawn from the most proximal pulmonary artery location possible and at a very slow rate. A fast rate of blood withdrawal or a malpositioned catheter (distal migration or wedging) may cause a falsely elevated PV_{O2} and SV_{O2}. This is due to “contamination” of the mixed venous blood with arterialized pulmonary capillary blood and should be suspected if the CO₂ tension of mixed venous blood (PV_{CO2}) is equal to or lower than a simultaneously determined Pa_{CO2}.

Proper sample handling before arterial or venous blood-gas analysis is a prerequisite to accurate blood gas measurement. The two principal requirements are that the sample be obtained under strict anaerobic conditions and immediately placed on ice until analyzed. Because room air has a partial pressure of oxygen (P_{O2}) of about 150 mmHg and a partial pressure of carbon dioxide (P_{CO2}) of essentially zero, equilibration of a blood sample with air bubbles may significantly alter the results. Placement of the sample on ice is necessary to reduce the metabolic rate of the red blood cells and prevent continued oxygen consumption and CO₂ production if analysis is to be delayed beyond 15 to 20 min. The addition of excessive heparin also will alter the results, and therefore, after aspiration, the heparin in the syringe should be expelled, leaving only the heparin wetting the barrel. Alternatively, a commercially available syringe containing dry heparin can be used.

Because blood gas values can change rapidly in critically ill patients, intermittent sampling for blood-gas analysis might miss significant changes. Advances in fiberoptic and microprocessor technology have been combined with fluorescent dye chemistry to develop miniaturized intravascular gas sensors that permit continuous measurement of pH, P_{O2}, and P_{CO2}. The performance of fiberoptic continuous intraarterial blood gas monitors is comparable with that of modern blood gas analyzers. Further studies are needed, however, to determine the clinical utility of this new methodology.

Parameters Derived from Blood-Gas Analysis

Just as the derived hemodynamic parameters can be used to evaluate the choice and effects of hemodynamic interventions, parameters derived from blood-gas analysis (Table 12-3) yield information about the adequacy of cardiopulmonary function in meeting the tissue demands for oxygen.

The oxygen content of the blood is equal to the amount of oxygen bound to hemoglobin plus the amount dissolved in plasma. The amount of bound oxygen is directly related to the concentration of hemoglobin and to how saturated this hemoglobin is with oxygen (i.e., Sa_{O_2} or SV_{O_2}). The amount of oxygen dissolved in plasma depends on the oxygen tension (i.e., Pa_{O_2} or PV_{O_2}). Oxygen delivery ($\dot{V}_{O_2}$) is the volume of oxygen delivered from the heart each minute and is calculated as the product of cardiac output and arterial oxygen content (Ca_{O_2}). Oxygen consumption ($\dot{V}_{(dot) O_2}$) is the amount of oxygen that diffuses from the capillaries into all tissues and can be calculated according to the Fick principle as the product of CO and arteriovenous oxygen content difference [$C(a - PV)_{O_2}$]. If this equation is rearranged, the arteriovenous oxygen content difference relates oxygen consumption and CO ($\dot{V}_{(dot) O_2}/CO$). An increase in the arteriovenous oxygen content difference indicates that either consumption is too high or flow is too low. Finally, the oxygen utilization coefficient or extraction ratio (O_2UC), relates oxygen consumption and oxygen delivery ($\dot{V}_{(dot) O_2}/\dot{V}_{O_2}$). This parameter has been used in many ICUs to evaluate the adequacy of oxygen transport.

The adequacy of oxygen transport also must be assessed in relation to oxygen demand, which is the amount of oxygen *required* by the body tissues to use aerobic metabolism. Although oxygen demand cannot be measured clinically, the relative balance between consumption and demand is best indicated by the presence of excess lactate in the blood. Lactic acidosis means that demand exceeds consumption and anaerobic metabolism is present.

Although precise numerical end points cannot be defined, the parameters already listed provide a framework for testing a clinical hypothesis: If oxygen delivery or consumption is low, if utilization is high, or if lactic acidosis is present, arterial oxygen content might be augmented by increasing hemoglobin concentration or oxygen saturation, or cardiac output might be increased by manipulation of preload, afterload, or contractility. A response might be considered beneficial if oxygen consumption increases, if utilization returns to the normal range, or if lactic acidosis resolves.

Physiologic right-to-left shunt or venous admixture ($_{sp/t}$) estimates the fraction of total blood flow reaching the left side of the circulation without participating in gas exchange. Shunt may occur (uncommonly) in adults via intracardiac shunts. More commonly, increased venous admixture in critically ill patients is due to alterations in the balance of pulmonary ventilation and perfusion (lung areas that are perfused but not ventilated). Before calculating venous admixture, it is necessary to calculate arterial, mixed venous, and pulmonary end-capillary oxygen contents. The latter can be calculated by using the *alveolar* oxygen tension (Pa_{O_2}) to estimate pulmonary end-capillary oxygen tension and the oxyhemoglobin dissociation curve to estimate pulmonary end-capillary hemoglobin saturation (assume 100% if $Pa_{O_2} > 150$ mmHg) (see Table 12-3).

Other indices, such as the alveolar-arterial oxygen partial pressure difference ($Pa_{O_2} - Pa_{O_2}$) and the arterial-to-alveolar oxygen tension ratio (Pa_{O_2}/Pa_{O_2}), have been suggested for evaluating the efficiency of gas exchange. These oxygen tension–based indices, however, are inaccurate in predicting efficiency of gas exchange. The relationship between physiologic shunt and the oxygen tension–based indices is nonlinear and substantially influenced by changes in inspired oxygen concentration and arteriovenous oxygen content difference.

The collection of the measured and derived cardiopulmonary parameters has been called the *cardiopulmonary profile*. Normal values can be seen in Tables 12-2 and 12-3. The measured and derived data can be used to formulate a plan of interventions designed to improve oxygen delivery relative to myocardial and systemic needs. This analysis is a dynamic process that evolves as new data are obtained and response to therapy is incorporated. The process of generating a cardiopulmonary profile has been greatly simplified by the use of programmable calculators and microcomputers.

Capnography

Capnography is the graphic display of CO₂ concentration as a waveform. It should not be confused with *capnometry*, which refers to only the numerical presentation of the concentration without a waveform. Capnography includes capnometry when the capnographic display is calibrated.

Currently available systems for CO₂ analysis include infrared spectroscopy, mass spectrometry, and Raman scattering. In addition, a disposable, noninvasive, and inexpensive colorimetric device (Easy Cap; Nellcor Puritan Bennett, Inc., Pleasanton, CA) is available. This device permits a semiquantitative measurement of the end-tidal CO₂ concentration when it is attached between an endotracheal tube and a resuscitation bag.

In the majority of stand-alone capnographs, the CO₂ concentration is measured by infrared spectroscopy. A beam of infrared light is passed through the sampled gas. CO₂ molecules in the light path absorb some of the infrared energy. The capnograph compares the amount of infrared light absorbed by the patient gas in the sample cell with the amount absorbed either by gas in a reference cell or by the sample cell during a time of known zero-gas concentration. The capnograph then displays the instantaneous CO₂ concentration.

Gas for analysis of CO₂ may be aspirated from the airway (sidestream capnography) or may be analyzed as it flows through a sensor placed in the airway (mainstream capnography). Sidestream analyzers offer advantages in that gas is sampled close to the patient's mouth with the use of an inexpensive, lightweight connector, and they can be used in nonintubated patients. The major disadvantage of these systems is that analysis is delayed because gas is routed through a capillary tube to the capnograph.

Mainstream analyzers generate a capnogram practically instantaneously because the gas is analyzed as it passes through a sampling cuvette. The major disadvantage of these systems is the weight of the sensor and sampling cuvette. Because the sensor itself is a sophisticated instrument, it needs to be treated carefully: It is fragile, and replacements are expensive. The volume of the cuvette adds dead space to the system.

Normally, there is a fairly predictable relationship between the peak exhaled or end-tidal CO₂ (Pet_{CO_2}) and the Pa_{CO_2} . In healthy subjects with normal lungs, the Pa_{CO_2} is 4 to 6 mmHg higher than the Pet_{CO_2} . Patients with chronic obstructive lung disease and other derangements associated with increased dead space (see section on Lung Volumes) have an increased arterial to end-tidal CO₂ gradient [$P(a - et)_{CO_2}$]. This difference occurs because the exhaled gas from the alveolar dead space, which contains little or no CO₂, dilutes the CO₂-containing gas from the normally ventilated and perfused alveoli.

Measurement of Pet_{CO_2} and $P(a - et)_{CO_2}$ provides insight into several normal and pathologic processes. Pet_{CO_2} measurement is at present perhaps one of the most reliable means of determining proper endotracheal tube placement. Esophageal intubation may produce one or a few breaths containing CO₂ during expiration, but because there is no CO₂ in the stomach cavity, Pet_{CO_2} rapidly decreases to zero.

Pet_{CO_2} has been found to correlate with cardiac output and coronary perfusion pressure during cardiopulmonary resuscitation (CPR) and with successful resuscitation from and survival after cardiac arrest. Because circulatory arrest creates total dead space, if ventilation is continued, Pet_{CO_2} disappears. An increase in Pet_{CO_2} provides an immediate bedside validation of the efficacy of CPR, and if the increase is abrupt, it provides the earliest evidence of successful resuscitation. The use of Pet_{CO_2} to monitor resuscitation is predicated on maintaining a constant minute ventilation so that changes in Pet_{CO_2} result from changes in lung perfusion (and therefore cardiac output) and not ventilation.

Pet_{CO_2} monitoring is extremely useful as a diagnostic tool in several situations unique to the operating room. These include the detection of air emboli during neurosurgical procedures requiring the sitting position, the detection of increased CO₂ production in malignant hyperthermia, and the detection of disconnection or malfunction of the anesthesia breathing circuit.

In the ICU environment, Pet_{CO_2} monitoring also can be used as a ventilator disconnect alarm as well as a system to determine ventilator malfunction. Measurement of Pet_{CO_2} has been proposed as a substitute for arterial blood gas sampling during mechanical ventilation adjustment and weaning in critically ill patients. Pet_{CO_2} trends in these patients, however, are often misleading because the $P(a - et)_{CO_2}$ varies greatly in a single individual.

The $P(a - et)_{CO_2}$ is primarily a reflection of dead-space ventilation, and its size can serve as a gauge of physiologic aberration. Factors related to the instrumentation and the technique used, however, also may contribute to the $P(a - et)_{CO_2}$. For example, aspiration of room air through a loose connection or break in the circuit or sampling tube, a leak around the cuff, or aspiration of fresh gases will dilute the exhaled CO₂ and result in an increased $P(a - et)_{CO_2}$ and an altered waveform.

Analysis of the CO₂ waveform can provide valuable information. A detailed review of waveform analysis is outside the scope of this chapter but can be found elsewhere (Gravenstein and associates).

Pulse Oximetry

Pulse oximetry provides a reliable, real-time estimation of arterial hemoglobin oxygen saturation. This noninvasive monitoring technique has gained clinical acceptance in the operating room, recovery room, and ICU.

Pulse oximeters estimate arterial hemoglobin saturation by measuring the absorbance of light transmitted through well-perfused tissue, such as the finger or ear. The light absorbance is measured at two wavelengths—660 (red) and 940 nm (infrared)—to distinguish between two species of hemoglobin—oxyhemoglobin and deoxyhemoglobin. Oxyhemoglobin absorbs less red light than deoxyhemoglobin, accounting for its red color; at infrared wavelengths, the opposite is true (Fig. 12-7). Light absorbances at both wavelengths have two components: the pulsatile (or ac) component, which is attributed to the pulsating arterial blood, and the baseline (or dc) component, which represents the absorbances of the tissue bed, including venous blood, capillary blood, and nonpulsatile arterial blood (Fig. 12-8). The pulse oximeter first determines the ac components of absorbance at each wavelength and divides this by the corresponding dc component to obtain a pulse-added absorbance that is independent of the incident light intensity. It then calculates the ratio (*R*) of these pulse-added absorbances:

$$R = AC_{660}/DC_{660} / AC_{940}/DC_{940}$$

The ratio of the pulse-added absorbances at the two wavelengths is used to generate the oximeter's estimate of arterial saturation (Sp_{O_2}). The relationship between this ratio and Sp_{O_2} is empirical. The algorithm was created by measuring pulse-added absorbances in healthy, awake volunteers breathing hypoxic gas mixtures. These absorbances were then correlated with actual Sa_{O_2} as determined by a laboratory co-oximeter.

In practice, pulse oximeters use two light-emitting diodes (LEDs) and one photodiode as transmitting and sensing transducers, usually placed on opposite sides of a digit. The microprocessor of the pulse oximeter is programmed to distinguish arterial pulse waveforms; minimize the effects of ambient light, patient motion, and electrocautery; and vary the intensity of transmitted light required to obtain the waveforms.

In most studies of pulse oximetry accuracy, data have been collected only when the pulse oximeter heart rate equaled the ECG heart rate. It has been assumed that this is a necessary condition for accuracy because it implies that the pulse oximeter is detecting pulses produced by heartbeats.

Most manufacturers claim that their pulse oximeters are accurate within ±2 percent (SD) from 70 to 100 percent saturation. Although pulse oximetry may provide erroneous measurements when Sa_{o2} is less than 70 percent, these values occur quite rarely (or *should* occur quite rarely) in patients, because Pa_{o2} would be less than 40 mmHg. Sa_{o2} values in the range of perhaps 70 to 95 percent will reflect changes in Pa_{o2}; it is in this range that pulse oximetry finds great value in monitoring cardiorespiratory disease and directing therapy. High levels of saturation give no information about Pa_{o2}. Because of the sigmoid shape of the oxyhemoglobin dissociation curve (see Fig. 12-6), Sa_{o2} may not decrease despite a significant deterioration in pulmonary gas exchange, i.e., if Pa_{o2} fell from 200 to 100 mmHg. Since delivery of oxygen to the tissues is proportional to Sa_{o2}, however, pulse oximeters will detect changes before tissue oxygenation is impaired.

Various physiologic and environmental factors interfere with the accuracy of pulse oximetry. These include decreased amplitude of peripheral pulses (hypovolemia, hypotension, hypothermia, vasoconstrictor infusions), motion artifact, electrosurgical interference, backscatter from ambient light, and dyshemoglobinemias. Predictors of pulse oximeter data failure in the operating room include ASA physical status 3, 4, or 5; cardiac, vascular, and orthopedic surgery; hypotension; hypertension; and duration of procedure.

The pulse oximeter can only distinguish oxyhemoglobin and deoxyhemoglobin. If other hemoglobin species are present, an error is introduced. Laboratory co-oximeters, on the other hand, generally use more than two wavelengths and often can quantify other hemoglobin species directly. When dyshemoglobins such as carboxyhemoglobin and methemoglobin can be measured, it becomes meaningful to distinguish between functional saturation [100 × oxyhemoglobin/(oxyhemoglobin + deoxyhemoglobin)] and fractional saturation [100 × oxyhemoglobin/(oxyhemoglobin + deoxyhemoglobin + carboxyhemoglobin + methemoglobin)]. Barker and colleagues have shown that in the presence of elevated carboxyhemoglobin or methemoglobin levels, Sp_{o2} *overestimates* fractional saturation at all saturation values. Carboxyhemoglobinemia may occur in heavy smokers or in patients who suffer carbon monoxide inhalation. Methemoglobinemia may be induced by a large number of drugs, including local anesthetics (prilocaine, benzocaine), nitroglycerin, phenacetin, phenytoin, Pyridium, and sulfonamides.

Intravenously administered dyes, particularly methylene blue and indocyanine green, can temporarily induce artifactually low saturation readings. Deeply pigmented skin and opaque nail polish coatings may significantly decrease light transmission, rendering oximeters inoperative. The presence of fetal hemoglobin, hyperbilirubinemia, or moderate anemia (with hematocrits as low as 15 percent) does not affect the accuracy of pulse oximeters. Despite its limitations, pulse oximetry is generally acknowledged as one of the most significant advances in clinical monitoring.

Continuous Mixed Venous Oximetry

Measurement of the oxygen saturation of mixed venous hemoglobin (SV_{o2}) is helpful in the assessment of the oxygen supply-demand relationship in critically ill patients. The use of improved fiberoptic oximetry systems in conventional pulmonary artery catheters has permitted continuous monitoring of SV_{o2} and made bedside monitoring of this relationship practical.

SV_{o2} can be derived from the Fick equation (see Table 12-3) that relates oxygen consumption, cardiac output, and arteriovenous oxygen content difference. If the small quantity of physically dissolved oxygen in the blood is considered negligible, solving the Fick equation for SV_{o2} yields

SV_{o2} = Sa_{o2} - V_{(dot) O2} / CO × Hb × 1.39 × 10

Therefore, the determinants of SV_{o2} include the principal components of oxygen delivery [CO, hemoglobin (Hb), and Sa_{o2}] and oxygen consumption. There is a poor correlation between SV_{o2} and any single component of the equation (V_{(dot) O2}, CO, Sa_{o2}, Hb), as would be expected, because there are four separate determinants. There is, however, a good correlation between SV_{o2} and all these components acting at once.

With the preceding formula in mind, it is easy to understand that the SV_{o2} will decrease when there is an imbalance between oxygen consumption and delivery caused by an increase in V_{(dot) O2} or a decrease in CO, Hb, or Sa_{o2}. SV_{o2} will increase when the imbalance is due to changes in the opposite direction.

The normal range for SV_{o2} in healthy subjects is 0.65 to 0.80, with an average value of 0.75 corresponding to a PV_{o2} of 40 mmHg at a normal pH of 7.4. A rapid or prolonged fall from the normal range is indicative of a significant deterioration in the patient's clinical condition. Values below the normal range may be associated with increased oxygen consumption due to fever, shivering, seizures, exercise, and agitation or associated with decreased oxygen delivery due to low cardiac output, anemia, or arterial hemoglobin desaturation. Values of about 0.53 correspond to a PV_{o2} of about 28 mmHg; values at or below this level often have been associated with anaerobic metabolism, lactic acidosis, and death. Astiz and colleagues, however, were unable to identify the critical level of SV_{o2} associated with lactic acidosis in patients with sepsis or acute myocardial infarction.

Values above the normal range indicate an increase in oxygen delivery relative to consumption and are associated with the hyperdynamic phase of sepsis, cirrhosis, peripheral left-to-right shunting, general anesthesia (when V_{(dot) O2} is low), cellular poisoning such as cyanide toxicity (rare), marked arterial hyperoxia, or a technical malfunction of the system (e.g., wedged catheter). Normal or high SV_{o2} values do not *ensure* that the oxygen supply-demand balance is satisfactory because accurate interpretation assumes intact and consistent vasoregulation, which is not the case in some disease states (e.g., sepsis).

Pulmonary artery catheter oximetry differs from pulse oximetry in several ways. First, the pulmonary artery catheter measures *reflected* rather than *transmitted* light. Second, being immersed in blood, the pulmonary artery catheter has no need for the pulse-added signal analysis used by the pulse oximeter. Finally, one of these catheters, the Opticath (Abbott Critical Care Systems, Mountain View, CA) uses three wavelengths (670, 700, and 800 nm) rather than the two wavelengths (660 and 940 nm) employed by most pulse oximeters.

The Oximetrix 3 System used by the Opticath has three light-emitting diodes (LEDs) contained in an optical module that provide the light sources for the three selected wavelengths. Light from each of these diodes is sequentially transmitted through a single optical fiber to illuminate the blood flowing past the catheter tip. This illuminating light is absorbed, refracted, and reflected depending on the color and, therefore, oxyhemoglobin concentration of the blood. The reflected light is collected by a second fiber and returned through the catheter to a photodetector in the optical module (Fig. 12-9). Using the relative intensities of the signals representing the light levels at the various wavelengths, a computer calculates the oxygen saturation, and the average for the preceding 5 s is displayed.

The saturation measured by catheter oximetry correlates well with values obtained from a laboratory co-oximeter. The most common sources of error when measuring Sv_{o2} are incorrect calibration and catheter malposition. Carboxyhemoglobinemia, methemoglobinemia, and intravenous administration of methylene blue also can affect the measurements.

Continuous SV_{o2} monitoring serves three major functions. First, it serves as an indicator of the adequacy of the oxygen supply-demand balance of perfused tissues. In clinically stable patients, a normal and stable SV_{o2} may be considered an additional assurance of cardiopulmonary stability. Further assessments of cardiac output and arterial and mixed venous blood gas analyses are not necessary. Second, continuously measured SV_{o2} may function as an early warning signal of untoward events. In this situation, although an alert has been given, the cause of the change in SV_{o2} is not necessarily clear because the change in SV_{o2} is sensitive but not specific. It may be necessary to measure cardiac output, Sa_{o2}, and Hb in this setting to identify the etiology of the SV_{o2} change. Third, continuously monitored SV_{o2} may improve the efficiency of the delivery of critical care by providing immediate feedback as to the effectiveness of therapeutic interventions aimed at improving oxygen transport balance.

Finally, an important application of continuous venous oximetry must be one of cost containment in the ICU. The potential of cost savings lies in the decreased use of other modes for assessing oxygen transport balance, e.g., cardiac output measurements and venous blood gas analyses. The savings in some institutions are greater than the price of the catheter, and its use has been judged cost-effective.

GASTRIC TONOMETRY

General Considerations

Ischemia signifies failure to satisfy the metabolic needs of the cell secondary to either impaired oxygen delivery or impaired cellular oxygen extraction and utilization. Although hemodynamic and oxygen-transport variables document the severity of tissue hypoxia and oxygen debt, they fail to accurately portray the complex interactions between energy requirements and supplies at the tissue level. Gastric tonometry has been proposed as a relatively noninvasive monitor of the adequacy of aerobic metabolism in organs whose superficial mucosal lining is extremely vulnerable to low flow and hypoxemia and in which blood flow is sacrificed first in both shock and the systemic inflammatory response syndrome. The gastrointestinal tract therefore will display metabolic changes before other indices of oxygen utilization. In the anoxic cell, uncompensated adenosine triphosphate (ATP) hydrolysis is associated with the intracellular accumulation of adenosine diphosphate (ADP), inorganic phosphate, and hydrogen ions with resulting intracellular acidosis. These hydrogen ions lead to tissue acidosis, with unbound hydrogen ions combining with interstitial bicarbonate to form the weak acid carbonic acid that dissociates to produce CO₂ and water.

Measurements

A tonometer is comprised of a semipermeable balloon connected to a sampling tube. A dual-purpose product—a tonometer in combination with a standard vented gastric sump—is commercially available (TRIP NGS Catheter; Tonometrics Division, Instrumentarium Corp., Tewksbury, MA). The annealed balloon allows CO₂ generated in the superficial layers of the mucosa to equilibrate within the saline instilled into the balloon. The tonometer P_{CO2} is multiplied by an equilibration factor (based on the equilibration period) to derive the tissue P_{CO2} value. Using a modified version of the Henderson-Hasselbach equation, intramucosal pH (pHi) is then calculated as follows:

pHi = 6.1 + log₁₀ HCO₃ / 0.03 × P_{CO2 ss}
where HCO₃ represents the arterial bicarbonate concentration (from a contemporary sample of arterial blood) in milliequivalents per liter, P_{CO2 ss} represents the tonometrically measured steady-state carbon dioxide tension, and 0.03 represents a constant that converts carbon dioxide tension in plasma in milliequivalents per liter per millimeter of mercury to milliequivalents per liter of carbonic acid. The measurement of intramucosal pH depends also on the assumption that the bicarbonate concentration in the wall of the organ is the same as that which is delivered to it by arterial blood and that the pK (the dissociation constant) is the same as that in the plasma. The pK in plasma is not the same as that in the cytosol, but the value 6.1 is the best approximation of the pK within the interstitial fluid of the superficial layers of the mucosa.

Clinical Utility

Incomplete splanchnic cellular resuscitation has been associated with the development of multiple organ system failure, more frequent septic complications, and increased mortality in the critically ill patient. Many studies have demonstrated the utility of gut tonometry in various settings where the perfusion status of the intestinal mucosa has been of importance,

such as in patients undergoing elective cardiac or abdominal aortic operations. In critically ill patients, gastric tonometry has been used as a predictor of both organ dysfunction and mortality and has been shown to be a better predictor of mortality than base deficit, lactate, oxygen delivery, and oxygen consumption.

Failure of splanchnic resuscitation correlated with multiple organ system failure and increased length of ICU stay in the hemodynamically unstable trauma patient admitted to the ICU at the University of Miami/Jackson Memorial Hospital. The relative risk or likelihood of death among incompletely resuscitated patients (pHi < 7.32) at 24 h as compared with completely resuscitated patients (pHi ³ 7.32) was 4.5. In parallel, the relative risk of developing multiple organ system failure was 5.4 in patients with pHi < 7.32.

In a subsequent audit, we evaluated consecutive patients who met state trauma triage criteria, who were admitted to the Ryder Trauma Center at Jackson Memorial Hospital, and who had a nasogastric tube placed during resuscitation. The trauma patients judged after clinical evaluation to have minimal injury and who were treated in routine care areas were found to have a normal pHi on transfer from the resuscitation area. The mean pHi was 7.4 ± 0.11, >7.2 in 95 percent of patients and >7.25 in 88 percent of patients. All patients survived; none developed multiple organ system failure.

Measurement of pHi can provide clinicians with a metabolic end point of resuscitation. pHi therefore can be used to ensure the completion of resuscitation as judged by normalization of gastric pHi. Current methods reported in the literature focus only on increasing oxygen delivery using fluid therapy and vasoactive agents with a-adrenergic action. Because these induce splanchnic vasoconstriction, which leads to gastric intramucosal acidosis, our strategy employs splanchnic vasodilatory agents to optimize systemic and mesenteric blood flow (isoproterenol, dobutamine, nitroprusside, nitroglycerine, prostaglandin E₁), reserving those agents which cause splanchnic vasoconstriction (epinephrine, high-dose dopamine, phenylephrine, norepinephrine) to treat severe hypotension (MAP < 55 mmHg). If pHi falls unexpectedly, we search for intraabdominal catastrophe, intraabdominal hypertension, sepsis, tissue necrosis, line sepsis, nosocomial infection, unappreciated excess patient ventilatory work, hypovolemia, and hypoxemia.

Interventions to block and modify the ischemia-reperfusion injury and restore splanchnic perfusion can be incorporated into a resuscitation algorithm to reduce the incidence of bacterial translocation and systemic white cell priming before the ensuing systemic inflammatory response.

RENAL MONITORING

The primary reason for monitoring renal function is that the kidney serves as an excellent monitor of the adequacy of perfusion. The second major indication for monitoring kidney function is to prevent acute parenchymal failure. Finally, renal function monitoring is helpful in predicting drug clearance and proper dose management.

Urine output frequently is monitored but may be misleading. Although very low urine outputs, less than 0.5 mL/kg/h, are consistently associated with low *glomerular filtration rate (GFR)* values, levels greater than this also can be associated with low GFR values. Diuresis created by an osmotic load (radiographic contrast material or glucose), administration of diuretics, or nonoliguric renal failure may give the clinician a false sense of security while the patient has deteriorating renal function. Other methods of monitoring renal function are necessary. These include tests of glomerular function and tests of tubular function.

Glomerular Function Tests

Blood urea nitrogen (BUN) often has been used to estimate renal function. BUN is affected by GFR and urea production. Production may be increased if large amounts of nitrogen are administered during parenteral nutritional support, as a result of gastrointestinal bleeding, or in catabolic states induced by trauma, sepsis, or steroids. Urea production may be lowered during starvation and in advanced liver disease. Because these factors are often interrelated in an unpredictable manner in critically ill patients, BUN is not a reliable monitor of renal function.

The value of plasma creatinine as a measure of renal function far exceeds the value of the BUN. The serum creatinine level is directly proportional to the level of creatinine production and inversely related to the GFR. In contrast to BUN concentration, plasma creatinine levels are not influenced by protein metabolism or the rate of fluid flow through the renal tubules. When creatinine production is constant, the serum creatinine level reflects GFR. The plasma creatinine level will double with a 50 percent reduction in GFR, assuming that creatinine production remains constant. Acute reductions in the GFR rate are not immediately reflected, however, because it takes 24 to 72 h for equilibration to occur.

Creatinine production is directly proportional to the muscle mass and its metabolism. In rhabdomyolysis, creatinine formation exceeds its filtration rate, such that measured serum creatinine levels increase. In conditions where the skeletal muscle mass is reduced (e.g., advanced age, immobilization), the endogenous creatinine pool is diminished, and thus the serum creatinine concentration does not rise appropriately with impairment of renal function. Only with measurement of creatinine clearance can the severity of such renal function loss be determined.

Serial determination of creatinine clearance is currently the most reliable method for clinically assessing GFR and the most sensitive test for predicting the onset of perioperative renal dysfunction. Although measurements traditionally are performed using a 24-h urine collection, measurements using a 2-h collection are reasonably accurate and easier to perform. When urine output is measured in clearance studies, special efforts should be made to ensure complete bladder emptying at the beginning and end of collection periods. Creatinine clearance (C_{cr}) is calculated from the formula

$$C_{cr} = U_{cr} \times V / P_{cr} \times 1.73 / BSA$$

where U_{cr} = urinary creatinine concentration, mg/dL

V = urinary volume flow, mL/min

P_{cr} = plasma creatinine concentration, mg/dL

BSA = body surface area, m²

Clearance results are expressed as milliliters per minute per 1.73m².

An alternative approach to creatinine clearance estimation is to forgo urine collection and utilize criteria formulated by Cockcroft and Gault. The Cockcroft-Gault equation for males is

$$C_{cr} = (140 - \text{age}) \times \text{weight in kg} / 72 \times P_{cr}$$

For females, the derived C_{cr} is multiplied by 0.85. Using the lower of ideal or total body weight and the higher of actual serum creatinine or corrected serum creatinine concentration to 1 mg/dL in this formula results in more accurate predictions of GFR. Although the Cockcroft-Gault equation provides an inexpensive and accurate estimate of GFR in patients with stable renal function, it is unlikely that it would detect early renal deterioration because the serum creatinine, on which the equation depends, does not begin to increase above normal until the GFR decreases to less than 50 mL/min/1.73 m².

Tubular Function Tests

Tests that measure the concentrating ability of the renal tubules are used primarily in the differential diagnosis of oliguria to differentiate a prerenal cause unresponsive to judicious fluid therapy from intrinsic renal failure due to tubular dysfunction. Table 12-4 summarizes the differential diagnosis based on tubular function studies. The utility of each depends on the ability of the renal tubular cells to physiologically respond to a decreased extracellular fluid volume. Thus, with prerenal azotemia, the tubules can appropriately reabsorb sodium and water. In intrinsic renal failure, tubular function is markedly compromised, and the ability to reabsorb sodium and water is impaired. Multifactorial renal dysfunction is most common; rarely is an isolated etiology discovered.

Tubular function tests are useful in oliguric patients (urine output < 500 mL/day) because nonoliguric individuals typically have less severe tubular damage and their laboratory findings are likely to show more overlap with the values of patients with prerenal azotemia.

The fractional excretion of sodium (FE_{Na}) appears to be the most reliable of the laboratory tests for distinguishing prerenal azotemia from acute tubular necrosis. This test requires only simultaneously collected “spot” urine and blood samples. FE_{Na} can be calculated as follows:

$$FE_{Na}(\%) = U_{Na}/P_{Na} / U_{cr}/P_{cr} \times 100\%$$

where U_{Na} is the urinary sodium concentration (in milliequivalents per liter), and P_{Na} is the plasma sodium concentration (in milliequivalents per liter).

The FE_{Na} value is normally less than 1 to 2 percent. In an oliguric patient, a value of less than 1 percent is usually due to a prerenal cause. A value greater than 2 to 3 percent in this setting suggests compromised tubular function. When the value ranges between 1 and 3 percent, the test is not discriminating.

Although the FE_{Na} is very useful, it is now apparent that a number of causes of acute renal failure other than prerenal disease can, on occasion, be associated with a FE_{Na} value of less than 1 percent. These include nonoliguric acute tubular necrosis, acute tubular necrosis superimposed on chronic prerenal disease (e.g., advanced cardiac or liver disease), administration of radiocontrast media or release of heme pigments (hemoglobin or myoglobin), and renal allograft rejection.

Thus the FE_{Na} test must be interpreted in light of the specific clinical setting and other laboratory data to be useful in patient management. Correct interpretation of FE_{Na} or any of the other urinary indices is not possible if the patient had received diuretics in the 6 to 12 h preceding the test.

NEUROLOGIC MONITORING

Monitoring the function of the central nervous system may permit early recognition of cerebral dysfunction and facilitate prompt intervention in situations in which aggressive early treatment favorably influences outcome. In the perioperative and trauma settings, several methods have been used to evaluate brain function and the effects of therapy. These include intracranial pressure monitoring, electrophysiologic monitoring, transcranial Doppler ultrasonography, and jugular venous oximetry.

Intracranial Pressure Monitoring

Physical findings are often unreliable to ascertain the presence of increased *intracranial pressure (ICP)*. Thus the only direct assessment of ICP is obtained by measurement.

Measuring ICP permits calculation of cerebral perfusion pressure (CPP), which is defined as the difference between the MAP and ICP. Thus isolated increases in ICP or decreases in MAP will result in a reduction in CPP. The CPP may be insufficient if ICP increases to more than 20 mmHg. Although in the past one of the end points of central nervous system monitoring was felt to be the control of ICP within safe levels, emphasis has shifted to following CPP itself. Maintaining cerebral blood flow appears to require using an elevated minimal CPP threshold when treating the injured brain. A CPP level of at least 70 mmHg has been suggested.

The most common indication for ICP monitoring is severe head injury. Patients with a Glasgow Coma Scale (GCS; see Chap. 40, Table 40-1) score of 8 or less or a GCS motor score of 5 or less (i.e., not following commands) should be strongly considered for ICP monitoring. Narayan and associates demonstrated that patients with a GCS score of 8 or less who have a normal CT scan have a very low probability of developing intracranial hypertension if they have fewer than two of the following features: (1) prior episodes of hypotension, (2) age greater than 40 years, or (3) motor posturing. They suggested that these patients may be managed initially without monitoring ICP. In such instances, however, any deterioration should prompt immediate reconsideration of ICP monitoring and reimaging.

Other conditions for which ICP monitoring has been recommended include subarachnoid hemorrhage, hydrocephalus, postcraniotomy, and Reye's syndrome. Although some investigators also have advocated this form of monitoring in patients with massive strokes, encephalitis, and post–cardiac arrest states, little evidence has been generated to suggest a beneficial impact.

Several methods of ICP measurement are available (Fig. 12-10). A ventricular catheter connected to a standard strain-gauge transducer via fluid-filled lines offers excellent waveform characteristics and permits withdrawal of cerebrospinal fluid (CSF). This catheter, however, may be difficult to insert when cerebral edema or hematoma causes shifting or collapse of the lateral ventricle system. A subarachnoid bolt is easily inserted under any circumstance, although at times it may give erroneous readings, depending on its placement relative to the site of injury. Compared with ventricular catheters, the waveforms obtained are not as good, and CSF drainage is usually not possible. Epidural bolts have a lower risk of complications but are less accurate than ventricular catheters or subarachnoid bolts and do not permit withdrawal of CSF. Non-fluid-coupled systems utilizing fiberoptic or catheter-tip strain-gauge technology can be placed into ventricular, subdural, and parenchymal sites. These devices appear to offer advantages over conventional ICP monitors, especially in their ability to measure brain parenchymal pressures. Without an associated ventricular catheter, however, catheter-tip strain-gauge or fiberoptic devices cannot be recalibrated after insertion. Consequently, if the device measurement drifts, there is potential for inaccurate measurements, especially if the ICP monitor is used for several days.

Complications of ICP devices include infection, hemorrhage, malfunction, obstruction, and malposition. Bacterial colonization of ICP devices increases significantly after 5 days of implantation; however, significant intracranial infections are uncommon.

Electrophysiologic Monitoring

The electroencephalogram (EEG) reflects spontaneous and ongoing electrical activity recorded on the surface of the scalp. Intraoperative EEG recording has been used primarily for monitoring the adequacy of cerebral perfusion during carotid endarterectomy. Other procedures in which EEG recording has been used include cerebrovascular surgery, open heart surgery, epilepsy surgery, and induced hypotension for a variety of surgical procedures. In the ICU, EEG recordings can detect the existence of subclinical epileptic seizures, which can cause a decreased level of consciousness. Standard EEG recording, however, is not used routinely in the ICU because of insufficient technical personnel, the volume of data generated in a short period, the difficulty of on-line EEG interpretation, numerous electrically induced artifacts, and drug-induced suppression of electrical activity. To simplify EEG recording and to make it more useful for clinical application in the operating room and ICU, some monitors process the raw data automatically. The compressed spectral array (CSA) is the most commonly used method of visually displaying such processed EEG information.

Sensory-evoked potentials (SEPs) are minute electrophysiologic responses elicited by a stimulus and extracted from an ongoing EEG by signal averaging. They reflect the functional integrity of specific sensory pathways and serve to some extent as more general indicators of function in adjacent structures. Somatosensory evoked potentials (SSEPs) reflect the integrity of the dorsal spinal columns and the sensory cortex and may be useful for monitoring during resection of spinal cord tumors, spine instrumentation, carotid endarterectomy, and aortic surgery. Brainstem auditory-evoked potentials (BAEPs) reflect the integrity of the eighth cranial nerve and the auditory pathways above the pons and are used for monitoring during surgery of the posterior fossa. Visual evoked potentials (VEPs) may be used to monitor the optic nerve and upper brainstem during resections of large pituitary tumors. Several studies have promoted the prognostic value of SEPs in the ICU, primarily in head trauma patients. Continuous monitoring in the ICU is still rare.

Transcranial Doppler Ultrasonography

Transcranial Doppler ultrasonography (TCD) is one of a number of methods currently being used to monitor cerebral blood flow. This technique employs the Doppler principle to record the blood flow velocity in the basal cerebral arteries and can provide valuable information regarding the integrity of the intracranial circulation. TCD also may detect vasospasm following spontaneous or traumatic subarachnoid hemorrhage and can help identify hyperemic or low-flow states.

The most commonly used TCD technique is “free-handing” the transmitter so that the ultrasound beam penetrates one of several natural “acoustical windows.” Modified probes are now available that may be kept in place for prolonged periods using a headband or other device. TCD is a valuable monitoring tool that is noninvasive, portable, and reproducible. It requires, however, that the studies be performed by a technician familiar with its use.

Jugular Venous Oximetry

Jugular venous oximetry is an invasive method of continuously monitoring jugular venous bulb oxyghemoglobin saturation ($S_{jv\ O_2}$). Changes in $S_{jv\ O_2}$ provide a measure of the relationship between total cerebral blood flow and total cerebral oxygen consumption. When arterial oxygenation remains constant, a decrease in $S_{jv\ O_2}$ from control values reflects a decrease in cerebral blood flow or an increase in cerebral metabolic oxygen consumption unmatched by an increase in flow. Jugular venous oximetry offers the potential to minimize secondary insults after severe head injury by facilitating recognition of cerebral ischemia. Other applications include monitoring during neurosurgical procedures, carotid endarterectomy, and cardiopulmonary bypass.

The technique for determination of $S_{jv\ O_2}$ is analogous to the determination of $SV\ O_2$ on a systemic basis (see above). A fiberoptic catheter is placed retrograde into the jugular bulb, and the $S_{jv\ O_2}$ is recorded in a continuous fashion. The range of $S_{jv\ O_2}$ in normal subjects is 55 to 71 percent. In head-injured patients, the range for $S_{jv\ O_2}$ is considerable wider, but most investigators agree that a sustained desaturation of 50 to 55 percent warrants evaluation. $S_{jv\ O_2}$ levels below 50 percent are indicative of cerebral ischemia. Artifactual recordings, however, are not uncommon and usually are caused by catheter malposition from head and neck movement.

METABOLIC MONITORING

General Considerations

The need to substitute artificial feedings during recovery from surgery and trauma turns the simple everyday function of ingestion of food into a complicated area involving mathematics, suppositions, high technology, and the potential for creating harmful side effects.

Assessment of Caloric Expenditure

Energy requirements depend on a number of factors including the body surface area, age, and sex. Basal energy expenditure (BEE) can be predicted with reasonable accuracy (± 5 percent) by the Harris-Benedict equation:

Men: $66.47 + (13.75 \times W) + (5.00 \times H) - (6.76 \times A) = \text{BEE kcal/day}$

Women: $655.10 + (9.56 \times W) + (1.85 \times H) - (4.68 \times A) = \text{BEE kcal/day}$

where W
= body weight, kg

H = height, cm

A = age, years

Resting energy expenditure (REE) can be approximated from the BEE by increasing it by 10 percent, adding the calories necessary to compensate for the specific dynamic action of food.

The stress of illness, the change in hormonal milieu relating to the stress state, alterations in substrate utilization, and fever all can be predicted to increase REE. While early studies emphasized increases of 25 percent for multiple-trauma patients and 50 percent for burn patients, even an increase of 60 percent above BEE would only result in a need for 40 kcal/kg/day, or less than 3000 kcal in a 70-kg patient. Excessive caloric administration is potentially detrimental. Carbohydrates given in excess of requirements are turned into fat, resulting in an increase in CO_2 production. The liver may develop fatty infiltration resulting in hepatic dysfunction.

In addition, many patients may have protein malnutrition despite being overweight due to obesity or overhydration. In a study of critically ill patients, Makk and colleagues found that 58 percent were overweight. Forty-two percent had a kwashiorkor-like pattern of malnutrition, and 11 percent had a marasmus-like pattern. Protein malnutrition necessitates administration of higher levels of protein to avoid or reverse end-organ dysfunction and impaired acute-phase protein synthesis, which sets the stage for nosocomial infections and the multiple organ system failure syndrome.

Assessment of Oxygen Consumption

If caloric expenditures can be considered the fuel, then another aspect of metabolic monitoring is the flame. Oxidative metabolism or oxygen consumption reflects metabolic activity. Cuthbertson described the ebb- and-flow phase of the metabolic response to injury. In his terms, the ebb phase, lasting 24 to 48 h, is a period of “diminished circulatory vitality”—decreased cardiac output, diminishing oxygen delivery, and resulting decreased oxygen consumption. The recognition of the association between diminished oxygen delivery in the ebb phase with the late occurrence of sepsis and multiple organ system failure has focused attention on improving oxygen delivery in an attempt to forestall this seemingly inevitable progression. Thus monitoring and optimizing oxygen delivery as described previously have been given additional significance in terms of minimizing long-term detrimental metabolic effects secondary to stress and injury.

Measurements

Oxygen delivery or cardiac output times arterial oxygen content and oxygen consumption (normally about 150 mL/min/m²) assess oxidative metabolism. CO₂ production is a measure of a by-product of oxidative metabolism. The ratio of CO₂ production to oxygen consumption is termed the *respiratory quotient* (RQ). During normal oral dietary intake, carbohydrates, protein, and fat are ingested, giving an average RQ of approximately 0.8. During prolonged starvation, the body adapts to fat metabolism, and the RQ may fall to as low as 0.6 to 0.7. On the other hand, during excessive carbohydrate administration, the transformation into fat releases additional CO₂, and the RQ rises above 1.0. Thus monitoring oxygen consumption and CO₂ production and calculating the RQ provide inferences into the adequacy of total calories as well as the mixture of substrates.

In the past few years, clinicians, recognizing the number of variables affecting REE and total energy expenditure (TEE), have attempted direct measurements in order to meet an individual patient's needs at a particular time in the course of the illness. It is clear that estimates of REE from the Harris-Benedict equation, even modified by estimates to adjust for increased metabolic activity, still lead to inaccurate assessment of TEE. Direct calorimetry measures body heat production and is correlated with energy use. The subject, however, must be placed in a closed chamber for measurement of heat production, and clearly, this is not applicable to patient care. Indirect calorimetry permits derivation of caloric requirements from the measurements of oxygen consumption and CO₂ production. Methods used include Douglas bag collection of expired gases, use of the Fick equation, and computerized open circuit measurements.

Douglas Bag Collection

Samples of inspiratory and mixed expiratory gases are analyzed for oxygen and CO₂ concentrations. Unfortunately, this technique is prone to many errors. Gas leakage, incomplete emptying, inaccurate measurement of total expired gases, and incomplete mixing or leakage through incompletely sealed connections are but a few of the problems encountered. Finally, it is a tedious method that does not lend itself to frequent or routine clinical use.

The Reverse Fick Method

The classic Fick equation (see Table 12-3) relates oxygen consumption to the product of cardiac output and arterial venous oxygen content difference. Repeated cardiac output determinations have an accuracy in the range of ±5 percent but are not as important as variability in the patient's physiology, in which changes may exceed ±10 percent in a short time. Pulse oximetry and mixed venous oximetry show that minute-to-minute variations in these values also occur. Smithies has shown that these factors result in a 10 percent variation between measurements and lower total values compared with validated spirometric techniques. This latter difference reflects the oxygen consumption of the lung, which is included in the spirometric method but not in the reverse Fick technique.

Computerized Open Circuit Indirect Calorimetry

Several commercial indirect calorimeters have been evaluated by Makita and associates. The Datex Deltatrac Metabolic Monitor (Datex Instrumentarium, Helsinki, Finland), the Engström Metabolic Computer (Gambro Engström A.B., Bromma, Sweden), and the SensorMedics MMC Horizon (SensorMedics, Anaheim, CA) use slightly different techniques and formulas. Mean relative errors of measurement for all three monitors, however, were in the range of 1.4 to 6 percent for oxygen consumption, CO₂ production, and respiratory quotient.

In routine clinical use, however, there are many potential errors. Instruments lose calibration easily. High inspired oxygen concentrations (Fi_{O2} > 0.6) render measurements inaccurate. Fluctuations in hospital gas- line pressure cause 1 to 2 percent fluctuations in inspired Fi_{O2}, sufficient to impair the accuracy of overall oxygen consumption. Leaks at joints and connections occur frequently and must be eliminated before and during studies. Measurements of CO₂ production depend on a steady-state relationship between CO₂ production at the cellular level, transport to lungs, and CO₂ elimination via the lungs and measured in exhaled gases. Therefore, changes in the metabolic rate, changes in cardiac output, and changes in ventilation all affect the inherent supposition that CO₂ production and CO₂ elimination measured by the metabolic monitor are equal. Minute-to-minute variations may be minimized by ensuring that measurements encompass at least 15 min twice daily.

Clinical Utility

First, metabolic monitoring can be used to judge the end result of the interactions of all the unknowns (including degrees of illness, activity, and metabolism) in producing the current levels of oxygen consumption and CO₂ production. Second, either too little or incorrect proportions of nutritional support are undesirable. If we remember that approximately 32 to 35 kcal/day should suffice in most clinical circumstances and that there are no outcome data suggesting that ±10 or even 20 percent has a demonstrable adverse effect on any known variable, we should ensure that we stay within this range of measured values. Third, we could identify patients with significant hypometabolism or hypermetabolic states because clinical estimates are often incorrect. Adjusting nutritional support in these circumstances seems to be common sense, although it has not been proved that these adjustments make any real difference. Fourth, given the wide variations in caloric requirements and in substrate utilization, metabolic monitoring, allowing more appropriate partitioning of the substrates, seems more desirable than administering quantities by rote or formula. Fifth, measurements of respiratory quotient may be useful in patients who have respiratory failure and CO₂ retention while receiving high carbohydrate loads. Identification of a high respiratory quotient due to excessive carbohydrate administration is one correctable factor.

Because commercially available indirect calorimeters now can measure oxygen consumption and CO₂ production and calculate other parameters of metabolic cellular activity, the demonstrated accuracy in measurement can be used to support more precise prescription of nutritional therapy. Questioning whether this degree of obtainable precision alters outcome is relevant; at the same time, inaccurate prescriptions based on invalid estimates would not seem to be a viable objective. The costs of this approach are not inconsiderable, and while they may be offset by savings in wasted nutritional support, more data reflecting improvement in outcome are necessary before mandatory or daily usage even in critically ill patients can be supported.

TEMPERATURE MONITORING

Temperature, along with heart rate, blood pressure, and respiratory rate, remains one of the traditional four cardinal vital signs. Temperature is usually taken rectally in ill patients or orally when significant elevations are not expected.

Temperatures of the periphery of the body measured at the mouth, skin, or axilla are often unreliable and may be influenced by factors such as mouth breathing, temperature of recently ingested food, and/or environmental temperature. Therefore, it is recommended that deeper core temperatures be taken in the critically ill.

Core temperatures, which are relatively resistant to external influences, more accurately reflect the mean temperature of the body's vital organs. Core temperature can be measured by placing a thermistor probe into either the esophagus or the rectum. Esophageal wires are uncomfortable and invasive and are used exclusively in patients under general anesthesia. Rectal probes are used commonly in the operating room and ICU but may be extruded from the rectum and have a recognized risk of bowel wall perforation.

Three devices are available commercially for bedside measurement of core temperature in ICU patients: pulmonary artery thermistor catheters, urinary bladder thermistor catheters, and infrared auditory canal probes. Measurement of pulmonary artery blood temperature by the pulmonary artery thermistor catheter has been used increasingly as a reliable indicator of core temperature. The need for a catheter is an obvious disadvantage of this approach. Urinary bladder catheters have the advantage of giving both exact measurements of urine output and continuous urine temperature. Infrared probes noninvasively measure tissue temperature in the ear canal; however, their measurements have more variability than bladder readings. Moderate variation is probably inherent in infrared ear thermometry due to differences in ear canal anatomy and probe positioning.

CHAPTER 13 - Skin and Subcutaneous Tissue

David M. Young
Stephen J. Mathes

INTRODUCTION

The skin is the largest and one of the most complex organs of the body. Its uniform appearance belies its great variation from region to region of the body and the complex organization and interaction of the many different cells and matrices of the skin. Although the skin functions simply as a protective barrier and interface with our environment, its structure and physiology are complex.

The skin is an extremely good interface with our environment. It is protective against most of the noxious agents, such as chemicals (by the impermeability of the epidermis), solar radiation (by means of pigmentation), infectious agents (through efficient immunosurveillance), and physically deforming forces (by the durability of the dermis). The skin is the major organ responsible for thermoregulation, having an efficient ability to conserve or disperse heat. To direct all these functions, the skin has a highly specialized nervous structure.

These various functions are better served by different components of skin, so teleologically there developed regional variation. The palms and soles are particularly thick, to bear weight. The fingertips have the highest density of sensory innervation and allow for intricate tasks. Even the lines of the skin, first described by Langer, are oriented perpendicularly to the long axis of muscles to allow the greatest degree of stretching and contraction without deformity.

The relative ease of observing and obtaining skin specimens for examination and experiments has made skin one of the best-studied tissues of the human body. Thus skin is not just the subject of the field of dermatology, but also the study of the skin launched the fields of immunology, transplantation, and wound healing. Although this chapter emphasizes surgically treated diseases of the skin, it is important for students of surgery to be familiar with the basic physiology and structure of skin since many of the future advances in medicine will come from these studies.

ANATOMY AND PHYSIOLOGY

The skin has been traditionally divided into three layers: the epidermis, the basement membrane, and the dermis (Fig. 13-1). The epidermis is composed mainly of cells, with very little extracellular matrix. Each cell type serves a specific barrier function. Keratinocytes provide a mechanical barrier, melanocytes a radiation barrier, and Langerhans' cells an immunologic barrier. The dermis contains mostly extracellular matrix, providing support for nerves, vasculature, and adnexal structures. The dermis allows skin to resist deforming forces and return to its resting state, thus providing durability. The basement membrane is a specialized structure that anchors the epidermis to the dermis.

The main cell type in the epidermis is the keratinocyte. The deep, mitotically active, basal cells are a single cell layer of the least-differentiated keratinocytes. Some multiplying cells leave the basal layer and begin to travel upward. In the spinous layer they lose the ability to undergo mitosis. These differentiated cells start to accumulate keratohyalin granules in the granular layer. Finally, in the horny layer, the keratinocytes age, the once- numerous intercellular connections disappear, and the dead cells are shed. Using radioactive and fluorescence labeling, experiments have shown the keratinocyte transit time to be from 40 to 56 days. The control of keratinocyte multiplication and subsequent maturation is an area of active study and may clarify the complex mechanism of cellular differentiation.

Melanocytes migrate to the epidermis from precursor cells in the neural crest. They lie scattered beneath basal cells and have dendritic processes that reach out to surrounding keratinocytes. They number approximately one for every 35 keratinocytes. The melanocytes produce a pigment, melanin, from tyrosine and cysteine. The pigment is packaged in melanosomes and transported to the tips of the dendritic processes. The tips are sheared off (apocoptation) and then phagocytized by the keratinocyte, thus transferring the pigment to the keratinocyte. Once in the keratinocyte they aggregate on the superficial side of the nucleus in an umbrella shape. The density of melanocytes is constant between individuals of different skin color. The rate of melanin production, transfer to keratinocytes, and melanosome degradation determine the degree of skin pigmentation. These activities are influenced by genetically activated factors as well as ultraviolet radiation and hormones such as estrogen, adrenocorticotrophic hormone, and melanocyte-stimulating hormone.

The Langerhans' cells migrate from the bone marrow and function as the skin's macrophages. The Langerhans' cells constitutively express class II major histocompatibility antigens and have antigen-presenting capabilities. These cells play a crucial role in immunosurveillance against viral infections and neoplasms of the skin, and may initiate skin allograft rejection.

The dermis consists mostly of several structural proteins. Collagen constitutes 70 percent of the dry weight of dermis and is responsible for its remarkable tensile strength. Tropocollagen consists of three polypeptide chains (formed mainly of hydroxyproline, hydroxylysine, and glycine) wrapped in a helix. These long molecules are then cross-linked to one another to form collagen fibers. Of the seven structurally distinct collagens, the skin contains mostly type I. Early fetal dermis contains mostly type III (reticulin fibers) collagen, but this remains only in the basement membrane zone and the perivascular regions in postnatal skin. Elastic fibers are highly branching proteins that are capable of being reversibly stretched to twice their resting length. This allows skin to return to its original form after stretching. Ground substance is an amorphous material that fills the remaining spaces. It consists of various polysaccharide-polypeptide (glycosaminoglycans) complexes. The nonsulfated form is mostly hyaluronic acid, and the sulfated forms are heparin sulfate, dermatan sulfate, and chondroitin-6-sulfate. Glycosaminoglycans, which can hold up to 1000 times their own volume in water, constitute most of the volume of dermis.

Fibroblasts are scattered throughout the dermis and are responsible for production and maintenance of the protein matrix. Recently proteins that control the proliferation and migration of fibroblasts have been isolated. The study of fibroblast activity by these growth factor interactions is crucial to our understanding of wound healing and organogenesis.

The basement membrane zone of the dermoepidermal junction is a highly organized structure of proteins that anchors the epidermis to the dermis. Mechanical disruption or a genetic defect in the synthesis of this structure (epidermolysis bullosa) results in separation of the epidermis from the dermis.

In the dermis are situated the remaining structures of the skin. An intricate network of blood vessels regulates body temperature. Two horizontal plexuses, one at the dermal-subcutaneous junction and one in the papillary dermis, are interconnected by vertical vascular channels. Glomus bodies are tortuous arteriovenous shunts that allow a tremendous increase in blood flow to the skin when open. This large amount of blood flow in excess of its nutritional needs allows skin to dissipate a vast amount of body heat when needed.

Thermoregulation is carried out by autonomic fibers that synapse to sweat glands, the hair erector muscles, and control points in the vasculature. Sensory innervation follows a dermatomal distribution from segments of the spinal cord. These fibers connect to corpuscular receptors (pacinian, Meissner's, and Ruffini's) that respond to pressure, vibration, and touch, to "unspecialized" free nerve endings associated with Merkel cells of the basal epidermis, or to hair follicles. These nerves are stimulated by temperature, touch, pain, and itch.

The skin has three main adnexal structures. The eccrine glands, which produce sweat, are located all over the body but are concentrated on the palms, soles, axillae, and forehead. The hair follicles consist of a mitotically active germinal center that produces a cylinder of tightly packed cornified epithelial cells. Control of the growth cycle of the hair is little understood. The sebaceous glands produce an oily substance that coats the skin. Together these two structures form a pilosebaceous unit. The apocrine glands are found primarily in the axillae and the anogenital region. In lower mammals these glands produce scent hormones (pheromones).

TRAUMA

Penetrating Injuries

Disruption of the continuity of the skin allows the entry of organisms that can lead to wound infection. Sharp lacerations, bullet wounds, "road rash" (injury from scraping against road pavement), and degloving injuries should be treated by gentle cleansing, debridement of all foreign debris and necrotic tissue, and application of a proper dressing. Dirty or infected wounds should be left open to heal by secondary intention or delayed primary closure. Clean lacerations may be closed primarily. Road rash injuries are treated as second-degree burns and degloving injuries as third-degree burns. The degloved skin can be placed back on the wound like a skin graft and assessed for survival prospects. If the skin becomes necrotic it is removed and the wound is covered with split-thickness skin grafts.

Pressure Ulcers (Decubitus Ulcers)

Pressure ulcers, as the name implies, are caused by excessive, unrelieved pressure. In animal studies, 60 mmHg pressure applied to the skin for 1 h produces histologically identifiable injuries such as venous thrombosis, muscle degeneration, and tissue necrosis. The average human being exerts 60 to 70 mmHg pressure on such body areas as the sacrum, occiput, and heels while lying in bed or on the ischia while sitting in a chair. Healthy people, however, regularly shift their body weight, even while asleep. Sitting in one position causes pain in areas of increased pressure, thus stimulating movement. Patients unable to sense pain or to shift their body weight, such as paraplegics or bedridden individuals, develop prolonged elevated tissue pressures and, eventually, necrosis. Muscle tissue is more sensitive to ischemia than the overlying skin. That is why the necrotic area is always wider and deeper than it appears on first inspection (Fig. 13-2).

Treatment of pressure sores requires relief of pressure with special cushions and beds and nutritional support to promote healing. The necrotic tissue should be removed, often along with the underlying bony prominence. Shallow ulcers may close by secondary intention, but deeper wounds with involvement of the underlying bone require surgical debridement and soft tissue and skin coverage. To prevent future breakdown of the area, stable coverage should be obtained with local myocutaneous or fasciocutaneous flaps. Prevention of ulcers is best achieved by close attention to susceptible areas and frequent repositioning of paralyzed patients. Air flotation mattresses and gel seat cushions redistribute pressure, decrease the incidence of pressure ulcers, and are cost effective in the care of patients at high risk. The addition of growth factors to these wounds has been found to increase healing and offers promising therapy in the future.

Keloids and Hypertrophic Scars

All wounds heal by scar formation. Hypertrophic scars are raised, red, and nodular, but remain within the limits of the original incision or trauma. Keloids are much bulkier, and their nodularity and firmness extend beyond the wound (Fig. 13-3). Although there are distinct histologic and biochemical differences between keloids and hypertrophic scars, the distinction is largely clinical. Dark-skinned individuals are more likely to develop keloids and hypertrophic scars, and a genetic component has been found. The location of a wound, such as across a joint and on the sternum, is an important factor in development of these lesions. Fibroblasts isolated from patients with keloids synthesize increased amounts of extracellular matrix proteins and growth factors.

Medical treatment includes intradermal injections of corticosteroids (triamcinolone acetonide) to reduce the itching and flatten the scar. Mechanical pressure (as with pressure garments) also can soften and flatten raised scars. Excision of keloids and hypertrophic scars remains the most effective treatment. These lesions are prone to recur unless steroid injections or pressure therapy with silicone gel sheeting is begun soon after surgery. Laser treatment and radiation therapy of these lesions have been found to be effective. With a better understanding of the pathogenesis of these abnormal states of wound repair, more effective therapy with local growth factors or their blockers is being developed.

INFECTIONS

Bacterial Infections

Folliculitis, Furuncles, and Carbuncles

Folliculitis is infection and inflammation of a hair follicle. The causative organism is usually *Staphylococcus* and occasionally a gram-negative organism. A furuncle (boil) begins as folliculitis but progresses to form a nodule that eventually becomes fluctuant. The abscess eventually ruptures and usually resolves. Deep-seated infections that result in multiple draining cutaneous sinuses are called carbuncles.

Folliculitis usually resolves with time and adequate hygiene. Warm soaks to a furuncle may hasten liquefaction, speed drainage, and encourage healing. Occasionally antibiotics are used to manage surrounding cellulitis. Carbuncles are more difficult to treat and require incision and drainage or wide excision of the infected tissue and sinuses.

Hidradenitis Suppurativa

Bacterial infection of a plugged apocrine gland occurs most commonly in the axillae and inguinal and perianal regions. An abscess forms with subsequent drainage and sinus formation. Repeated infections create a wide area of inflamed and scarred tissue that is foul-smelling and painful (Fig. 13-4). Treatment of acute infections includes application of warm compresses, antibiotics, and open drainage. Proper hygiene and discontinuation of deodorants may prevent recurrence. Chronic hidradenitis requires excision of the entire area of infection and closure with skin grafts.

Pilonidal Disease

Infected pilonidal cysts of the sacrococcygeal region occur primarily in young adults and are four times more common in males. The pathogenesis of the disease is much debated, but sweaty activity and buttock friction, such as occurred in jeep drivers in World War II (jeep driver's disease), is associated with a high incidence of pilonidal disease. The infection probably begins in a pilosebaceous unit in the natal cleft. Recurrent trauma causes obstruction of a hair follicle and leads to infection. The localized folliculitis spreads into the surrounding soft tissue and produces an abscess. This eventually drains to the surface and produces a sinus that is usually located lateral to the midline. The sinus is lined with granulation tissue but over time can epithelialize. Constant movement and friction of the buttocks causes hair and loose debris to enter the tract, inciting a foreign-body reaction.

Acute pilonidal abscesses should be drained. Without further therapy, many will recur. Use of perioperative antibiotics does not affect the outcome of the disease. There are many different ways of treating the chronic sinus tract, including tract curettage, local excision and closure, wide excision and marsupialization, and wide excision and flap closure. Another method currently gaining favor is fistulotomy and marsupialization. Each method has its drawbacks. Patients undergoing primary closure stay in the hospital longer but return to work sooner than patients with the wound left open after excision. Nonsurgical treatment of a pilonidal lesion by natal- cleft shaving and perineal hygiene requires the least amount of hospitalization but may have a higher recurrence rate. The most cost- effective method remains to be determined.

Toxic Epidermal Necrolysis and Staphylococcal Scalded Skin Syndrome

These two diseases create a similar clinical picture, which includes erythema of the skin, bullae formation, and, eventually, wide areas of skin loss. Staphylococcal scalded skin syndrome (SSSS) is caused by an exotoxin produced during a staphylococcal infection of the nasopharynx or middle ear in the pediatric population. Toxic epidermal necrolysis (TEN) is thought to be an immunologic reaction to certain drugs, such as sulfonamides, phenytoin, barbiturates, and tetracycline. Diagnosis can be made with a skin biopsy examination because SSSS produces a cleavage plane in the granular layer of the epidermis, whereas TEN occurs at the dermoepidermal junction. The injury is similar to a second-degree burn. Treatment involves fluid and electrolyte replacement and wound care as in a burn injury. In Stevens-Johnson syndrome epithelial sloughing of the respiratory and alimentary tracts occurs, with resultant respiratory failure and intestinal malabsorption.

Patients with TEN should be treated in burn units to decrease the morbidity from the wounds. The skin slough has been successfully treated with cadaveric or porcine skin or semisynthetic biologic dressings (Biobrane). Temporary coverage with a biologic dressing allows the underlying epidermis to regenerate spontaneously. Corticosteroid therapy has not been efficacious.

Actinomycosis

Actinomycosis is a localized inflammatory mass, usually of the jaw area, that spreads by multiple fistulas and abscesses into the neck and face. The underlying bone also can become infected, as can the apex of the lung. The causative agent is *Actinomyces*, an organism of the Actinomycetaceae family, in the Actinomycetales order. Other actinomycetes, including *Nocardia*, *Actinomadura*, and *Streptomyces*, cause mycetomas, which are deep cutaneous infections that present as nodules and spread to form draining tracts to the skin and surrounding soft tissue. Chronic disease causes fibrosis and contractures. The most common site for infection is the foot (Madura foot).

The gram-negative bacteria that cause these infections were once believed to be fungi because they grow slowly as branched filaments and chains. Diagnosis depends on the presence of characteristic sulfur granules on microscopic examination. Special stains should be used to exclude fungal infection. Penicillin and sulfonamides are effective against these infections. Abscesses and areas of chronic scarring may require surgical therapy.

Lymphogranuloma Venereum

Chlamydia trachomatis is a sexually transmitted, intracellular, gram- negative bacterium. After infection and a 2-week incubation period, an inconspicuous ulcer appears on the penis or labia, although in more than half the cases this lesion is not noticed or does not appear. A few weeks later, inguinal lymphadenopathy erupts. The nodes become very large and painful (buboes) and are occasionally confused with an incarcerated inguinal hernia. Adenopathy can occur above and below the inguinal ligament, forming a characteristic groove. The matted nodes may suppurate, and occasionally they rupture. Surgical drainage of unruptured abscesses is not recommended because a chronic draining sinus often develops. Active infection is treated with doxycycline for 1 week or azithromycin in one dose. Inflammation from infection can lead to lymphatic obstruction and chronic lower extremity edema. Rectal strictures also can occur.

Viral Infections

Warts are epidermal growths associated with human papillomavirus infection. Histologically they are characterized by hyperkeratosis (hypertrophy of the horny layer), acanthosis (hypertrophy of the spinous layer), and papillomatosis. Koilocytes, large keratinocytes with eccentric nuclei, are present. Different morphologic types have a propensity to occur on different parts of the body. The common wart (verruca vulgaris) is found on the fingers and toes, and has a rough, gray-brown surface. Plantar warts (verruca plantaris) occur on the soles and palms, and may look like a callus. Flat warts (verruca plana), which are flat but slightly raised, appear on the face, legs, and hands. Venereal warts (condylomata acuminata) grow in the moist areas around the vulva, anus, and scrotum.

Warts can be removed by a number of chemicals, including formalin, podophyllum, and phenol-nitric acid. Curettage with electrodesiccation also can be used for scattered lesions. Treatment of extensive areas of skin requires surgical excision under general anesthesia. Because of the infectious etiology, recurrences are common, and repeated excisions often are necessary to eliminate lesions. Some warts (especially human papillomavirus types 5, 8, and 10) are associated with squamous cell cancers, and therefore lesions that grow rapidly or ulcerate should be biopsied.

Condylomata acuminata are sexually transmitted and can be particularly bothersome. Patients with human immunodeficiency virus (HIV) infection are more likely to develop clinically significant venereal warts. The lesions often are multiple and can grow to large size (Buschke-Lowenstein tumor). Small lesions can be treated with podophyllotoxin cream. Larger lesions have a significant risk of malignant transformation and should be excised. The lesions often recur. Adjuvant therapy with interferon, isotretinoin, or autologous tumor vaccine decreases recurrence rates.

BENIGN TUMORS

Cysts (Epidermal, Dermoid, Trichilemmal)

Epidermal cysts are the most common type of cutaneous cyst. They occur anywhere on the body, as a single firm nodule. On the scrotum they are often multiple and can calcify. Trichilemmal (pillar) cysts, the next most common, occur more often in females and usually on the scalp. When ruptured these cysts have a characteristic strong odor. Dermoid cysts are present at birth and may result from epithelium trapped during midline closure in fetal development. Dermoids are most often found in the midline of the face (e.g., on the nose or forehead) and are also common on the eyebrow (Fig. 13-5).

On gross examination, it is difficult to distinguish one type of cyst from another. They are all subcutaneous, thin-walled nodules containing a white, creamy center. Histologic examination is needed to differentiate them. The walls of all these cysts consist of a layer of epidermis oriented with the basal layer superficial and the more mature layers deep (i.e., with the epidermis growing into the center of the cyst). The desquamated cells (keratin) collect in the center and form the creamy substance of the cyst. Epidermal cysts have a completely mature epidermis containing a granular layer. Trichilemmal cyst walls do not contain a granular layer but do have a distinctive outer layer resembling the outer root sheath of the hair follicle (trichilemmoma). Dermoids have a squamous epithelium, eccrine glands, pilosebaceous units, and, occasionally, bone, tooth, or nerve tissue. Surgeons often refer to cutaneous cysts as sebaceous cysts because they appear to contain sebum; this is a misnomer because the substance is actually keratin.

Cysts usually are asymptomatic and ignored until they rupture and cause local inflammation. The area becomes infected and an abscess forms. Incision and drainage is recommended for an acutely infected cyst. After resolution of the abscess the cyst wall must be excised or the cyst will recur. Similarly, when excising an unruptured cyst, care must be taken to remove all of the wall in order to prevent recurrence.

Keratoses (Seborrheic, Solar)

Seborrheic keratoses commonly occur on the chest, back, and abdomen of older individuals. The lesions are light brown or yellow and have a velvety, greasy texture. They are rarely mistaken for other lesions, so biopsy and treatment are seldom needed. Sudden eruptions of multiple lesions in elderly patients may be associated with internal malignancies.

Solar (or actinic) keratoses are also found in the older age group. They arise in sun-exposed areas of the body, such as the face, the forearms, and the back of the hands.

Histologically they contain atypical-appearing keratinocytes and evidence of solar damage in the dermis. These are thought to be premalignant lesions, and squamous cell carcinoma may develop over time. Treatment is by local removal or application of topical 5- fluorouracil. Malignancies that do develop rarely metastasize.

Nevi (Acquired, Congenital)

Acquired melanocytic nevi are classified as junctional, compound, or dermal, depending on the location of the nevus cells. This classification does not represent different types of nevi but rather different stages in the maturation of nevi. Initially, nevus cells accumulate in the epidermis (junctional), migrate partially into the dermis (compound), and finally rest completely in the dermis (dermal). Eventually most lesions undergo involution.

Congenital nevi are much more rare, occurring in only 1 percent of neonates. These lesions are larger and may contain hair. Histologically they appear similar to acquired nevi. Congenital giant lesions (giant hairy nevus) most often occur in a bathing trunk distribution or on the chest and back (Fig. 13-6). These lesions are a major cosmetic problem. In addition, they develop malignant melanoma in 5 percent of the cases. Excision of the nevus is the treatment of choice, but often the lesion is so large that closure of the wound with autologous skin grafts is not possible because of the lack of adequate donor sites. Serial excisions over several years with either primary closure or skin grafting is the present mode of therapy. Tissue expansion of normal surrounding skin is now also used to accelerate the rate of nevus excision and avoid the use of skin grafts.

Vascular Tumors

Hemangiomas (Capillary, Cavernous)

Hemangiomas are benign vascular neoplasms that arise soon after birth. They undergo rapid cellular proliferation initially and slowly involute through early childhood. Capillary (strawberry) hemangiomas are soft, compressible papular lesions with sharp borders located mostly on the shoulders, face, and scalp. Cavernous hemangiomas are bright red or purple and have a spongy consistency. Histologically capillary hemangiomas are composed of endothelial cells seen primarily in fetal veins. Cavernous lesions contain large, blood-filled spaces lined by normal-appearing endothelial cells.

Hemangiomas can enlarge during the first year of life, and more than 90 percent of them involute over time. Allowing lesions to regress spontaneously usually gives optimal cosmetic results (Fig. 13-7). Acute treatment is limited to lesions that interfere with bodily functions, such as vision, feeding, and urination, or lead to systemic problems, such as thrombocytopenia and high-output cardiac failure. The growth of these rapidly enlarging lesions can be stopped with a course of prednisone or interferon-alpha-2a. Hemangiomas that remain after early adolescence will probably not involute further. Surgical excision is recommended.

Vascular Malformations (Port Wine Stains, Arteriovenous Malformations, Glomus Tumors)

Vascular malformations are a result of structural abnormalities formed during fetal development and hence are not neoplasms. Unlike hemangiomas, vascular malformations do not undergo rapid growth and involution but rather grow in proportion to the body. Histologically they contain enlarged vascular spaces lined by nonproliferating endothelium, and not the mitotically active endothelial cells of a hemangioma.

The port wine stain (nevus flammeus) is a flat, dull red capillary malformation that can be located on the trunk, extremities, and, most commonly, along a trigeminal distribution on the face. Histologically these nevi are composed of ectatic capillaries lined by mature endothelium. They may be part of the Sturge-Weber syndrome (leptomeningeal angiomatosis, epilepsy, and glaucoma). Unsightly lesions can be covered with cosmetics, treated with pulsed dye laser, or surgically excised.

Arteriovenous malformations are high-flow lesions. They appear as a mass under the skin with locally elevated temperature, a dermal stain, and a thrill and bruit. Overlying ischemic ulcers, adjacent bone destruction, or local hypertrophy may occur. Large malformations can cause cardiac enlargement and congestive heart failure.

Complications of arteriovenous malformations, such as pain, hemorrhage, ulceration, cardiac effects, and destruction of surrounding structures, should be treated by elimination of the lesion. Therapy consists of angiography with selective embolization or complete surgical resection. Embolization is particularly useful for lesions not accessible to surgery or in cases in which resection would cause too much mutilation. Embolization also can be used preoperatively to reduce blood loss during surgery. Occasionally hypothermia and cardiac bypass are required in order to minimize blood loss during surgical excision of large lesions.

Glomus tumors are blue-gray nodules that are extremely tender. They can occur anywhere on the body, but the most common location is subungual. The tumor arises from a glomus body and histologically resembles the arterial portion of the glomus. Excision of the tumor relieves the pain.

Soft Tissue Tumors (Acrochordons, Dermatofibromas, Lipomas)

Acrochordons (skin tags) are fleshy, pedunculated masses located on the axillae, trunk, and eyelids. They are composed of hyperplastic epidermis over a fibrous connective tissue stalk. These lesions usually are small and are always benign.

Dermatofibromas are usually solitary nodules measuring approximately 1 to 2 cm in diameter. They are found primarily on the legs and sides of the trunk. The lesions are composed of whorls of connective tissue containing fibroblasts. The mass is not encapsulated, and vascularization is variable. Dermatofibromas can be diagnosed by clinical examination. When lesions enlarge to 2 to 3 cm, excisional biopsy is recommended to assess for malignancy.

Lipomas are the most common subcutaneous neoplasm. They are found mostly on the trunk but may appear anywhere. They may sometimes grow to a large size. Microscopic examination reveals a lobulated tumor containing normal fat cells. Excision is performed for diagnosis and to restore normal skin contour.

Neural Tumors (Neurofibromas, Neurilemmomas, Granular Cell Tumors)

Benign cutaneous neural tumors arise primarily from the nerve sheath. Neurofibromas can be sporadic and solitary, but they are more commonly noted in multiple formations associated with café-au-lait spots and an autosomal dominant inheritance (von Recklinghausen's disease). The lesions are firm, discrete nodules attached to a nerve. Histologically there is proliferation of perineurial and endoneurial fibroblasts and Schwann cells embedded in collagen. Neurilemmomas are solitary tumors found along peripheral nerves of the head and extremities. They are discrete nodules that may be locally painful or radiate along the distribution of the nerve. Microscopically the tumor contains Schwann cells with nuclei packed in palisading rows.

Granular cell tumors usually are solitary lesions of the skin or, more commonly, the tongue. They consist of granular cells derived from Schwann cells that often infiltrate the surrounding striated muscle.

MALIGNANT TUMORS

The most common cancers of the skin arise from the cells of the epidermis; they are, in order of frequency, basal cell carcinoma, squamous cell carcinoma, and melanoma. Malignancies arising from cells of the dermis or adnexal structures are much less common.

Environmental influences and concomitant diseases are associated with an increased incidence of epidermal malignancies. These factors have been extensively studied and form some of our best understanding about the causes of cancer.

Epidemiology

Increased exposure to ultraviolet radiation is associated with an increased development of all three of the common skin malignancies. Epidemiologic studies have shown that people with outdoor occupations have skin malignancies more often than people who work indoors. Squamous cell cancer is much more common on the lower lip than the upper. People with fair complexions are more prone to skin cancer. These same people also are more likely to develop malignancies if they live in areas of the world that receive more sunlight, such as New Zealand, as compared to Great Britain. Albino individuals of dark-skinned races are prone to develop cutaneous neoplasms that usually are rare in the nonalbino members, suggesting that melanin has a large role in protection from carcinogenesis.

Other factors associated with skin malignancies also have been identified. Chemical carcinogens have long been known. In the eighteenth century Sir Percival Pott noted the association of soot and scrotal cancer in chimney sweeps. Tar, arsenic, and nitrogen mustard are known carcinogens. Human papillomavirus has been found in certain squamous cell cancers and may be linked with oncogenesis. Radiation therapy in the past for skin lesions such as acne vulgaris, when it resulted in radiation dermatitis, is associated with an increased incidence of basal and squamous cell cancers in the treated areas. Any area of skin subjected to chronic irritation, such as burn scars (Marjolin's ulcers), repeated sloughing of skin from bullous diseases, and decubitus ulcers, all have an increased chance of developing squamous cell cancer. A variant of this type of lesion develops on skin that has suffered repeated burns.

Systemic immunologic dysfunction is related to an increase in cutaneous malignancies. Immunosuppressed patients receiving chemotherapy for other malignancies or immunosuppressants for organ transplants have an increased incidence of basal cell and squamous cell cancers and malignant melanoma. The acquired immunodeficiency syndrome (AIDS) is associated with an increased risk of developing skin neoplasms. Patients with HIV infection should be monitored vigilantly for early diagnosis of skin cancer.

Basal Cell Carcinoma

Basal cell carcinomas contain cells that resemble the basal cells of the epidermis. It is the most common skin cancer and is subdivided into several types by gross and histologic morphology. The nodulocystic or noduloulcerative type accounts for 70 percent of basal cell carcinomas. It is a waxy, cream-colored lesion with rolled, pearly borders (Fig. 13-8). It often contains a central ulcer. When these lesions are large they are called "rodent ulcers." Pigmented basal cell carcinomas are tan to black in color and should be distinguished by biopsy examination from melanoma. Superficial basal cell cancers occur more commonly on the trunk and form a red, scaling lesion sometimes difficult to distinguish grossly from Bowen's disease. A rare form of basal cell carcinoma is the basosquamous type, which contains elements of basal cell and squamous cell cancer. These lesions can metastasize more like a squamous cell carcinoma and should be treated aggressively. Other types include morpheaform, adenoid, and infiltrative carcinomas.

Basal cell carcinomas usually are slow growing, and patients often neglect these lesions for years. Metastasis and death from this disease is extremely rare, but the lesions can cause extensive local destruction. The majority of small (less than 2 mm), nodular lesions may be treated by dermatologists with curettage and electrodesiccation or laser vaporization. A major drawback to these procedures is that no pathologic specimen can be obtained to confirm the diagnosis. Larger tumors, lesions that invade bone or surrounding structures, and more aggressive histologic types (morpheaform, infiltrative, and basosquamous) are best treated by surgical excision with a 2- to 4-mm margin of normal tissue. Histologic confirmation that the margins of resection do not contain tumor is required. Because nodular lesions are less likely to recur, the smaller margin may be used, whereas the other types need a wider margin of resection. Alternative methods of treatment, such as radiation therapy and Mohs' surgery, are discussed later.

Squamous Cell Carcinoma

Squamous cell carcinomas arise from keratinocytes of the epidermis. It is less common than basal cell carcinoma but is more devastating because it can invade surrounding tissue and metastasize more readily. In situ lesions have the eponym of Bowen's disease, and in situ squamous cell carcinomas of the penis are referred to as erythroplasia of Queyrat. Contrary to previous reports, Bowen's disease is not a marker for other systemic malignancies.

Tumor thickness correlates well with its biologic behavior. Lesions that recur locally are more than 4 mm thick and lesions that metastasize are 10 mm or more. The location of the lesion also is important. Tumors arising in burn scars (Marjolin's ulcer), areas of chronic osteomyelitis, and areas of previous injury metastasize early. Lesions on the external ear frequently recur and involve regional lymph node basins early. Squamous cell cancers in areas with solar damage behave less aggressively and usually require only local excision.

Although small lesions can be treated with curettage and electrodesiccation, most surgeons recommend excision of the tumor. Lesions should be excised with a 1-cm margin, if possible, and histologic confirmation that the margins are tumor-free is mandatory. Tumor invading bone should be excised if recurrence is to be avoided. Regional lymph node excision is indicated for clinically palpable nodes (therapeutic lymph node dissection). Lesions arising in chronic wounds behave aggressively and are more likely to spread to regional lymph nodes. For these lesions lymphadenectomy before the development of palpable nodes is indicated (prophylactic lymph node dissection). Metastatic disease is a poor prognostic sign, with only 13 percent of patients alive after 10 years.

Alternative Therapy

Alternatives to surgical therapy for squamous and basal cell cancers consist of radiation therapy or topical 5-fluorouracil for patients unable or unwilling to undergo surgery. Radiation therapy for small and superficial lesions obtains cure rates comparable to surgical excision. Radiation damage to surrounding normal skin with inflammation and scarring can be a problem. Also the development of cutaneous malignancies in irradiated skin is a serious long-term risk with this method.

For lesions on the face near the nose or eye, resection of a wide rim of normal tissue to remove all the tumor can cause significant functional and cosmetic problems. These lesions can be removed by Mohs' micrographic surgery. Mohs' technique, developed in 1932, is a method to serially excise a tumor by taking small increments of tissue until the entire tumor is removed. Each piece of tissue removed is frozen and immediately examined microscopically to determine whether tumorous tissue has been resected. The advantage of this method over that of standard histologic examination after wide surgical resection is that the entire margin of resection is evaluated. The major benefit is the ability to remove a tumor with the least sacrifice of uninvolved tissue. This technique is effective for treating carcinomas around the eyelids and nose, where tissue loss is most conspicuous. The procedure is extremely lengthy (up to several days) since complete excision may require multiple attempts; this remains its major drawback. Cure rates are comparable to those of wide excision.

Patients with basal cell carcinomas have been treated with intralesional injection of interferon. The majority of the lesions were eliminated or controlled by the injections. The lesions that did not respond required surgical excision. When lesions respond to injections, operation is avoided and no reconstruction of the defect is required. The major disadvantages of this treatment are the need for multiple office visits over several weeks for injections, the systemic side effects of interferon, and a potential need for surgery if the lesions do not respond to injections. Clinical trials with combinations of retinoids (vitamin A derivatives) and interferon have demonstrated good response rates in patients with advanced, inoperable squamous cell carcinomas. These results suggest that interferon is likely to have a greater role in therapy of cutaneous neoplasms in the future.

Malignant Melanoma

What was a relatively rare disease 50 years ago has now become alarmingly more common. The rise in the rate of melanoma is the highest of any cancer in the United States. In 1935 the annual incidence of the disease was 1 per 100,000 people. By 1991 the incidence had risen to 12.9 per 100,000. There were 32,000 new cases of melanoma in 1991. The case fatality rate has fallen over the years, probably as the result of earlier detection and treatment.

Because melanoma is becoming so common, it is important for all physicians to be familiar with this disease. The important clinical features of a melanoma include a pigmented lesion with an irregular, raised surface and irregular borders. About 5 to 10 percent of melanomas are not pigmented. Lesions that change in color and size and ulcerate over a few months' time are suspicious and should be biopsied. Surgery is still the mainstay of therapy for melanoma, so it is imperative that surgeons be aware of the latest methods of diagnosis, staging, and therapy.

Pathogenesis

Melanoma arises from transformed melanocytes and can arise anywhere that melanocytes have migrated during embryogenesis. The eye, central nervous system, gastrointestinal tract, and even the gallbladder have been reported as primary sites of the disease. Over 90 percent are found on the skin; however, 4 percent of melanomas are discovered as metastases without an identifiable primary site. Many melanomas, especially in the early phases of growth, are found to contain areas of tumor regression on histologic examination. Regression represents a host immune response to the tumor. Metastatic melanomas with unknown primary sites probably arise from completely regressed lesions that are difficult to locate.

Nevi are benign melanocytic neoplasms found on the skin of most people. Dysplastic nevi are much rarer and contain a histologically identifiable focus of atypical melanocytes. This type of nevus may represent an intermediate between a benign nevus and a true malignant melanoma. It is well documented that patients with melanoma have significantly more nevi and dysplastic nevi than matched controls. The relative risk of developing melanoma increases with the number of dysplastic nevi that a patient develops. The relationship is similar to that between the number of colonic polyps and the development of colon cancer. Patients with dysplastic nevi and family members with dysplastic nevi and melanoma are at increased risk for developing melanoma, suggesting that in these patients there is a genetic component to the risk of developing the malignancy.

Once the melanocyte has transformed into the malignant phenotype, the growth of the lesion is radial in the plane of the epidermis. Even though microinvasion of the dermis can be observed during this radial growth phase, metastases do not occur. Only when the melanoma cells form nests in the dermis are metastases observed. The transformed cells in the vertical growth phase are morphologically different and express different cell-surface antigens than those in the radial phase or cells of the dysplastic nevus. In addition, these cells behave differently in cell culture. They can grow in a less enriched media and have a longer life span.

Types

There are four common distinct types of melanoma. These are, in order of decreasing frequency, superficial spreading, nodular, lentigo maligna, and acral lentiginous. Each has distinct characteristics and behaviors.

The most common type, representing 70 percent of melanomas, is the superficial spreading type. These lesions occur anywhere on the skin except the hands and feet. They are flat, commonly contain areas of regression, and measure 1 to 2 cm in diameter at the time of diagnosis (Fig. [13-9](#)). There is a relatively long radial growth phase before vertical growth begins.

The nodular type accounts for 15 to 20 percent of melanomas. These lesions are darker and raised. The histologic criterion for a nodular melanoma is the lack of radial growth peripheral to the area of vertical growth; hence all nodular melanomas are in the vertical growth phase at the time of diagnosis. Although it is an aggressive lesion, the prognosis for a patient with a nodular-type lesion is the same as that for a patient with a superficial spreading lesion of the same depth of invasion.

The lentigo maligna type, accounting for 5 to 10 percent of melanomas, occurs mostly on the neck, the face, and the back of the hands of elderly people. These lesions are always surrounded by dermis with heavy solar degeneration. They tend to become quite large before a diagnosis is made but also have the best prognosis because invasive growth occurs late.

The rarer acral lentiginous type is distinctly different. It occurs on the palms and soles and in the subungual regions. Although melanoma among dark-skinned people is relatively rare, the acral lentiginous type accounts for a higher percentage in dark-skinned people than in people with less pigmented skin. The subungual lesions appear as blue-black discolorations of the posterior nail fold and are most common on the great toe or thumb.

Prognostic Factors

The original staging system classified melanoma into local (Stage I), regional lymph node (Stage II), and metastatic (Stage III) disease. This staging system had the disadvantage of lumping most patients into Stage I disease, therefore limiting its usefulness in prognostic studies. The most current staging system, from the American Joint Committee on Cancer (AJCC), contains the best method of interpreting clinical information in regard to prognosis of this disease (Table [13-1](#)).

The T classification of the lesion comes from the original observation by Clark that prognosis is directly related to the level of invasion of the skin by the melanoma. Whereas Clark used the histologic level (I, superficial to basement membrane [in situ]; II, papillary dermis; III, papillary/reticular dermal junction; IV, reticular dermis; and V, subcutaneous fat), Breslow modified the approach to obtain a more reproducible measure of invasion by the use of an ocular micrometer. The lesions were measured from the granular layer of the epidermis or the base of the ulcer to the greatest depth of the tumor (I, 0.75 mm or less; II, 0.76 to 1.5 mm; III, 1.51 to 3.0 mm; IV, 3.0 mm or more). These levels of invasion have been subsequently modified and incorporated in the AJCC staging system (Fig. [13-10](#)).

Evidence of tumor in regional lymph nodes is a poor prognostic sign. This is accounted for in the staging system by advancing any T classification from Stage I or II to Stage III. The 10-year survival rate drops precipitously with the presence of lymph node metastasis. The number of positive lymph nodes also is correlated with survival rates.

The presence of distant metastasis is a grave prognostic sign (Stage IV). The median survival ranges from 2 to 7 months, depending on the number and site of metastases, but survival up to a few years has been reported (Fig. [13-11](#)).

Other independent prognostic factors have been identified:

(1) Anatomic location. Independent of histologic type and depth of invasion, people with lesions of the extremities do better than people with melanomas of the trunk or face (82 percent 10-year survival rate for localized disease of the extremity, compared to 68 percent survival with a lesion of the face).

(2) Ulceration. Presence of ulceration in a lesion carries a worse prognosis. For unknown reasons these melanomas act more aggressively than nonulcerated ones. The 10-year survival rate for patients with local disease (Stage I) and an ulcerated melanoma was 50 percent, compared to 78 percent for the same stage lesion without ulceration.

(3) Sex. Women have melanomas in more favorable anatomic sites, and these lesions are less likely to contain ulceration. Despite correction for these factors, females have a higher survival rate than men (80 percent 10-year survival for women versus 61 percent for men with Stage I disease).

(4) Histologic type. Nodular melanomas have the same prognosis as superficial spreading types when lesions are matched for depth of invasion. Lentigo maligna types, however, have a better prognosis even after correcting for thickness, and acral lentiginous lesions have a worse prognosis.

Treatment

The treatment of melanoma is primarily surgical. The indication for procedures such as lymph node dissection, superficial parotidectomy, and resection of distant metastases have changed somewhat over time, but the only hope for cure and the best treatment for regional control and palliation remains surgery (Fig. [13-12](#)). Radiation therapy, regional and systemic chemotherapy, and immunotherapy are effective in a limited set of circumstances, but none is a first-line option.

All suspicious lesions should undergo excisional biopsy. A 1-mm margin of normal skin is taken if the wound can be closed primarily. If removal of the entire lesion creates too large a defect, then an incisional biopsy of a representative part is recommended. Biopsy incisions should be made with the expectation that a subsequent wide excision of the biopsy site may be done. Once a diagnosis of melanoma is made, the biopsy scar and any remains of the lesion need to be removed to eradicate any remaining tumor. For in situ lesions a 0.5- to 1-cm margin of normal skin is adequate for cure. A T1 melanoma (less than 0.76 mm deep) requires a 1-cm margin to prevent local recurrence. For thicker lesions a 2- to 3-cm margin is recommended. Any wider margin of resection does not decrease local recurrence rates. The surrounding tissue should be removed down to the fascia to remove all lymphatic channels. If the deep fascia is not involved by the tumor, removing it does not affect recurrence or survival rates, so the fascia is left intact. If the defect cannot be closed primarily, a skin graft or flap is used.

All clinically positive lymph nodes should be removed by regional nodal dissection. If possible, the lymphatics between the lesion and the regional nodes are removed in continuity. Leaving tumor behind results in recurrence of lesions that cause great morbidity. When groin lymph nodes are removed, the deep (iliac) nodes must be removed along with the superficial (inguinal) nodes, or disease will recur in that region. For axillary dissections the nodes medial to the pectoralis minor muscle must also be resected. For lesions on the face, anterior scalp, and ear, a superficial parotidectomy to remove parotid nodes and a modified neck dissection is recommended. Disruption of the lymphatic outflow does cause significant problems with chronic edema, especially of the lower extremity.

Treatment of regional lymph nodes that do not obviously contain tumor in patients without evidence of metastasis (Stage I and II) is determined by considering the possible benefits of the procedure as weighed against the risks. In patients with thin lesions (less than 0.75 mm) the tumor cells are still localized in the surrounding tissue, and the cure rate is excellent with wide excision of the primary lesion; for these patients treatment of regional lymph nodes is not beneficial. With very thick lesions (more than 4 mm), it is highly likely that the tumor cells have already spread to the regional lymph nodes and distant sites. Removal of the lymph nodes has no effect on survival. Most of these patients die of metastatic disease before developing problems in regional nodes. Because there are significant morbid effects of lymphadenectomy, most surgeons defer the procedure until clinically evident disease appears. Approximately 40 percent of these patients eventually develop disease in the lymph nodes and require a second palliative operation. Elective lymphadenectomy is sometimes performed in these patients as a staging procedure before entry into clinical trials.

In patients with intermediate-thickness tumors (T2 and T3, 0.76 to 4.0 mm) and no clinical evidence of nodal or metastatic disease, the use of prophylactic dissection (elective lymph node dissection on clinically negative nodes) is controversial. To date, prospective, randomized studies have not definitively demonstrated that elective lymph node dissection improves survival in patients with intermediate-thickness melanomas. Careful examination of specimens in patients undergoing elective lymph node dissection have found that in 25 to 50 percent of the cases, specimens contain micrometastases. Among patients who do not have an elective lymph node dissection, 20 to 25 percent eventually develop clinically evident disease and require lymphadenectomy. More evidence suggests that there may be improved survival with elective lymph node dissection in patients with higher risk of developing metastasis (i.e., lesions with ulceration or on the trunk, head, and neck). The most compelling argument for the potential benefits of elective lymph node dissection comes from evidence in large clinical trials; patients with intermediate-thickness melanomas without elective node dissection, continue to die of the disease 10 years later, whereas patients who had an elective lymph node dissection do not. Although not yet statistically significant, these differences may become significant in the future.

One surgical modality gaining acceptance is the use of intraoperative methods to locate the pattern of lymphatic drainage from the primary lesion. Vital blue dye or a radioisotope is injected at the site of the melanoma. This permits identification of the first (sentinel) lymph node draining the tumor. The node is removed, and if micrometastases are identified in frozen-section examination, a complete lymph node dissection is performed.

When the sentinel node can be identified, it serves as an accurate indication of the status of the rest of the nodes in the region. This method may be used to identify patients who would benefit from lymph node dissection while sparing others an unnecessary operation. Whether this procedure actually improves survival in these patients awaits the results of clinical trials.

When patients develop distant metastases surgical therapy may be indicated. Solitary lesions in the brain, gut, or skin that are symptomatic should be excised when possible. Although cure is extremely rare, the degree of palliation can be high and asymptomatic survival prolonged. A decision to operate on metastatic lesions must be made after careful deliberation with the patient.

The most promising area of melanoma treatment is in the use of immunologic manipulation. The only adjuvant therapy known to influence survival so far is the use of intravenous interferon alpha-2b (INF alpha-2b) in patients with lesions of 4 mm or more (T4) or nodal metastasis (N1). In these patients both the relapse-free interval and overall survival are improved with use of INF alpha-2b. Toxicity while under therapy was a problem; the majority of the patients required modification of the initial dosage, and 24 percent discontinued treatment. These recent findings are encouraging because trials of adjuvant therapy in the past have never demonstrated a beneficial effect.

Vaccines have been developed with the hope of stimulating the body's own immune system against the tumor. Melanoma cells contain a number of distinctly different cell-surface antigens. Monoclonal antibodies have been raised against these antigens. These antibodies have been used alone or linked to a radioisotope or cytotoxic agent in an effort to selectively kill tumor cells. All treatments are currently investigational.

Although initially thought to be ineffective in the treatment of melanoma, radiation therapy has been shown to be useful. High-dose-per-fraction radiation produces a better response rate than low-dose, large-fraction therapy. Radiation therapy is the treatment of choice for patients with symptomatic multiple brain metastases.

Hyperthermic regional perfusion of the limb with a chemotherapeutic agent (e.g., melphalan) is the treatment of choice for patients with local recurrence or in-transit lesions (local disease in lymphatics) on an extremity and not amenable to excision. The goal of regional perfusion therapy is to increase the dosage of the chemotherapeutic agent to maximize tumor response while limiting systemic toxic effects. While difficult to perform and associated with complications, it does produce a high response rate (greater than 50 percent). The introduction of tumor necrosis factor alpha and interferon-g to the limb perfusate may increase the tumor response rate without increasing toxicity. Prospective clinical trials are under way to evaluate the use of regional perfusion for melanoma of the limbs as adjuvant therapy for patients with Stage I disease. In addition, regional perfusion therapy for metastatic disease to the liver is under investigation.

Pathologic Conditions Associated with Skin Malignancies

There are several well-recognized diseases associated with an increased incidence of skin malignancies. Some are associated with a specific neoplasm, whereas others appear to have the less specific effect of leaving the patient susceptible to a variety of neoplasms.

Diseases linked with basal cell carcinoma include the basal cell nevus syndrome and nevus sebaceus of Jadassohn. Basal cell nevus syndrome is an autosomal dominant disorder characterized by the growth of hundreds of basal cell carcinomas during young adulthood. Palmar and plantar pits are a common physical finding and represent foci of neoplasms. Treatment is limited to excision of only aggressive and symptomatic lesions. Nevus sebaceus of Jadassohn is a lesion containing several cutaneous tissue elements that develops during childhood. This lesion is associated with a variety of neoplasms of the epidermis, but most commonly basal cell carcinoma.

Diseases associated with squamous cell carcinoma may have a causative role in the development of carcinoma. Skin diseases that cause chronic wounds, such as epidermolysis bullosus and lupus erythematosus, are associated with a high incidence of squamous cell carcinoma. Epidermodysplasia verruciformis is a rare autosomal recessive disease associated with infection with human papillomavirus. Large verrucous lesions develop early in life and often progress to invasive squamous cell carcinoma in middle age.

Xeroderma pigmentosum is an autosomal recessive disease associated with a defect in cellular repair of DNA damage. The inability of the skin to correct DNA damage from ultraviolet radiation leaves these patients prone to cutaneous malignancies. Squamous cell carcinomas are most frequent, but basal cell carcinomas, melanomas, and even acute leukemias are seen.

Dysplastic nevi may represent a precursor to melanoma. Familial dysplastic nevus syndrome is an autosomal dominant disorder. Patients develop multiple dysplastic nevi, and longitudinal studies have demonstrated an almost 100 percent incidence of melanoma. Familial dysplastic nevus syndrome is similar to familial polyposis coli and the association with colon cancer. While the development of colon cancer can be arrested with total proctocolectomy, a similar solution is not possible with familial dysplastic nevi. Close surveillance and frequent biopsy of all suspicious lesions constitutes the best therapy.

Other Malignancies

Merkel Cell Carcinoma (Primary Neuroendocrine Carcinoma of the Skin)

Originally thought to be a variant of squamous cell carcinoma, it has only recently been demonstrated by immunohistochemical markers that Merkel cell carcinomas are of neuroepithelial differentiation. These tumors are associated with a synchronous or metasynchronous squamous cell carcinoma 25 percent of the time. These tumors are very aggressive, and wide local resection with 3-cm margins is recommended. Local recurrence rates are high, and distant metastases occur in one-third of patients. Prophylactic regional lymph node dissection and adjuvant radiation therapy are recommended. Overall, the prognosis is worse than for malignant melanoma.

Extramammary Paget's Disease

This tumor is histologically similar to the mammary type. It is a cutaneous lesion that appears as a pruritic red patch that does not resolve. Biopsy demonstrates classic Paget's cells. Paget's disease is thought to be a cutaneous extension of an underlying adenocarcinoma, although an associated tumor cannot always be demonstrated.

Adnexal Carcinomas

This group includes apocrine, eccrine, and sebaceous carcinomas, all rare tumors. They are locally destructive and can cause death by distant metastasis.

Angiosarcomas

Angiosarcomas may arise spontaneously, mostly on the scalp, face, and neck. They usually appear as a bruise that spontaneously bleeds or enlarges without trauma. Tumors also may arise in areas of prior radiation therapy or in the setting of chronic lymphedema of the arm, such as after mastectomy (Stewart-Treves syndrome). The angiosarcomas that arise in these areas of chronic change occur decades later. The tumors consist of anaplastic endothelial cells surrounding vascular channels. While total excision of early lesions can provide occasional cure, the prognosis usually is poor, with 5-year survival rates under 20percent. Chemotherapy and radiation therapy are used for palliation.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) appears as rubbery bluish nodules that occur primarily on the extremities but may appear anywhere on the skin and viscera. These lesions are usually multifocal rather than metastatic. Histologically the lesions are composed of capillaries lined by atypical endothelial cells. Early lesions may resemble hemangiomas, while older lesions contain more spindle cells and resemble sarcomas.

Classic KS is seen in people of Eastern Europe or sub-Saharan Africa. The lesions are locally aggressive but undergo periods of remission. Visceral spread of the lesions is rare, but a subtype of the African variety has a predilection for spreading to lymph nodes. A different variety of KS has been described for people with AIDS or with immunosuppression from chemotherapy. For reasons not yet understood, AIDS-related KS occurs primarily in male homosexuals and not in intravenous drug abusers or hemophiliacs. In this form of the disease, the lesions spread rapidly to the nodes, and the gastrointestinal and respiratory tract often are involved. Development of AIDS-related KS may be associated with concurrent infection with a herpes-like virus.

Treatment for all types of KS consists of radiation to the lesions. Combination chemotherapy is effective in controlling the disease, although most patients develop an opportunistic infection during or shortly after treatment. Surgical treatment is reserved for lesions that interfere with vital functions, such as bowel obstruction or airway compromise.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans consists of large nodular lesions located mainly on the trunk. They often ulcerate and become infected. With enlargement the lesions become painful. Histologically the lesions contain atypical spindle cells, probably of fibroblast origin, located around a core of collagen tissue. Sometimes they are mistaken for an infected keloid. Metastases are rare, and surgical excision can be curative. Excision must be complete because local recurrences are common.

Fibrosarcoma

Fibrosarcomas are hard, irregular masses found in the subcutaneous fat. The fibroblasts appear markedly anaplastic with disorganized growth. If they are not excised completely, metastases usually develop. The 5-year survival rate after excision is about 60 percent.

Liposarcoma

Liposarcomas arise in the deep muscle planes and, rarely, from the subcutaneous tissue. They occur most commonly on the thigh. An enlarging lipoma should be excised and inspected to distinguish it from a liposarcoma. Wide excision is the treatment of choice, with radiation therapy reserved for metastatic disease.

FUTURE DEVELOPMENTS IN SKIN SURGERY

The major challenge in surgical therapy for diseases of the skin is in the lack of replacement for diseased or damaged tissue. The development of autologous skin grafting for treatment of skin defects was a tremendous advancement. However, technical limitations, such as graft contraction and donor site problems, and biologic limitations, such as the limited amount of autologous skin available, make autografts less than a universal solution. The future of surgical therapy for diseases of the skin lies in the development of skin replacement. Current research is directed at tissue expansion, cell culture expansion, and neogenesis of skin.

Techniques for tissue expansion have been reported since 1982. During skin expansion with subcutaneous balloon implants (Fig. 13-13), new epidermis and some collagen is produced. Much of this new tissue, however, is rearrangement of the old tissue. Expansion of skin produces a limited amount of tissue for use.

The expansion of epidermis by the growth and maturation of keratinocytes in culture can be performed. The use of a postage-stamp-sized biopsy specimen to produce enough autologous epithelium to cover a burn area of more than 90 percent of total body surface area has been reported (Fig. 13- 14). Although this was a major advancement in covering large wounds, the final results are less than optimal. The cultured epidermis often blisters and sloughs, and wound contractures are common. Skin (comprising dermis, vasculature, adnexal structures, and pigmentation) is much more complex than just epidermis, and replacement of these other structures is under investigation.

Dermal replacements from synthetic materials or cadaveric sources are in clinical use. A bilaminar collagen and proteoglycan dermis (Integra) has been approved by the Food and Drug Administration for clinical use. This prosthetic dermis, available in ready-to-use form, can be used to cover large surface areas, decreasing fluid losses through the wound, which is crucial in burn patients. Vascularization of this dermis takes 2 weeks, and final epidermal coverage of the wound requires a thin skin graft. The final result is functionally and aesthetically quite good. Despite its limitations, it is the first promising dermal replacement to be widely used. Autologous skin grafts revascularize in 2 to 4 days because they already contain a network of capillaries in the dermis. For synthetic dermis to survive as well as an autologous graft, the problem of delayed vascular ingrowth must be solved. Pigmentation problems also may be addressed by repopulating skin replacements with cultured melanocytes; however, melanocyte biology is very complex, and pigmentation control is still rudimentary. With more sophisticated methods of tissue culture, a more complex skin replacement will become available.

As investigators learn more about the protein factors that control wound healing and tissue growth, the replacement for damaged skin will eventually come from complete neoorganogenesis of tissue. Characterization of these growth factors on a structural and functional level is just beginning, but the information obtained to date has been substantial. Factors have been isolated that cause specific mesenchymal cells to proliferate (fibroblast growth factor), migrate (epidermal growth factor), and organize into structures such as capillaries (transforming growth factor-beta) or even rudimentary organoid tissue. This may allow generation of new tissue in situ for skin replacement.

CHAPTER 14 - Breast

Kirby I. Bland
Michael P. Vezeridis
Edward M. Copeland III

INTRODUCTION

The breast or mammary gland is a distinguishing feature of the class Mammalia. From puberty to death, the breast is subjected to constant physical and physiologic alterations that are related to menses, pregnancy, gestation, and menopause. The impact of breast disease in Western societies assumes greater importance as the incidence of breast cancer continues to increase steadily. One of every two women will consult her physician for breast disease, approximately one of every four women will undergo breast biopsy, and one of every nine American women will develop some variant of breast carcinoma.

EMBRYOLOGY

The breast is a highly modified sudoriferous gland that develops as ingrowths from ectoderm form the alveoli and ducts. Supporting vascularized connective tissue is derived solely from mesenchyme. At the fifth or sixth week of fetal development, two ventral bands of thickened ectoderm (mammary ridges, “milk lines”) are evident in the embryo. In the majority of the class Mammalia, paired glands develop along these ridges and extend from the base of the forelimb (future axilla) to the region of the hind limb (inguinal area). These ridges are not prominent in the human embryo and disappear shortly thereafter, except for a small portion that may persist in the pectoral region. Accessory mammary glands (polymastia) or accessory nipples (polythelia) may occur along the original mammary ridge or milk line (Fig. 14-1) if the normal regression fails.

Each mammary gland develops as an ingrowth of ectoderm and initiates a primary bud of tissue in underlying mesenchyme. Each primary bud initiates the development of 15 to 20 secondary buds or outgrowths. In the fetus, epithelial cords develop from the secondary buds and extend into the surrounding connective tissues of the chest wall. Lumina develop in the outgrowths to form lactiferous ducts with prominent branches. By birth, lactiferous ducts open into shallow epithelial depressions referred to as the mammary pit. In infancy, the pit becomes elevated and transformed into the nipple as a consequence of proliferation of mesenchyme. If there is failure of the pit to elevate above skin level, a congenital malformation, recognized in 2 to 4 percent of patients as inverted nipples, is evident.

In newborn females or males, transient enlargement of the breast bud may be evident, and the bud may produce a secretion referred to as “witch’s milk.” These transitory changes occur in response to maternal hormones that cross the fetal-maternal circulation of the placenta.

At birth the breasts appear essentially identical in both sexes and demonstrate only the presence of major lactiferous ducts. The gland remains undeveloped in the female until puberty. Thereafter the organ enlarges rapidly in response to estrogen and progesterone secretion by the ovaries. Hormonal stimulation initiates proliferation of glandular tissue as well as fat and connective tissue elements associated with breast support. Glandular tissues remain incompletely developed until pregnancy occurs. With parturition, the intralobular ducts undergo rapid development and form buds that become alveoli.

Unilateral absence of the breast (amastia) is more common than bilateral amastia; both conditions occur more commonly in females. This rare congenital anomaly occurs as a result of an arrested mammary ridge around the sixth week of fetal development. Typically no other abnormalities are associated with bilateral absence of nipple and breast tissue. By contrast, Alfred Poland described the absence of musculature (pectoralis major and minor) of the shoulder girdle and malformations of the ipsilateral upper limb with unilateral amastia. Hypoplasia or complete absence of the ipsilateral breast or nipple, costal cartilage and rib defects, hypoplasia of subcutaneous tissues of the chest wall, and brachysyndactyly is referred to as Poland’s syndrome.

Breast hypoplasia also may be induced iatrogenically. The failure of complete development of the vestigial male or female breast (developmental hypomastia) may be initiated by therapeutic manipulation or injury to the mammary anlage in infancy or in the prepubertal state. Recognized iatrogenic mechanisms that initiate hypoplasia of the organ include trauma, abscess, incisions, infectious lesions, and radiation therapy.

Symmastia is the term, coined relatively recently, for medial confluence of the breast. This rare anomaly is recognized as webbing across the midline in breasts that usually are symmetrical. The presternal blending (confluence) of tissue that is associated with macromastia is more common.

Accessory or supernumerary nipples, or polythelia, is a relatively common, minor congenital anomaly that occurs in both sexes with an estimated frequency of 1:100 to 1:500 persons. Polythelia may be associated with abnormalities of the urinary tract (renal agenesis and carcinoma), abnormalities of the cardiovascular system (conduction disturbance, hypertension, congenital heart anomalies), and other conditions (pyloric stenosis, epilepsy, ear abnormalities, and arthrogryposis).

Supernumerary nipples or breasts may occur in any size or configuration along the mammary milk line, usually between the nipple and the symphysis pubis. Turner syndrome (ovarian agenesis and dysgenesis) and Fleischer syndrome (lateral displacement of nipples to the midclavicular line with bilateral renal hypoplasia) may have polymastia as a component. Accessory or ectopic axillary breast tissue is relatively uncommon but, when present, usually is bilateral.

ANATOMY AND DEVELOPMENT

Located within the superficial fascia of the anterior thoracic wall, the breast is composed of 15 to 20 lobes of glandular tissue of the tubuloalveolar type (Fig. 14-2). Fibrous connective tissues connect the lobes; adipose tissue is abundantly interposed between the lobules. Subcutaneous connective tissues surround the gland and extend as septa between lobes and lobules, providing structural support for glandular elements. The deep layer of superficial fascia lies on the posterior surface of the breast adjacent to and at some points fusing with the deep (pectoral) fascia of chest wall. The retromammary bursa may be identified surgically on the posterior aspect of the breast between the deep layer of superficial fascia and deep investing fascia of the pectoralis major and contiguous muscles of the thoracic wall. Fibrous bands of connective tissue interdigitate between parenchymal tissue to extend from the deep layer of the superficial fascia (hypodermis) and attach to the dermis of the skin. These suspensory ligaments (of Cooper) insert perpendicular to the delicate superficial fascial layers of the dermis and permit mobility of the breast while providing structural support.

The mature breast of the female extends from the level of the second or third rib to the inframammary fold at approximately the sixth or seventh rib. Transversely, it extends from the lateral border of the sternum to the anterior axillary or midaxillary line. The deep or posterior surface rests on portions of the deep investing fascia of the pectoralis major, serratus anterior, and external oblique abdominal muscles and the upper extent of the rectus sheath. The axillary tail (of Spence) extends superolaterally into the anterior axillary fold. The upper half of the breast, and particularly the upper outer quadrant, contains a greater volume of glandular tissue than do other sectors.

At maturity, glandular components of the breast take a protuberant conical form. The base of the cone is roughly circular, measuring 10 to 12 cm in diameter and 5 to 7 cm in thickness. Tremendous variations in size, contour, and density of the breast are evident at maturity. The nulliparous breast has a typical hemispheric configuration with distinct flattening above the nipple. By contrast, with multiparity and the hormonal stimulation that accompanies pregnancy and lactation, the organ assumes a larger and more pendulous form and increases in volume and density. With senescence, the aging breast assumes a flattened, flaccid, and more pendulous configuration with decreased volume.

Nipple and Areola

The epidermis of the nipple and areola is highly pigmented and variably corrugated. The complex is covered by keratinized stratified squamous epithelium. During puberty, the skin becomes increasingly pigmented and the nipple assumes an elevated, prominent configuration. During pregnancy, the areola enlarges and pigmentation is enhanced. Smooth muscle bundle fibers arranged radially and circumferentially in the dense connective tissue and longitudinally along the lactiferous ducts extend upward into the nipple. These muscle fibers are responsible for erection of the nipple, which occurs with various sensory and thermal stimuli.

The areola contains sebaceous glands, sweat glands, and accessory areolar glands. These accessory glands produce small elevations on the surface of the areola (Montgomery tubercles). The tip of the nipple contains numerous sensory nerve cell endings and Meissner’s corpuscles in the dermal papillae; the areola contains few of these structures. The rich sensory innervation of the breast, particularly the nipple and areola, is of great functional importance because the sucking infant initiates a chain of neurohumoral events that result in “milk letdown.”

Inactive Mammary Tissue

The tubuloalveolar glands derived from modified sweat glands of the epidermis lie in the subcutaneous tissues. Each of the 15 to 20 irregular lobes of branched tubuloalveolar glands in the adult terminates in a lactiferous duct (2 to 4 mm in diameter), which opens into a constricted orifice (0.4 to 0.7 mm in diameter) with entry into the ampulla of the nipple (see Fig. 14-2). Immediately under the areola, each duct has a dilated portion, the lactiferous sinus. Lined with stratified squamous epithelium, these ducts show a gradual transition to two layers of cuboidal cells, which then become a single layer of columnar or cuboidal cells in the remaining duct system. Myoepithelial cells of ectodermal origin reside between surface epithelial cells in the basal lamina. In the secretory portion of the gland and in the larger ducts, these cells contain myofibrils and are microscopically similar to smooth muscle cells.

In the inactive gland, the glandular component is sparse and consists chiefly of duct elements (Fig. 14-3). During menstruation, the breast undergoes cyclical changes. In early phases of the cycle, ductules appear as cords with sparse or absent lumina. With estrogen stimulation at or about the time of ovulation, secretory cells increase in height, lumina appear, and a small volume of secretions accumulates. Thereafter, fluid and lipids accumulate in connective tissue. In the absence of prolonged hormonal stimulation, the glandular components regress to a more inactive state throughout the remainder of the menstrual cycle.

Active Mammary Gland—Pregnancy and Lactation

With pregnancy and preparation for lactation, glands undergo marked proliferative and developmental maturation. As the breast enlarges in response to hormonal stimulation, lymphocytes, plasma cells, and eosinophils infiltrate and accumulate within fibrous components of connective tissue.

Development of glandular tissue is asymmetric; variation in degree of development may occur within a single lobule. With cellular division following mitotic phases, ductules branch and alveoli begin to develop. In the third trimester of pregnancy, alveolar development becomes more prominent (Fig. 14-4). With termination of pregnancy, proliferation declines and subsequent enlargement of the breasts occurs via hypertrophy of alveolar cells and accumulation of secretory products in the lumina of the ductules.

Secretory cells contain abundant endoplasmic reticulum, moderate numbers of large mitochondria, Golgi complexes, and a number of dense lysosomes. Two distinct substances

are produced by the cells and are released by different mechanisms: (1) the protein component of milk, synthesized in the granular endoplasmic reticulum; and (2) the lipid, or fatty, component of milk, which forms as free lipid droplets in the cytoplasm. These components of milk are formed by merocrine secretion (protein) and apocrine secretion (lipid).

Milk released in the first few days after parturition is termed *colostrum*. Colostrum has a low lipid content but contains considerable quantities of antibodies that are passively transferred from the mother to the fetus via the placenta. Lymphocytes and plasma cells infiltrate the stroma of the breast during proliferation and development and are believed to be the source of the components of colostrum. With reduction of these cellular structures, the production of colostrum is terminated and lipid-laden milk is released.

Blood Supply

The gland receives its principal blood supply from: (1) perforating branches of the internal mammary artery; (2) lateral branches of the posterior intercostal arteries; and (3) various branches from the axillary artery, including the highest thoracic, lateral thoracic, and pectoral branches of the thoracoacromial artery (Fig. 14-5). The second, third, and fourth anterior perforating arteries give off branches that arborize in the breast as medial mammary arteries. The lateral thoracic vessel gives off branches to the serratus anterior, pectoralis major and minor, and subscapularis muscles. It also gives rise to lateral mammary branches that invest lateral portions of the pectoralis major.

Veins of the breast follow the course of the arteries; primary venous drainage is toward the axilla. Three principal groups of veins for drainage of the thoracic wall and breast are: (1) perforating branches of the internal thoracic vein; (2) tributaries of the axillary vein; and (3) perforating branches of the posterior intercostal veins. Lymphatics usually parallel the course of blood vessels.

The vertebral venous tributaries (Batson's plexus) may provide a secondary route for metastases of breast cancer. This plexus invests the vertebrae and extends from the base of the skull to the sacrum. Venous channels exist between this plexus and veins associated with thoracic, abdominal, and pelvic organs. These potential pathways explain metastases to the vertebrae, skull, pelvic bones, and central nervous system in the absence of pulmonary metastases.

Innervation of the Breast

Lateral and anterior cutaneous branches of the second through sixth intercostal nerves provide sensory innervation. Nerves of the breast are principally derived from the fourth, fifth, and sixth intercostal nerves. A limited area of skin over the upper portion of the breast is supplied by nerves that arise from the cervical plexus, specifically the anterior or medial branches of the *supraclavicular nerve*.

Lateral branches of the *intercostal nerves* exit the intercostal spaces through slips of the serratus anterior muscle. These nerves supply the anterolateral thoracic wall; the third through sixth branches, also known as *lateral mammary branches*, supply the breast. The *intercostal brachial nerve* is the lateral branch of the second intercostal nerve and is commonly visualized during surgical dissection of the axilla. Resection of the intercostal brachial nerve causes loss of sensation from the upper medial aspect of the arm and axilla.

Lymphatic Drainage

The boundaries of lymphatic drainage of the axilla are not well demarcated. There is also considerable variation in the positions of regional nodes. Although anatomists usually define five groups of axillary nodes, surgeons identify six primary groups (Figs. 14-6 and 14-7). (1) The *axillary vein group*, or *lateral group*, consists of four to six nodes medial or posterior to the vein; these receive most of the lymph drainage from the upper extremity. (2) The *external mammary group* (anterior or pectoral group) harbors five or six nodes along the lower border of the pectoralis minor muscle contiguous with the lateral thoracic vessels. This group receives the majority of lymphatic drainage from the lateral breast. (3) The *scapular group* (*posterior* or *subscapular*) consists of five to seven nodes from the posterior wall of the axilla at the lateral border of the scapula and is contiguous with the subscapular vessels. These nodes receive lymph principally from the lower posterior neck, posterior trunk, and posterior shoulder. (4) The *central group* consists of three or four large groups of nodes that are embedded in the fat of the axilla immediately posterior to the pectoralis minor muscle. This group receives lymph from the three preceding groups but may receive lymphatics directly from the breast. (5) The *subclavicular group* (*apical*) consists of 6 to 12 nodal groups posterior and superior to the upper border of the pectoralis minor muscle. This group receives lymph from all groups of axillary nodes and unites with efferent vessels from the subclavicular nodes to form the *subclavian trunk*. (6) The *interpectoral* (*Rotter's*) *group* consists of one to four nodes interposed between the pectoralis major and minor muscles. Lymph from these nodes passes directly into the central and subclavicular groups.

As indicated in Fig. 14-7, these nodal groups are assigned levels according to their relationship to the pectoralis minor muscle. Nodes located lateral to or below the lower border of the pectoralis minor are referred to as *Level I nodes* and include the *external mammary*, *axillary vein*, and *scapular groups*. Nodes located deep to or behind the pectoralis minor are referred to as *Level II nodes* and include the *central group*. Nodes located medial to or above the upper border of the pectoralis minor are *Level III nodes* and include the *subclavicular lymph node group*.

Lymph Flow

Metastatic disease of the breast occurs predominantly by routes that are extensive and arborize in multiple directions through skin and mesenchymal lymphatics. Lymphatic flow is unidirectional except in the pathologic state and has preferential flow from the periphery toward the right side of the heart. Preferential lymphatic flow toward the axilla is observed in lesions of the upper anterolateral chest. The lymphatics of the dermis are intimately associated with deeper lymphatics of underlying fascial planes; this fact explains the multidirectional potential for drainage of superficial breast neoplasms. Two accessory directions for lymphatic flow from breast parenchyma to nodes of the apex of the axilla are the *transpectoral* and *retropectoral* routes. *Interpectoral* (*Rotter's*) *nodes*, between the pectoralis major and minor, receive lymph that terminates in the apical (Level III) group. The retropectoral pathway drains the superior and internal aspects of the breast and similarly terminates at the apex of the axilla in the apical group.

Accessory pathways provide major lymphatic drainage by way of the external mammary and central axillary node groups (Levels I and II, respectively). Internal mammary lymphatic trunks eventually terminate in subclavian node groups (see Figs. 14-6 and 14-7). The presence of supraclavicular nodes (stage IV disease) results from lymphatic permeation and subsequent obstruction of the inferior and deep cervical groups of the jugular-subclavian confluence. The supraclavicular node group is the termination of efferent trunks from subclavian nodes of the internal mammary nodal group. Central and medial lymphatics of the breast pass medially and parallel to the course of major blood vessels to perforate the pectoralis major muscle and terminate in the internal mammary nodal chain. This also is a major pathway for metastatic spread of carcinoma into the systemic circulation.

Cross-communication from the interstices of connecting lymphatic channels for each breast provides ready access of lymphatic flow to the opposite axilla. Communicating dermal lymphatics to the contralateral breast account for occasional metastatic involvement of the opposite breast and axilla.

Lymphatic vessels that drain the breast occur in three interconnecting groups: (1) within the gland in interlobular spaces that parallel lactiferous ducts; (2) within glandular tissue and overlying skin of the central part of the gland beneath the areola (subareolar plexus); and (3) on the posterior surface of the breast, communicating with minute vessels that parallel the perimysium in deep fascia. Lymphatic vessels from deeper structures of the thoracic wall drain principally into parasternal, intercostal, or diaphragmatic nodes.

More than 75 percent of lymph from the breast passes to the axillary lymph nodes (see Figs. 14-6 and 14-7); the remainder flows into parasternal lymphatics. Although it has been suggested that parasternal nodes receive lymph principally from the medial aspects of the breast, vital- dye flow studies report that both the axillary and the parasternal lymphatic groups receive lymph from all quadrants of the breast.

PHYSIOLOGY

Mammary development and function are initiated by a variety of hormonal stimuli, including estrogen and progesterone, prolactin, oxytocin, thyroid hormone, cortisol, and growth hormone. Estrogen, progesterone, and prolactin have profound trophic effects that are essential to normal breast development and function. Estrogen initiates ductal development; progesterone is primarily responsible for differentiation of epithelial cells and lobular development. Progesterone also may reduce estrogen binding in mammary epithelium and limit tubular system proliferation. Prolactin is the primary hormonal stimulus for lactogenesis in late pregnancy and in the postpartum period. Prolactin increases the number of estrogen receptors and stimulates epithelial cells to act synergistically with ductular and lobuloalveolar development.

Figure 14-8 depicts secretion of neurotrophic hormones from the hypothalamus that are responsible for regulation of secretion of mammogenic hormones. Secretion of the gonadotropins—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—regulates the ovarian secretory release of estrogen and progesterone. Release of LH and FSH from basophilic cells of the anterior pituitary gland are further regulated by secretion of *gonadotropin-releasing hormone (GnRH)* from the hypothalamus. Secretion of LH, FSH, and GnRH is regulated by positive and negative feedback effects of circulating levels of estrogen and progesterone.

The secretion of these mammogenic hormones throughout the life of the normal female is responsible for alterations in the hormonal milieu and for development, function, and maintenance of lobuloalveolar tissues (Fig. 14- 9). In the human female *neonate*, plasma estrogen and progesterone levels decrease after birth. Throughout childhood these levels remain low as a result of the regulatory sensitivity of the hypothalamic-pituitary axis to the negative feedback effects of sex steroids. With onset of *puberty* an increase in the central drive of the hypothalamus occurs, with a concurrent decrease in sensitivity to negative feedback by estrogen and progesterone. Thereafter, an increase in sensitivity to positive feedback by estrogen is evident. These physiologic events thereby initiate an increase in GnRH secretion, an increase in FSH and LH secretion, and ultimately an increase in ovarian estrogen and progesterone secretion. With the development of positive feedback by estrogen, the *menses* are initiated.

Cyclic Changes During the Menstrual Cycle

There are great variations in breast volume during the menstrual cycle. Volume is greatest in the second half of the cycle, after a premenstrual increase in size, nodularity, density, and sensitivity. Progesterone may stimulate glandular growth in the luteal phase. Changes in the mitotic rate of glandular components are greater in the luteal phase than in the follicular phase. The premenstrual increase in volume occurs as a consequence of the increase in size of the lobule without any evidence of epithelial proliferation. Thereafter, engorgement of the stroma, lobules, and ducts is evident, with an increase in the size of ducts and acini as the lumina dilate. Parenchymal engorgement and edema subside with onset of menses.

Pregnancy

A dramatic increase in secretion and release of circulating ovarian and placental estrogens and progestins is evident with pregnancy. These hormones initiate striking alterations in the form and substance of the breast (Fig. 14-9 B). The gland enlarges, the areolar skin darkens, and the areolar glands become prominent as ducts and lobules proliferate. In the *first trimester*, lobuloalveolar formation is initiated as ducts branch to form multiple alveoli. With increases in lobular size, proliferating glandular epithelium replaces connective tissue and the components of adipose tissue. In the *second trimester*, proliferation of ductular elements increases after stimulation by estrogens and progestins secreted by the placenta. These sex steroids cause arborization of glandular structures to further develop alveoli. As this glandular system enlarges, the secretory capacity of the epithelium increases, as is evident by the accumulation of colloid in the alveoli.

During the *third trimester*, fat droplets accumulate in the alveolar cells and colostrum fills the alveolar and ductular spaces. Mammary blood flow increases and myoepithelial cells hypertrophy. The mammogenic action of prolactin requires the presence of cortisol, insulin, growth hormone, and epidermal growth factor. In late pregnancy, limited synthesis of milk fats and proteins is initiated. This process is stimulated by the lactogenic effects of prolactin on breast lobular tissue; other pituitary lactogenic hormones may also have trophic effects.

Postpartum Lactation

After delivery of the placenta, progesterone and estrogen levels diminish. These quantitative decreases in the plasma estradiol and progesterone levels allow full expression of the lactogenic action of prolactin. Maintenance of lactation requires regular removal of milk and stimulation (“milk letdown”) of the neural reflexes to prolactin secretion. The magnitude of the suckling-induced surge of prolactin decreases with time, probably as a consequence of the decreased duration and frequency of nursing. Milk production and ejection in nursing women are controlled by neural reflex arcs that originate in free nerve endings of the nipple-areolar complex.

Oxytocin initiates contraction of smooth muscle components of myoepithelial cells that surround the alveoli; compression of the alveoli occurs, and expulsion of milk under pressure into the lactiferous sinuses is evident. Oxytocin release can result from auditory, visual, olfactory, or other stimuli associated with nursing. Maintenance of lactation requires an intact hypothalamic-pituitary axis, adequate diet and nutrition, regular suckling release of milk, and the absence of psychologic stresses that interfere with normal control of prolactin and oxytocin release.

After the weaning of the infant, the gland returns to an inactive, nonsecretory state. Prolactin and oxytocin release subside. The secretory activity of the lactogenic epithelium decreases, and unremoved dormant milk increases pressure within the ductular and alveolar structures. The lobular structure thereafter atrophies and the secretory cells degenerate (Fig. [14-9 C](#)).

Postmenopausal Breast

After menopause and the concomitant decrease in ovarian secretion of estrogen and progesterone, there is a progressive involution of ductular and glandular components. A decrease in the number and size of glandular elements is evident; the epithelium of the lobules and ducts becomes atrophic or hypoplastic. Surrounding fibrous tissue increases in density, and the parenchyma is replaced with adipose and stromal tissue rather than supporting glandular structure. With aging there is loss of fat content and the supporting stroma, thereby initiating loss of lobular structure, density, form, and contour (Fig. [14-9 D](#)).

Gynecomastia

Gynecomastia implies the presence of a female-type mammary gland in the male. Most examples of gynecomastia should not be considered a disease, because enlargement of the male breast is common. *Physiologic gynecomastia* occurs mostly during three phases of life: (1) neonatal period, (2) adolescence, and (3) senescence. Common to each is an excess of estrogens in relation to circulating testosterone. Neonatal physiologic gynecomastia is caused by the action of placental estrogens on neonatal breast parenchyma. In adolescence there is an excess of estradiol relative to testosterone. With aging, the plasma testosterone level falls, and senescent gynecomastia is caused by a relative hyperestrinism.

Pathology

The few ductal structures of the male breast enlarge, elongate, and branch with an ensheathing connective tissue. There is a combined increase in glandular and stromal elements, with regular distribution of each element throughout the enlarged breast. In the pubertal male, the condition often is unilateral and typically occurs between the ages of 12 and 15 years. By contrast, senescent gynecomastia usually is bilateral, although there may be asymmetry.

In the nonobese patient, at least 2 cm of subareolar breast tissue must be present before gynecomastia can be confirmed. Mammography and ultrasonography are used to differentiate indistinguishable or ill-defined contiguous fatty tissue from male breast lesions and soft-tissue structures. Dominant nontender masses and local areas of firmness, irregularity, or asymmetry suggest the possibility of an early male breast cancer in the aging patient. Gynecomastia does not predispose the male breast to the development of cancer. By contrast, the hypoandrogenic state of primary testicular failure in Klinefelter’s syndrome (47,XXY) is associated with a higher risk for breast cancer in men.

Pathophysiology

Table [14-1](#) identifies the pathophysiologic mechanisms that may initiate gynecomastia. *Estrogen excess states* result from an increase in the secretion of estradiol from the testicles or from nontesticular tumors. Endocrine disorders, such as hyperthyroidism or hypothyroidism, or hepatic disease (nonalcoholic and alcoholic cirrhosis) may initiate estrogen excess. Estrogen excess states also may be induced by nutritional alterations such as protein and fat starvation. “Refeeding gynecomastia” is perhaps related to the resumption of pituitary gonadotropin secretion after pituitary shutdown.

Androgen deficiency states such as aging initiate gynecomastia. Concurrent with decreased plasma testosterone levels is an elevation in the level of plasma testosterone-binding globulin, resulting in a reduction of unbound testosterone. Senescent hypertrophy occurs most commonly in men between the ages of 50 and 70 years. Klinefelter’s syndrome of 47,XXY karyotype is manifested by gynecomastia, hypergonadotropic hypogonadism, and azoospermia. Other causes of primary testicular failure include ACTH deficiency, hereditary defects of androgen biosynthesis, and eunuchoidal males (congenital anorchia).

Secondary testicular failure as a cause of gynecomastia may result from trauma, orchitis, cryptorchidism, abdominal or genital irradiation, hydroceles, varicoceles, and spermatoceles. Renal failure, regardless of cause, may initiate gynecomastia.

Drugs with estrogenic or estrogen-related activity (digitalis, estrogens, anabolic steroids, marijuana) may be causative. Drugs that inhibit the action or synthesis of testosterone (cimetidine, ketoconazole, phenytoin, spironolactone, antineoplastic agents, diazepam) also may be implicated. Drugs that enhance estrogen synthesis (human chorionic gonadotropin) or drugs with idiopathic mechanisms may induce gynecomastia (reserpine, theophylline, verapamil, tricyclic antidepressants, furosemide).

Treatment

Medical therapy of gynecomastia is rarely of value except when a specific diagnosis has been established. For disorders of androgen deficiency, testosterone administration may effect breast regression. For large, progressive gynecomastia refractory to drug discontinuance or therapy of an endocrine defect, the most effective therapy, especially in the young adult, is transareolar mastectomy. Surgical therapy is reserved, however, for idiopathic causes of gynecomastia in which exhaustive attempts to define endocrine, metabolic, or drug-related causes have failed. Attempts to reverse gynecomastia with danazol have been successful, although side effects from the androgenic properties of the drug are significant. Tamoxifen citrate, as therapy for benign breast disorders including gynecomastia, has had encouraging initial results.

DIAGNOSIS

Presentation

A lump in the breast is a common premenopausal and postmenopausal physical finding in the female. Up to one-half of patients presenting with breast complaints have no evidence of breast pathology; 65 percent or more of all breast lumps are discovered by the patient. In patients who commonly perform breast self-examination, more than 85 percent of definable lesions are detected by the patient. The patient also may note breast pain, but this symptom more commonly represents a proliferative benign breast disorder rather than carcinoma. Other presenting symptoms of breast cancer that occur less frequently include enlargement, nipple discharge, changes of the nipple, retraction or alterations of symmetry, ulceration, erythema, axillary mass, and infrequently bone or musculoskeletal discomfort. While many women recognize these symptoms, the delay in seeking medical attention persists.

Examination

The technique for examination of the breast should include inspection and palpation of the entire breast and draining lymph node sites. The clinician, standing in front of the patient, should first inspect the breast with the patient’s arms by her side (Fig. [14-10 A](#)); with her arms straight up in the air (Fig. [14-10 B](#)); and with her hands on her hips with and without pectoral muscle contraction. Symmetry, size, and shape of the breast should be recorded, as well as any evidence of edema (*peau d’orange*), nipple inversion or change, skin retraction, or erythema. With the arms extended forward and the patient in a sitting position, a forward lean accentuates skin retraction.

Palpation

All regions of concern in the breasts that were identified by inspection should be recorded and the entire breast mass should be carefully palpated.

Examination of the patient in the supine position (Fig. [14-10 C](#)) is best performed with the benefit of a pillow supporting the ipsilateral hemithorax. The examiner should gently palpate the breast from the ipsilateral side, making certain to examine all quadrants of the breast from the sternum to the clavicle, laterally to the latissimus dorsi muscle and inferiorly to the upper rectus sheath. The physician should perform the examination with the palmar aspects of the fingers; a grasping or pinching motion should be avoided. The breast may be cupped or molded in the examiner’s hands to check for retraction.

A systematic search for lymphadenopathy is essential if breast cancer is suspected. The position for examination of the axilla is indicated in Fig. [14-10 D](#). The shoulder girdle is stabilized by supporting the upper arm and elbow. Using gentle discrete palpation, all three levels of potential lymphatic enlargement in the axillary sites are assessed; this technique allows bimanual palpation of disease at the level of the pectoralis minor muscle. Careful palpation of subclavicular, supraclavicular, cervical, and parasternal sites is performed. A diagram of the chest and contiguous nodal sites is useful for recording location, size, and characteristics of any palpable disease (Fig. [14-11](#)). Size, consistency, shape, mobility, and fixation of any palpable breast mass or nodal site should be recorded.

Mammography

Mammography has been used in North America since the 1960s. Techniques for mammography have been modified and improved to enhance image quality, and proper use of mammography requires special techniques and film and a radiologist skilled in interpretation. Conventional mammography uses a low-dose film/screen technique that delivers as little as 0.1 cGy per study. By comparison, each chest roentgenogram delivers one-quarter of this radiation volume. There is no proven escalation of breast cancer risk related to low-dose irradiation with screening mammography. The benefits of mammography’s ability to detect a small cancer that is often curable far outweigh any theoretic risk.

Mammography should not be considered a substitute for biopsy; rather, this technique is an adjunctive, complementary study that supplements history and physical examination. The technique is useful for (1) examination of an indeterminate mass that presents as a solitary lesion that may be a neoplasm; (2) examination of an indeterminate mass that cannot be considered a dominant nodule, especially when multiple cysts or other vague masses are present and the indication for biopsy is uncertain; (3) follow-up examination of

breast cancer treated by segmental mastectomy and radiation therapy; (4) follow-up examination of the contralateral breast after segmental or total mastectomy; and (5) evaluation of the large, fatty breast in the symptomatic patient in whom nodules are not palpable (Fig. 14-12).

Additional value of diagnostic mammography lies in the early detection of an occult cancer before it reaches 5 mm. When abnormalities have been detected by the patient or the clinician, mammography can more precisely define the abnormality, detect multicentric disease, and identify the presence of synchronous cancers.

The presence of fine, stippled calcium in the radiogram of an occult or suspicious lesion is suggestive of cancer. Calcification occurs in one-third to one-half of nonpalpable cancers, but fewer than one-half of these calcific foci demonstrate the classical appearance suggestive of malignancy (Fig. 14-13). Fewer than one-half of the dominant mass lesions have spiculated or irregular margins, and approximately one-fifth of cancers are discovered by secondary signs such as architectural distortions, duct dilatation, asymmetry, and fibronodular densities. Microcalcification as a sign of malignancy assumes greater importance in younger women, in whom it may be the sole mammographic feature. The importance of calcification as a sign of breast cancer diminishes with age.

Careful analysis of direct and indirect signs is essential to document that the benign:malignant biopsy ratio is surgically acceptable. The positive predictive value of certain mammographic signs dramatically increases when parenchymal distortion, poorly defined mass lesions, typical malignant-type calcifications, and stellate opacities are evident. It is estimated that a skilled radiologist can detect cancer of the breast with a false-positive rate of approximately 10 percent and a false-negative rate of 6 to 8 percent.

The clinical impetus for screening mammography came from the Health Insurance Plan (HIP) study and the Breast Cancer Detection Demonstration Project (BCDDP). The HIP study demonstrated a reduction of 33 percent in mortality in patients who were screened by mammography; these data have been verified by the BCDDP. The BCDDP confirmed that mammography conducted in an optimal environment provided a true-positive rate that exceeded 90 percent and was significantly greater in accuracy than clinical examination for detection of occult or early tumors. In both studies, 80 percent of the patients with mammographically detected carcinomas had no axillary nodal metastases. These findings contrast significantly with patients whose breast cancer was detected clinically, in whom more than 50 percent have positive axillary nodes. Reports suggest that screening of breast cancers in women under 50 years of age allows earlier diagnosis and treatment of breast cancer. Disease-free, 5-year survival in this younger cohort exceeded 90 percent.

The current guidelines of the American Cancer Society recommend that all women initiate breast self-examination at the age of twenty and that a “baseline” mammographic examination be obtained at about 35 years of age after consultation with a physician. The patient should consult her physician regarding the need for regular mammographic screening between the ages of forty and fifty; annual mammographic examination should be conducted thereafter.

Prospective randomized studies of routine mammographic screening confirm a 40 percent reduction for stage II disease and more advanced cancers in the screened population; a corresponding 30 percent increase in survival was evident in patients found to have cancer. The enlarging population of patients with occult (nonpalpable) cancers detected in annual screening programs often necessitates needle-localization biopsy techniques. Postexcision confirmation of the suspicious mass or calcifications using specimen radiography is essential (Fig. 14-14); otherwise, histologic confirmation of benignity of the lesion cannot be assured. With the increasing availability of stereotactically guided biopsy for cytology and histology, the requirement for open breast biopsy may be reduced.

Xeromammography

This technique is identical with mammography except that the image is recorded on a xerographic plate rather than a conventional transparency. The image produced is positive rather than negative (see Fig. 14-12 B). Edge enhancement and wide recording latitude allow details of the soft tissues of the breast, chest wall, and thinner peripheral portions of the breast to be recorded with one exposure. Current opinion favors film screening techniques for routine breast radiographic examination.

Magnification Mammography

This technique enhances the sharpness of detail and increases diagnostic accuracy for breast cancer. The optimal magnification is 1.5 times life size; margins of breast masses and the degree and specificity of microcalcifications are clearly defined. This technique may significantly reduce the number of patients referred for biopsy.

Ultrasonography

Ultrasonography has no ionizing radiation, it is highly reproducible, and it has high patient acceptability. The importance of ultrasonography lies in the resolution of equivocal mammography, the diagnosis of cystic disease, and the demonstration of solid abnormalities with specific echogenic features. The resolution of ultrasound is inferior to high-resolution mammography, and lesions 1 cm in diameter, unless cystic, will not be detected. In the presence of a normal physical examination and mammogram, ultrasonographically demonstrated abnormalities are, in the majority of cases, not significant.

Ultrasonography is also useful for guiding the aspiration of cysts to provide cytologic specimens. Cysts, on ultrasound examination, are always well circumscribed, with smooth margins, and have an echo-free center irrespective of the sensitivity setting (Fig. 14-15). There are reported to be criteria to distinguish benign from malignant lesions on sonography but these lack specificity. Benign solid masses usually show smooth contours, round or oval shapes, with weak internal echoes and well-defined anterior and posterior margins. Malignant lesions have characteristically jagged, irregular walls; malignant lesions, however, may have smooth margins with acoustic enhancement (Fig. 14-16).

Doppler Flow Studies

Blood flow in malignant breast lesions is enhanced. Doppler flow signals can be used to detect increased flow and may further distinguish benign from malignant lesions. Malignant lesions produce signals of high frequency and amplitude with continuous flow through diastole. Although Doppler flow studies may play a role in distinguishing benign from malignant lesions, this technique is not of adequate sensitivity to dictate treatment.

Thermography

Transmission of detectable heat from the breast is nonspecific, and in malignant lesions results from the hypervascularity that frequently accompanies carcinoma. Three thermographic methods are used: telethermography, contact thermography, and computed tomography. Using special heat scanners it is possible to delineate these “hot” perfusion sites on film. Results are so variable and inaccurate, however, that its use was terminated in the BCDDP. Sensitivity is less than 50 percent and it is not advocated as a routine screening method, because it is unable to detect minimal breast cancer.

Light Scanning of the Breast

This is a noninvasive and relatively inexpensive technique, and therefore it has attracted considerable attention as a diagnostic screening modality. This technique utilizes electromagnetic waves that impinge on a transparent medium; thereafter, the wave is scattered and absorbed. Light attenuation varies considerably, depending on the biologic characteristics and the hemoglobin content of the tissue studied. The most consistent and important sign of breast cancer is light absorption with a decrease in luminescence displayed in a black and white mode. In the normal breast there should be symmetrical absorption of light. The sensitivity of light scanning for detection of breast cancer remains limited, however. With lesions smaller than 1 cm in diameter, sensitivity varies from 19 to 44 percent.

Magnetic Resonance Imaging (MRI)

MRI has great value in detection of vertebral body metastases and musculoskeletal pathology related to breast cancer. However, its value as a potential screening method in breast cancer is questionable. The breast is examined using conventional spin-echo T₁- and T₂-weighted sequences, preferably in the sagittal plane, but coronal and axial images can be obtained. Malignant tissue may be identified on MRI using the same morphologic criteria as mammography. Irregularly marginated spiculated masses, secondary skin changes, and enlarged glandular tissue are signs of malignancy. MRI spectroscopy may have a role in determining the treatment rationale for patients.

Interventional Techniques

Ductography

Ductograms are performed by injecting radiopaque contrast media into one or more of the mammary ducts and performing subsequent mammographic imaging. The primary indication for this technique is discharge from the nipple, particularly when the fluid is serosanguineous or bloody. The duct is gently enlarged with a dilator. A small, blunt cannula is inserted under sterile conditions into the nipple ampulla, and with the patient in a supine position, 0.1 to 0.2 mL of dilute contrast media is injected until the patient reports a sense of fullness. Craniocaudal and mediolateral mammographic views are obtained without compression. Intraductal papillomas can be demonstrated as small filling defects surrounded by contrast media (Fig. 14-17). Cysts may opacify after injection of the contrast when they communicate with ducts. Carcinomas may appear as irregular masses; invasive tumors appear as multiple intraluminal filling defects.

Localization of Nonpalpable Breast Masses

An integral part of the management of breast disease includes localization of nonpalpable (occult) breast lesions. Although surface localization and spot method identification are in use in many institutions, mammographically controlled placement of a hooked wire is a more accurate, state-of-the-art technique. Under local anesthesia, the stylet is accurately placed parallel to the chest wall using acrylic plastic compression plates that contain multiple holes, each of which allows passage of a stylet needle. After needle withdrawal, the lesion is accurately localized on mammogram, and the tiny wire hook is left in position (see Fig. 14-13 D). Thereafter, the surgeon can adequately excise the suspicious lesion, sampling minimal breast tissue. Great advances in localization and diagnosis have been made with the use of stereotactic needle placement with cytologic aspiration. This technique has allowed localization of occult breast cancer successfully in more than 90 percent of patients, and the sensitivity and specificity of the cytologic aspirate for occult breast cancer exceed 95 percent.

In all cases, needle localization of suspicious occult masses and excision of the abnormal tissue must be evaluated by specimen radiography to ensure that mammographically detected abnormalities have been removed (see Fig. 14-14). Before dissection of the specimen, a radiograph of the excised tissue should be obtained using conventional mammographic equipment or, for better resolution, a dedicated specimen radiographic unit. A specimen radiograph further directs the pathologist to the precise location of the abnormality in the tissues to ensure that appropriate sampling is obtained.

Stereotactic core needle biopsy has gained acceptance as a diagnostic alternative to needle localization biopsy in appropriate cases. The advantages of this technique in comparison to needle localization biopsy are lower incidence of complications, avoidance of breast disfigurement, shorter recovery period, and lower cost. In addition, when the mammographically detected lesion is a cancer and the diagnosis is made by stereotactic core needle biopsy, the definitive surgical management can be accomplished with only one visit to the operating room. A recent study showed that in patients who underwent excisions of cancers after establishment of the diagnosis with stereotactic core needle biopsy the surgical margins were negative in all patients, while in patients who had needle location biopsies the surgical margins were positive in 55 percent of cases. Thus reexcision was required in a substantial proportion of patients after needle localization biopsies in the study.

INFLAMMATORY AND INFECTIOUS DISORDERS

Bacterial Infection

Staphylococcus aureus and streptococci are the organisms most frequently recovered from nipple discharge in an active infection of the breast. Abscesses often are related to lactation and typically occur within the first few weeks of breast feeding. Figure [14-18](#) depicts the progression of an inflammatory process that may result in diffuse breast cellulitis with localized subcutaneous, subareolar, interlobular (periductal), retromammary, or unicentric and multicentric abscesses. Streptococcal infections initiate diffuse cellulitis without localization until a more advanced stage. *S. aureus* abscesses tend to be more localized, deeply invasive, and suppurative. The multilocular abscess evident in Fig. [14-18](#) is typically seen in staphylococcal infections. Diffuse cellulitis of streptococcal origin with lymphatic permeation is adequately treated with local wound care, including focal heat compresses and administration of intravenous antibiotics (e.g., penicillin or cephalosporin derivatives).

All superficial or deep abscesses with overgrowth of any bacterial organism present with point tenderness, erythema, and hyperthermia. This presentation necessitates immediate and adequate operative drainage of fluctuant areas to avoid sepsis. Immediate surgical drainage is essential for the advanced breast abscess. Thorough debridement of the abscess via circumareolar or multiple nonradial incisions paralleling Langer's lines is recommended.

Breast infections may be chronic, with recurrent abscess formation. Appropriate cultures must be taken for acid-fast bacteria, fungi, and anaerobic and aerobic bacteria. Uncommon organisms might be encountered, and long-term antibiotic therapy could be indicated. In extreme cases, simple mastectomy may be required to eradicate a severe chronic infection.

Puerperal (Lactational) Mastitis

Hospital-acquired puerperal infections of the breast are much less common with isolated deliveries and standardization of breast and infant hygiene. Nursing women may present with milk stasis, noninfectious inflammation, or infectious mastitis. Epidermic mastitis is initiated by highly variant strains of penicillin-resistant *S. aureus* that are transmitted via the suckling neonate. This variant of mastitis is associated with other neonatal staphylococcal infections and, in the untreated patient, may result in substantial morbidity and, occasionally, death. The patient may have pus expressed from the nipple of a very tender hyperemic breast. The infant must be rapidly weaned from breast feeding.

Nonepidemic (sporadic) puerperal mastitis refers to involvement of the interlobular connective tissue of the breast parenchyma. Such patients present with nipple fissuring and milk stasis, which initiate the secondary invasive retrograde bacterial infection. Emptying of the breast has been shown to shorten duration of symptoms and improve outcome, with a remarkable reduction in recurrence of the infectious mastitis. The addition of antibiotics will result in an excellent outcome for 96 percent of cases treated.

Discontinuance of lactation is essential to enable resolution of the inflammatory process. The use of breast suction pumps helps to empty stagnant milk ducts and central abscess collections. Continuation of lactation after removal of the suckling reflex may necessitate the use of intramuscular injections of stilbestrol or testosterone/estradiol derivatives (e.g., Deladumone).

Superficial and Deep Mycoses

Fungal infestations of breast parenchyma are rare and most commonly include blastomycosis and sporotrichosis. Preoperative diagnosis is rarely established.

Fungal infections are most commonly initiated by intraoral fungi inoculated into the breast parenchyma by the suckling infant. These fungal infections present as recurrent mammary abscesses juxtaposed to the nipple or areola. Pus may be expressed from the sinus tracts near the nipple and discharge may be mixed with blood.

Diagnosis of *mammary blastomycosis* is confirmed by collecting material from the abscess and demonstrating round budding organisms in a potassium hydroxide mount or a McMannus-stained smear. Staining of biopsy smears with periodic acid-Schiff reaction after digestion with diastases commonly identifies the mammary fungi of *sporotrichosis*. Serologic and sensitivity reactions may assist in the diagnosis.

Amphotericin B and stilbamidine derivatives are the most effective antifungal agents for the treatment of blastomycosis. Iodides continue to provide specific chemotherapy for the typical cutaneous variant of sporotrichosis but are ineffectual for systemic fungal disease. Amphotericin B is essential therapy for the disseminated and noncutaneous forms. Antifungal therapy, continued for months, may eliminate the necessity of surgical intervention. Drainage of the abscess, simple mastectomy, or quadrantectomy may be necessary to eradicate the fungal disorder.

Candida

Candida albicans affecting the breast often presents as a relatively innocuous variant of systemic mycoses. Patients demonstrate large quantities of the fungus in scrapings from the lesions or in the purulent discharge from elevated lesions that have scalloped borders with a definable margin of sodden scales. Scrapings contain an abundant quantity of filaments and budding cells. Skin tests and serologic reactions are of little value. Therapy requires removal of the predisposing factors causing maceration. Water-miscible combinations of nystatin or clotrimazole are recommended. Antibacterials and steroids should not be used.

Hidradenitis Suppurativa

Hidradenitis suppurativa of the breast areola or axilla occurs infrequently. This chronic inflammatory state originates within the large sebaceous glands (apocrine glands of Montgomery or the axilla) that are located on the epithelial surface. Patients with chronic acne have a propensity to develop hidradenitis.

When located in and about the nipple-areola complex, this chronic inflammatory state may mimic invasive carcinoma, Paget's disease of the nipple-areola, or other chronic benign inflammatory states. When confined to the nipple, the breast parenchyma is well preserved without demonstrable abscess or other lesions on mammogram. With compression of sinus tracts, scars, or pustules, purulent discharge can be expressed from sebaceous glands. The patient frequently is ill.

Therapy is directed at control of the inflammatory process by elimination of the infection in the apocrine glandular system. Excision may be accomplished under local or general anesthesia. Losses of larger areas of skin may be covered with advancement flaps from the ipsilateral breast or split-thickness skin grafts from noncontiguous sites.

Mondor's Disease

This variant of thrombophlebitis involves the superficial veins of the anterior chest wall and breast. In 1939 the classic description was provided by the French surgeon Henry Mondor. Typically this disorder occurs in an area contiguous with the breast and is detected as a thrombosed vein presenting as a tender, cordlike structure ("string phlebitis"). The cause is unknown. Surgical procedures, infectious processes, and stress-related exercise of the upper extremity, especially repetitive movements, may initiate the syndrome. Superficial veins of the anterior chest wall and abdomen that are commonly involved include the lateral thoracic vein, the thoracoepigastric vein, and, more rarely, the superficial epigastric vein.

This benign self-limited disorder is not indicative of a neoplasm. Typically the patient presents with acute pain in the lateral half of the breast or the anterior chest wall. A tender, firm cord follows the distribution of one of the three major superficial veins of the chest or abdominal wall. Only rarely does bilateral presentation occur, and most patients have no evidence of thrombophlebitis in other anatomic sites.

When the clinical diagnosis is uncertain, or if a contiguous mass is present near the fibrous cord, confirmation must be established by excisional biopsy. Therapy includes liberal use of salicylates and heat compresses along the distribution of symptomatic venous involvement. Restriction of motion of the ipsilateral extremity and shoulder and brassiere support are encouraged. The process usually resolves over 2 to 6 weeks. When symptoms persist or are refractory to therapy, division of the vein above and below the area of involvement or excision of smaller lesions is appropriate.

BENIGN LESIONS

Nonproliferative Lesions

Fibrocystic disease, preferably termed *fibrocystic disorder*, is an ill-defined entity. Patients present with diffuse, often bilateral breast pain. Palpation reveals multiple irregularities. In biopsy examination the specimens are found to contain "fibrocystic elements." Most lesions are not risk factors for development of cancer of the breast. The risk for cancer is increased only when there is associated dysplasia.

Patients presenting with discomfort or pain associated with multiple cystic lesions of the breast defined by palpation or mammography are managed conservatively. Pain is generally accentuated in the second half of the menstrual period and is diminished with the onset of menses. Analgesics usually control the pain, and, in some instances, diuretics are helpful to reduce the extent of fluid accumulation.

A single dominant cyst is usually identifiable by palpation of a smooth, rounded mass. The cystic nature can be substantiated by ultrasonography, but this is generally not required. The cyst should be aspirated, and if the aspirate is clear or cloudy greenish-gray in color, it can be discarded without sending a sample for cytopathologic evaluation. If the fluid is bloody, the cyst should be excised. Recurrent cysts can be treated by recurrent aspiration, and in some patients excision is carried out if the cyst persists after multiple aspirations and is symptomatic.

Cysts

Cysts are considered foremost among all of the benign histologic changes in the breast, as are apocrine lesions that commonly accompany cysts. The size of cysts varies from 1 mm to as great as several centimeters. Most cysts are lined by cells that harbor multiple mitochondria with secretory granules that appear pink by usual eosin staining. Cysts originate as lobular lesions in which the individual acini or terminal ductules dilate or unfold to produce solitary lobules that enlarge as a cystic mass. No consistent relationship between cysts and breast cancer risk has been established. The studies of Dupont and Page demonstrate a slightly higher risk for women with a family history of cysts and breast cancer compared to women with a family history of breast cancer alone. *Apocrine cytoplasmic alterations* assume minimal importance with regard to breast cancer risk. Wellings and Alpers suggested that apocrine changes in breasts are associated with cancer risk. Nonetheless, this is not considered an indicator of cancer risk in a predictive manner. Neither cysts nor apocrine changes are indicators of increased cancer risk in the absence of other established factors. *Epithelial hyperplasia*, which is related to an increased cancer risk, may coexist with cysts, and either change could be present without the other in individual biopsy specimens. It is for this reason that cysts and hyperplastic epithelial lesions should be pathologically distinguished.

Proliferative Lesions

The relationship between extensive *hyperplasia* and associated carcinoma is supported in many prospective studies. Proliferative breast disease is distinguished by epithelial hyperplasia, in which there is an increased number of cells (≥2 cell layers) above the basement membrane. *Atypical ductal hyperplasia* (ADH) lesions must be differentiated from carcinoma in situ. Mild hyperplasia is characterized by three or more cells above the basement membrane in a lobular unit or duct. Such lesions commonly are an “inflammatory” type, with separation of the epithelial cells by inflammatory components. *Moderate* and *florid hyperplasia* are found in more than 20 percent of biopsy specimens. Moderate and florid degrees of hyperplasia are clinically important because these lesions imply a slightly higher risk (1.5 to 2 times) for subsequent invasive carcinoma.

Atypical Hyperplasia

Table 14-2 summarizes the risks for development of invasive breast carcinoma on the basis of histologic findings. Atypical hyperplasia (AH) indicates a specific pattern that has atypia with an increased disposition for development of subsequent breast cancer. The presence of atypical hyperplasia indicates a moderately higher risk (4 to 5 times) above that for apocrine changes, ductal ectasia, or mild epithelial hyperplasia. The presence of atypical *ductal* hyperplasia or *lobular* hyperplasia indicates a higher risk for breast cancer than the base population. These lesions have many features of carcinoma in situ (Fig. 14-19).

Localized Sclerosing Lesions

Sclerosing adenosis mimics invasive carcinoma. It is characterized by lobulocentric changes causing distortion and enlargement of lobular units; increased numbers of acinar structures are accompanied by fibrous changes. The lesions often contain foci of microcalcifications and, when present in an aggregate form, may be detectable mammographically (Table 14-3). Hutter and colleagues consider this lesion to indicate a slightly higher cancer risk (1.5 to 2 times) over that of the base population (see Table 14-2). These lesions carry a risk probability that is similar to that of moderate or florid hyperplastic lesions.

Radial Scar and Complex Sclerosing Lesions

These histopathologic entities are similar to sclerosing adenosis and may mimic carcinoma histologically or clinically. The lesions are not lobulocentric but incorporate various deformed lobular units that possibly originate from the area in which terminal ductules branch from the major duct. The lesions are characterized by a central scar from which elements radiate, with a full array of histologic presentations, including cystic dilatation with units that demonstrate hyperplasia and lobulocentric sclerosis, similar to sclerosing adenosis. The combination of cystic and apocrine changes, as well as hyperplasia, is evident as the lesion matures. Bilaterality and multifocality may be evident. Although radial scars may assume a diverse spectrum of histologic appearances, they are not premalignant.

Ductal Ectasia

This term is reserved for conditions in which the clinical presentation includes palpable lumpiness in the region of the breast beneath the areola. Ducts are involved in a segmental fashion; nipple discharge is a common feature, with periductal scarring and inflammation an attendant finding in later stages of the process. The process is initiated with periductal inflammation and progresses to destruction and dilatation of the ductular system and, eventually, periductal fibrosis and ectasia. These lesions typically occur in perimenopausal or late premenopausal age groups; differentiation from cancer may be difficult. Plaquelike calcifications that occur within the scar wall may be visible mammographically. Localized scarring of the ectatic lesion may cause lumps that are fixed within an inflamed scar of the breast, referred to as “comedo mastitis.” This refers to the grumous, pultaceous material within dilated ducts that may have many of the morphologic features of comedo carcinoma.

Fat Necrosis

Fat necrosis in the breast histologically is no different from its appearance in other organs. Although relatively uncommon, it may clinically and radiographically be confused with scirrhous or even inflammatory carcinoma. Fat necrosis may present after a history of chest wall or breast trauma. The mammographic appearance is quite characteristic and suggests benignity.

Collagenous scarring is the predominant feature in late stages of the disease; granular histiocytes surround “oil cysts” of varying size. These cysts contain free lipid material that results from necrosis of lipocytes. No associated risk for cancer has been established.

Fibroadenoma

This generic term refers to a benign focal tumor that has mixed glandular and mesenchymal elements. Fibrous tissue comprises most of the lesion; the stroma may surround rounded and easily definable ductlike epithelial structures, or epithelium may be skewed into a curvilinear arrangement (Fig. 14-20). The gross appearance is characteristic, with sharp circumscription and smooth boundaries; the cut surface is glistening white. If epithelial elements are excessive, they may appear as light brown areas.

Fibroadenomas typically stop growing when they reach 2 to 3 cm in diameter. Blacks have a greater propensity than whites to develop fibroadenomas and at a younger age. This lesion invariably has a relationship to estrogen sensitivity, and it occurs predominantly in the second and third decades of life. Pain and tenderness may be observed with pregnancy, and an inflammatory response may be accompanied by lymphadenopathy that mimics carcinoma.

Other variants of fibroadenoma are characterized by increased cellularity of the stroma or epithelium. “Adolescent cellular fibroadenoma” typically occurs in adolescence and bears some resemblance to *benign phyllodes tumors*, thus suggesting the term *juvenile adenofibroma*. Five to ten percent of adenofibromas occur around the time of menarche; they frequently have a ductal pattern of epithelial hyperplasia and stromal hypercellularity and are characterized by rapid growth.

Diagnosis of fibroadenomas can be established by fine-needle aspiration (FNA) cytologic techniques. While these tumors may evolve into phyllodes tumors, this is poorly documented. After cytologic documentation by FNA, it is the policy of many clinics simply to observe the characteristic 2- to 3- cm fibroadenoma. Data support this clinical approach for patients younger than 25 years and perhaps as old as 35 years; however, excision is appropriate in older women to exclude carcinoma, which has an increasing incidence above age thirty-five. In most patients, excision is readily accomplished under local anesthesia. Patients with the typical clinical and histologic fibroadenoma are *not* considered at greater risk than the general population for development of subsequent carcinoma. Approximately 100 cases of carcinoma arising in the lesion have been documented. The predominant carcinoma that presents concurrently with the fibroadenoma is *lobular carcinoma in situ*. *Tubular adenoma* is a variant of fibroadenoma that possesses tubular elements arranged in a circumscribed concentric mass with minimal supporting stroma. These lesions have fine nodularity, uniform tubular structures, and the absence of lobular anatomy. The *lactating adenoma* is analogous to tubular adenomas and represents the physiologic response to pregnancy. As a consequence of estriol excess to stimulate growth, these adenomas have a more pronounced anatomic alteration of the lobule than is evident in tubular adenomas.

Phyllodes Tumors

The nomenclature, presentation, and diagnosis of phyllodes tumors historically pose many problems for clinicians. This confusion was predicated on the classic terminology that placed the suffix “sarcoma” on benign and malignant examples of these lesions. Differential diagnostic problems arise with the separation of benign phyllodes tumors from closely related, but distinguishable, fibroadenomas and with recognition of the rare variant that is malignant.

No reliable histopathologic measures exist to differentiate the juvenile fibroadenoma from the benign phyllodes tumor. Typically, the latter harbors a sharp demarcation from the surrounding normal parenchyma, which is considerably compressed and distorted. Connective tissue composes the bulk of the mass, which is firm with mixed gelatinous, edematous, or dense areas. The cystic components owe their origin to sites of infarction, degeneration, and necrosis. These alterations give the breast surface its classic leaflike (phyllodes) appearance. The contour of the breast may assume a “teardrop” configuration with sarcomatous transformation (Fig. 14-21 A).

Histologically, phyllodes tumor may be indistinguishable from the large fibroadenoma. The stroma of the phyllodes tumor has greater cellular activity and cellular content than the fibroadenoma (<3 mitoses/high-power field). The epithelium is deformed into intracanalicular patterns seen in the more common fibroadenoma. Counting mitoses and evaluating margins with attention to identifying infiltrating foci may predict a more aggressive behavior.

Borderline lesions are less likely to assume true malignant potential but have greater potential to recur locally than the usual phyllodes tumor. The overwhelming majority of malignant phyllodes tumors that have metastasized harbor obvious sarcomatous elements (e.g., liposarcoma, rhabdomyosarcoma) rather than fibrosarcoma.

Mammographic foci of calcification and morphologic evidence of necrosis are evident for both malignant and benign phyllodes tumors and are of little value in differentiating the entities. With comprehensive sectioning for study of the lesion to grade the mitotic rate and margins, a more predictable assessment of clinical behavior will be achieved. Local recurrence has been documented in over one-half of the cases. These recurrences are not associated with unrecognized malignant features.

Treatment options are controversial. At the very least, the small phyllodes tumor should be locally excised with an obvious margin (≥1 cm) of normal breast tissue. Often these lesions have been initially enucleated after clinical confusion with a fibroadenoma. When the pathologic diagnosis of a phyllodes tumor with suspicious malignant elements is made (see Fig. 14- 21 B), reexcision of the biopsy scar is indicated to ensure complete local excision. With the larger phyllodes tumors, especially those with malignant elements, total (simple) mastectomy is often required for adequate treatment. Axillary dissection generally is not recommended; rarely, lymph node metastasis occurs.

Papilloma

The solitary papilloma is a mass of variable size that presents in epithelium of the large duct network of the subareolar breast. Peripherally, lesions may be multiple and continuous with hyperplastic alterations that occur within lobular units. These papillary lesions may harbor atypical hyperplasia and ductal carcinoma in situ that is contiguous with the papilloma.

The papilloma presents with a serosanguineous or bloody nipple discharge, typically unilateral. The natural history of solitary lesions suggests a higher propensity for subsequent development of carcinoma. The accompanying epithelial hyperplasia may be responsible for further elevating this risk. Multiple papillomas imply a higher risk for cancer.

The lesions are papillary epithelial outgrowths that occupy dilated ductal spaces. The papilloma may attain several centimeters in size and may appear encysted within the duct from which it arises. Microscopically, there is branching fibrovascular tissue surmounted by epithelium. Dense sclerotic foci may be present. Focal areas of hemorrhage and necrosis are observed. Sites of infarction may cause distortion and compression of epithelium that mimic the appearance of carcinoma on mammogram. When the double cell layer adjacent to the basement membrane is surmounted by excessive cellular columnar cells, the rules used for diagnosis of *atypia* and *in situ carcinoma* apply. If features of ductal carcinoma in situ are evident, the appropriate diagnosis is *noninvasive papillary carcinoma*. Intraductal papilloma is the most common cause of bloody nipple discharge but must be distinguished surgically from adenocarcinoma, which also may present with bloody nipple discharge. The offending duct is identified by radial compression of breast tissue and observation of which lactiferous duct the discharge emerges from. Ductography may identify the involved duct. Under local or general anesthesia, a probe can be placed in the offending duct and the nipple-areola complex partially elevated via a circumareolar incision. The

duct then can be identified by the contained probe and excised for pathologic confirmation of the diagnosis.

Nipple Adenoma

This lesion bears resemblance to the papilloma but presents in the nipple or tissues immediately adjacent to the ductal ampulla of the nipple. Hyperplasia and pseudoinvasion of dense stroma are basic features. *Paget's disease* of the nipple may mimic the lesion. Nipple adenomas have varying patterns of localized hyperplasia with supporting fibrous and cystic changes. Clinically the lesions are recognized when they enlarge to approximately 1 cm. They may demonstrate epithelial hyperplastic components and fibrosis, and confusion with a malignancy is possible.

Ductal Adenoma (Nodular Adenosis)

This lesion may clinically resemble the presentation of a papilloma; differentiation from carcinoma is essential. Histopathologically, adenomas are related to epithelial lesions that have unusual patterns of sclerosis and adenosis. Dense fibrous tissue within epithelial cells appears to be pseudoinvasive and may cause confusion with carcinoma.

CARCINOMA OF THE BREAST

Incidence

Carcinoma of the breast is the most common site-specific cancer in women and is the leading cause of death from cancer for females 40 to 44 years of age. Breast cancer accounts for 32 percent of all female cancers and is responsible for 19 percent of the cancer-related deaths in women. Approximately 180,200 invasive breast cancers were expected to be diagnosed in the United States in 1997; approximately 43,900 women will die because of the tumor. Cancer registries in Connecticut and upper New York State note that the age-adjusted incidence of new cases has been steadily increasing since the mid-1940s. In the 1970s the probability of a woman in the United States developing breast cancer was estimated at 1 in 13; in 1980 it was 1 in 11 and in 1996 the frequency was 1 in 8.

Until the past decade, breast cancer was the leading cause of cancer- related mortality in women. In 1985 the lung surpassed it as the leading site of cancer-related mortality in women (Fig. 14-22). Despite the steady increase in incidence, the overall breast cancer mortality has remained static. This relative decrease in mortality rate reflects the detection of an increasing percentage of early disease. From 1960 to 1963, 5-year survival rates were 63 percent and 46 percent for white and black women, respectively; the figures for the 1981 to 1987 interval were 78 percent and 63 percent, respectively.

Worldwide, breast carcinoma is an epidemiologic problem. England and Wales have the highest national age-adjusted mortality for breast cancer (27.7 per 100,000 population). The United States ranks thirteenth with 22.0 cases per 100,000. For 1986 to 1988, women of South Korea ranked lowest among all nations, with an incidence of 2.6 cancers per 100,000 population. Mormon, Seventh-Day Adventist, Alaskan, American Indian and Eskimo, Mexican-American, and Japanese and Filipino women living in Hawaii have a lower per capita incidence of breast cancer than other Americans; nuns and Jewish women have a higher than average incidence. There is at least a fivefold variation in the incidence of the disease reported among different countries, although this difference appears to be diminishing. Women living in less-industrialized nations tend to have lower rates of breast cancer than those living in industrialized countries, but Japan appears to be an exception.

Etiology

Genetic Factors

Henderson and associates and Lynch and associates (1991) have documented the importance of heredity and the genetic predisposition for breast cancer. Definitions suggested by Lynch and colleagues are as follows:

Sporadic Breast Cancer (SBC): A breast cancer patient with no family history of cancer of the breast through two generations involving siblings, offspring, parents, aunts and uncles, and both sets of grandparents.

Familial Breast Cancer (FBC): A breast cancer patient with a family history including one or more first- or second-degree relatives with breast cancer that does not fit the hereditary breast cancer definition.

Hereditary Breast Cancer (HBC): A breast cancer patient with a positive family history of breast cancer and, sometimes, related cancers (e.g., ovarian, colonic) and with high incidence and a distribution in the pedigree that is consistent with an autosomal dominant, highly penetrant, cancer susceptibility factor. Other factors supporting the HBC classification include frequent early age at premenopausal onset and an increased incidence of bilateral breast cancer and other multiple primary cancers.

Lynch and associates documented the frequency of *sporadic*, *familial*, and *hereditary breast cancer* variants. In an original cohort of 225 consecutive breast cancer patients, updated with 103 new patients, 68 percent of the 328 probands studied were sporadic, 23 percent were familial, and 9 percent were hereditary. The authors state that this may represent a considerable underestimation of the frequency of hereditary breast cancer. With documentation of pedigree, familial breast cancer may constitute as great as one-third of the total incidence of breast cancer cases. Approximately one-fourth of these cancers fall into the special subset of hereditary breast cancer and represent an autosomal dominant susceptibility pattern with early age of onset, with excess bilateral disease, and with other multiple primary cancers.

The risk for developing hereditary breast cancer is determined by pedigree, appears to be independent of age at first pregnancy, and is higher when a biopsy confirms atypical hyperplasia. Lynch considers HBC a site-specific heterogeneous entity in which other presentations may be evident. These variants include *SBLA syndrome* (sarcoma; *breast cancer and brain tumors*; *lung and laryngeal carcinoma and leukemia*; and *adrenal cortical carcinoma*) and *Cowden 's disease* (cancer-associated genodermatosis with multiple trichilemmomas, including cutaneous involvement of the face and multiple areas of the hands, feet, and forearms).

Currently biomarkers do not have the sensitivity or specificity to identify HBC individuals before cancer is expressed. BRCA1, a major breast cancer susceptibility gene, was mapped to a region of the chromosome 17q and identified. Linkage to BRCA1 is present in most breast-ovarian cancer families with hereditary site-specific breast cancer. Another major breast cancer susceptibility gene, BRCA2, was mapped to the q12-13 region of chromosome 13 and isolated. BRCA2 is linked to most families with male hereditary breast cancer. These two breast cancer susceptibility genes together account for most of the inherited breast cancer. However, it is likely that other undiscovered susceptibility genes may also play a role in the development of sporadic breast cancers.

Dietary Influences

The committee on Diet, Nutrition, and Cancer of the National Academy of Sciences concluded that a causal relationship exists between dietary mammalian fat and the incidence of breast cancer. Fried, high-fat foods can increase the risk of developing breast cancer approximately twofold. A study of five ethnic groups in Hawaii demonstrated a strong relationship between breast cancer incidence and consumption of total fat, saturated fat, animal fat, and unsaturated fat. A study conducted by the National Cancer Institute noted that dietary fat intake in breast cancer patients was contributory. Compared to controls, the highest quartile for beef or pork consumption was associated with a relative risk for cancer 2.7 times higher than that of the lowest quartile.

Both the quality and the quantity of dietary fat intake may influence the incidence of this disease. Epidemiologic studies also suggest that Japanese and Greenland Eskimo women have a low incidence of breast cancer despite consumption of large quantities of fat. Their diets include a large volume of omega-3 fatty acids, which are unique to the marine-derived lipids. The number of annual breast cancer deaths among Japanese women doubled over the 20-year interval from 1955 to 1975. During that period the Japanese diet became increasingly similar to that of Western societies. For second- and third-generation American offspring of Japanese immigrants, the incidence approaches that of Caucasian women born in the United States.

Hormone Usage

Kalache and associates demonstrated that combined oral contraceptives have no effect on breast cancer risk when used by women in the middle of their reproductive lives (ages 25 to 39 years). These data pertained even if oral contraceptives were taken for many years. By contrast, Lipnick and colleagues noted an adverse effect of these combined hormones on breast cancer risk when taken for a prolonged period at a very early age or when taken before the first full-term pregnancy. The World Health Organization study suggests that there is neither an increase nor a decrease in the risk of breast cancer with the use of the injectable contraceptive depot- medroxyprogesterone acetate (DMPA).

Vessey reviewed the epidemiologic literature and concluded that estrogen use by perimenopausal and postmenopausal women for hormonal replacement may slightly increase the risk of breast cancer. The risk is said to be accentuated in women with preexisting benign disease of the breast. The possibility exists that some of this excess risk is attributable to more thorough evaluation and diagnosis of breast cancer in women placed on estrogen supplementation therapy. This point of view is supported by a favorable stage distribution in estrogen users. Very little data have been generated on the effects for cancer risk with hormonal replacement therapy using combined estrogens and progestational agents.

Obesity

The majority of data suggest that breast cancer risk is directly correlated with relative weight; the risk for obese women is 1.5 to 2 times higher than for nonobese women. This relative risk is restricted to postmenopausal individuals. The increasing incidence of breast cancer mortality in Japanese women has been paralleled by a proportionate increase in both height and weight in this population.

Breast-Feeding and Menopause

Previously, breast-feeding of long duration (>36 months in a lifetime) was thought to reduce the risk of breast cancer. This observation is no longer considered valid. For women in whom menopause occurs after the age of fifty-five the risk of developing the disease is twice as high as for those whose menopause started before age forty-five. Artificially induced surgical menopause appears to be protective for breast cancer; protection is lifelong, and removal of endogenous estrogen dramatically reduces breast cancer risk. The earlier the surgical menopause, the lower the risk. The risk for breast cancer is one-third as high in women having oophorectomy at age thirty-five or younger as in women whose natural menopause was age fifty or later.

Child Bearing and Fertility

Infertility and nulliparity are associated with a higher probability (30 to 70 percent) for developing breast cancer in comparison with the probability for parous women. With decreasing age at the time of first pregnancy, the risk decreases proportionately. Women impregnated before 18 years of age who have a full-term pregnancy have a breast cancer risk approximately one- third that for women who become pregnant for the first time after 35 years of age. This increase in the relative risk in the latter group is related to persistent exposure to endogenous estrogens in the absence of appropriate concentrations of progesterone. Women who have their first full-term pregnancy after age thirty have an even greater risk for breast cancer than do nulliparas.

Multiple Primary Neoplasms

Harvey and Brinton concluded that women with a history of primary breast cancer have a risk three to four times higher for primary cancer in the contralateral breast. This risk for a second primary cancer in the breast is higher in women with a positive family history of the disease. Other factors that potentially affect the risk of a second primary cancer, including reproductive factors, body build, and prior radiation treatment for cancer, remain undetermined. Women with a history of previous ovarian or endometrial carcinoma have a relative risk of about 1.3 to 1.4 for development of a primary cancer of the breast.

Irradiation

Atomic bomb survivors from Nagasaki and Hiroshima, women treated with high-dose radiation for acute postpartum mastitis, and women who have received multiple chest fluoroscopic examinations for treatment of pulmonary tuberculosis have a higher incidence of breast cancer. Risk from multiple exposures to relatively low doses is similar to the risk of one large dose of similar radiation yield.

It was previously suggested that susceptibility to the carcinogenic potential of irradiation had its greatest magnitude between the ages of ten and twenty, with relative protection following exposure before age ten and after age forty. Data suggest that women exposed to ionizing radiation from infancy to age ten have an increased risk but that this risk is within the expectant ranges for development of breast cancer. Less than 1 percent of breast cancer cases result from diagnostic radiologic procedures. Radiotherapy for breast cancer may increase the risk for cancer of the contralateral breast. Risk of breast cancer is reduced after radiation treatment for cancer of the cervix as a result of reduction of estrogens.

Conclusions

Table 14-4 lists the established risk factors for cancer of the breast in women and the magnitude of these factors. With the exception of age, country of birth, and history of breast cancer in both mother and sister, all of the relative risks reported to date are of modest magnitude. Inconsistent data suggest protective effects from parity and lactation in various age groups and a higher risk associated with alcohol consumption and diethylstilbestrol (DES) exposure during pregnancy. Physical activity has emerged as a factor worthy of study.

Natural History

The natural history of breast cancer has been reported by Bloom and associates on the basis of the records of 250 patients with *untreated* lesions cared for on cancer charity wards in Middlesex Hospital, London, between 1805 and 1933. The median survival of this population was 2.7 years after initial diagnosis (Fig. 14-23). The 5-year and 10-year survival rates for these untreated patients were 18 and 3.6 percent, respectively; only 0.8 percent survived for 15 years or longer. Autopsy data confirmed that 95 percent of these patients died of breast cancer, and the remaining 5 percent died of intercurrent disease. Almost three-quarters of the patients had ulceration of the breast during the course of the disease.

The mean survival in the Middlesex series and for over 1,000 untreated cases obtained from the world literature was 38.7 months (range 30.2 to 39.8 months). It should be noted, however, that for all reports of untreated patients, survival is calculated from onset of first symptom. The longest survivor died in the nineteenth year after the onset of symptoms. Although this suggests that the disease may not always be a rapidly lethal one, 60 percent of patients who develop metastases do so within the first 24 months after mastectomy.

Evidence from the Middlesex data and from thousands of other reports suggests that 5-year survival does not always equate with cure. Metastatic foci may become evident 20 or 30 years after treatment of the index lesion; conclusive results cannot be derived from breast cancer data until at least 5 years have elapsed after institution of a therapeutic regimen. For the breast cancer patient, metastatic cancer is the most common cause of death for years 5 through 10 following mastectomy.

The typical carcinoma of the breast (80 to 85 percent) is a scirrhous adenocarcinoma with productive fibrosis that originates in the ductules and invades the parenchyma. For the majority of lesions, there is a long preclinical (occult) period when the tumor and/or host factors can modulate metastasis. If a tumor doubled in size every 100 days, it would take more than 8 years for a solitary neoplastic cell to grow to a 1-cm detectable clinical mass (10⁹) cells. Laboratory and clinical evidence suggests that growth rates are not consistent, especially within the first 30 doublings.

Metastases presumably may occur within any period of neoplastic growth after the first few doublings. Growth rates of tumors at distant sites have a wide range; this accounts for the observation that primary lesions may be diagnosed many years before the detection of metastases. Increasingly important roles of cytokines and growth factors on metastatic growth have been uncovered.

As the size of the small mass of breast cancer cells increases, numbers of these cells may be shed into cellular spaces and may be transported into the rich lymphatic network of the breast or into venous spaces. At approximately the twentieth doubling, these tiny tumor masses acquire their own blood supply as a network of neovascularization. Thereafter, these cells may be shed directly into the systemic venous blood. Fisher and colleagues suggest that these cells may enter the lymphatics with early crossover into the venous blood via lymphaticovenous communications. In systemic blood, tumor cells are rampantly scavenged by natural killer (NK) lymphocytes and macrophages. Successful implantation of metastatic foci from breast cancer rarely occurs until the index lesion exceeds 0.5 cm in transverse diameter; this size corresponds to the twenty-seventh doubling of the tumor mass.

In Table 14-5 observed survival rates for patients with breast cancer are related to the clinical and histologic stage. The number of lymph nodes that are involved with metastatic disease is inversely proportional to patient survival time. Tumor size is another important prognostic indicator and is directly correlated with the presence of nodal metastases. Occult (micrometastatic) axillary lymph node metastases of 5-year survivors closely parallel those for patients whose nodes are free of disease.

With tumor enlargement and invasion of the surrounding breast parenchyma, the accompanying fibrosis and desmoplastic response entrap and shorten the suspensory ligaments of Cooper to produce characteristic peau d'orange or retraction of the skin. Subdermal emboli of neoplastic cells fill the endolymphatic spaces and ultimately invade the corium. Skin invasion is preceded by localized edema; effective drainage of lymphatic fluid from the skin is disrupted. Should tumor cells in the corium continue to grow, ulceration of epithelium will occur. As new areas of skin are invaded, small satellite nodules are evident near the ulcer crater. Venous capillaries are invaded, and tumor cells seed the circulation passing via lateral, axillary, or medial central intercostal veins to enter the pulmonary circulation or via vertebral veins that course up and down the spinal column (Batson's plexus).

With expansion of the tumor mass after cellular doubling, tumor cells exfoliate and transgress along lymphatic spaces toward the upper-outer quadrants or enter the rich capillary plexus to communicate with parasternal nodes of the systemic circulation. Local, regional, or distant lymphatic implantation and growth are possible. With involvement of any regional lymphatic area, the nodes are at first ill-defined and soft, and then assume a firm, hard, or fixed configuration with increasing expansion of tumor growth. Eventually nodes adhere to each other and form a large conglomerate (fixed) mass. Tumor cells may break through the capsule with fixation of lymphatics to soft tissues or contiguous structures of the axilla or chest wall. Typically, axillary nodes are involved progressively from low (Level I) to central (Level II) to apical (Level III) regions.

Systemic dissemination is critical, because more than 95 percent of patients who die of uncontrolled breast cancer have distant metastases. The most important prognostic correlate for recurrent disease and survival is the nodal status (Fig. 14-24 A). Node-negative patients have a 20 to 25 percent incidence of relapse, compared to 50 to 75 percent for node- positive patients. Node-positive patients have recurrence preferentially in distant organs and tissues. The more common sites of disseminated disease are bone (49 to 60 percent), lung (15 to 20 percent), pleura (10 to 15 percent), soft tissues (7 to 15 percent), and liver (5 to 15 percent). In general, 10 to 30 percent of recurrences are local, 60 to 70 percent are distant, and 10 to 30 percent are both local and distant.

Staging of Breast Cancer

The staging of breast cancer is an attempt to predict potential survival rates from objective data.

Tumor Characteristics and Lymph Node Metastases

Koscielny and associates demonstrated that metastases are positively correlated with tumor size; this correlation does not occur in one-half of the cases until the primary tumor attains a size of 3.6 cm in diameter (Fig. 14-24 B). Nemoto and colleagues and Fisher and colleagues have shown a distinct relationship between the increase in tumor size, the probability of axillary nodal metastasis, and disease-free survival.

The single most significant predictive factor of 10- and 20-year survival is the absolute *number* of lymph nodes involved with metastatic neoplasm. Physical examination is notoriously inaccurate in determining the presence of lymphatic involvement and may have false-positive rates and false- negative rates for detection of axillary metastasis that range from 25 to 31 percent and from 27 to 33 percent, respectively. Henderson and Canellos report that patients with negative axillary lymphatics have 5-year and 10- year survival rates of 78 and 65 percent, respectively; for patients with four or more positive lymphatics, survival rates are 32 and 13 percent, respectively. Fisher and associates observed that the number of positive nodes is correlated with the percentage of 5-year and 10-year treatment failures. The absence of positive nodes was associated with a 20 percent failure rate at 10 years; the presence of more than four positive nodes was associated with a 71 percent treatment failure rate; the presence of more than 13 positive nodes increased the failure rate to 87 percent. Patients with occult micrometastases in lymph nodes initially reported as histologically negative may have survival rates that are not significantly different from those of patients with negative nodes.

The location of the nodes is important; apical axillary (Level III) node metastases carry an ominous prognosis that is distinctly worse than that of Level I involvement. Level I dissection can be predictive of axillary nodal involvement of the residual contents. Fisher and colleagues have determined that dissection of Levels I and II is more than adequate in most cases to predict systemic spread of disease. This report suggests that in order to achieve definition of axillary nodal involvement, sampling of more than ten nodes is necessary.

Clinical trials are investigating the issue of "sentinel node" biopsy as an alternative to formal axillary dissection for staging. A radioisotope or a dye is injected into the region of the tumor, and radioactivity or presence of dye is assessed in the axilla. When a node is identified by this technique, it is removed for biopsy. If this so-called sentinel node shows no tumor, this is regarded as equivalent to a negative axilla.

We do not recommend the sampling of internal mammary nodes in routine dissections. Positive internal mammary nodal metastasis may be expected in central and medial quadrant primary tumors; this frequency increases proportionately with size of the index tumor. Clinical or pathologic evidence of lymph node extension to supraclavicular sites is indicative of advanced (stage IV) disease, considered systemic. Routine scalene or supraclavicular nodal biopsies generally are not indicated.

Evolution of Staging

Three commonly used staging systems have evolved: the Manchester, the Columbia Clinical Classification, and the TNM (tumor, nodes, metastasis) systems. The American Joint Committee on Cancer (AJCC) modified the TNM system for breast cancer (Table 14-6).

A number of physical and radiologic parameters must be reevaluated: (1) comprehensive history and physical examination; (2) bilateral breast imaging (e.g., film screen mammography or xeromammography); (3) clinical pathology laboratory evaluations, including hemogram and hepatic function; (4) chest x-ray (posteroanterior and lateral); and (5) skeletal roentgenologic survey (indicated if symptomatic).

Select examinations include the following:

(1) Abdominal computed tomography (CT) when the following are evident:

(a) Abnormal liver function

(b) Hepatosplenomegaly

(2) Radionuclide bone scans for any of the following lesions:

(a) Advanced local disease (T3, T4)

(b) Lymph node metastasis (N1, N2, N3)

(c) Distant metastases (M1)

(d) Osseous symptoms in the absence of a, b, or c

Bone Scans

Bone scanning remains controversial. These radionuclide tests do not precisely identify metastatic disease. Inflammation associated with degenerative joint disease, osteoarthritis, or overlying soft tissues may provide false-positive results. The presence of a positive scan is indicative of advanced stages. Application of the technique should be applied in a cost-effective manner only for patients with T1, T2, or T1,N1 lesions. Scans are indicated in the presence of positive skeletal roentgenograms, bone pain, or palpable regional or metastatic disease.

CT/MRI

CT and MRI are equivalent methods for diagnosis of visceral metastases. Extracavitary ultrasonography and radionuclide scans for detection of hepatic or pulmonary metastases may complement CT or MRI. CT or MRI scanning is indicated for patients who have suspected distant metastatic disease as evidenced by symptoms, abnormal roentgenograms, abnormal liver function, bone metastases, or supraclavicular adenopathy. These modalities are state-of-the-art techniques for the detection of brain, chest, liver, abdominal, and pelvic metastases.

Future Staging Trends

New technology data allow the detection of hormonal, cytosol protein receptor, and functional characteristics in the cytoplasm of breast tumor cells. Flow cytometry, which evaluates cell surface and nuclear characteristics, has prognostic implications. Cytokine and growth factor analyses and the use of genetic information (e.g., on proto-oncogenes) will have increasing application in the staging process. Physical and cellular measurements of the primary tumor growth rate and percentage of malignant involvement of the breast have been developed. These refinements will potentially be included in future staging systems.

Histopathology

Noninfiltrating (In Situ) Carcinoma of Ductal and Lobular Origin General Considerations

The literature suggests that all cases of invasive breast cancer go through a period in which normal epithelial cells undergo malignant transformation but do not “invade” beyond the investing basement cell membrane. There is reason to question whether in situ carcinoma is truly a malignancy, whether it merits substantial efforts at detection, whether treatment affects the subsequent development of invasive cancer, and what form of therapy, if any, should be applied.

Foote and Stewart published the landmark description of *lobular carcinoma in situ (LCIS)* in 1941, and distinguished this pathologic entity, with its unique biologic behavior, from *ductal carcinoma in situ (DCIS)*. DCIS is the most common histologic variant of the noninvasive stage of carcinoma that originates in the major lactiferous ducts. In the late 1960s Gallagher and Martin published the results of their whole organ section studies and affirmed the transition that established a stepwise evolution of invasive breast cancer from benign epithelium through the in situ and subsequent invasive stages. This recognition allowed them to coin the term *minimal breast cancer* and to stress the importance of early detection of malignancy at a stage when proper therapy would translate into a 10-year cure probability of 90 percent or more. These authors further acknowledged that minimal breast carcinoma included LCIS, DCIS, and minimally invasive cancers smaller than 0.5 cm.

We now recognize that all of these entities have distinct clinical and biologic implications and that each entity deserves distinct therapeutic considerations. Figure 14-25 shows the histopathologic phases of proliferative changes that transform to atypical lobular or ductal hyperplasia and the potential pathway to initiate LCIS or DCIS. Although probably irreversible to normal epithelium, in situ carcinoma stages do not all inevitably transform to invasive disease.

Epidemiology

The increasing frequency of diagnosis of LCIS and DCIS is attributable primarily to mammography. When physical examination was the most common initiator for breast biopsy, in situ lesions constituted only 1.4 percent of all biopsies and only 3 to 6 percent of all breast malignancies. LCIS was more commonly diagnosed than DCIS by ratios of 2:1 or 3:1 in these series. Of 21 clinical series reported by Frykberg and Bland, a total of 9,472 mammographically detected nonpalpable breast lesions demonstrated a sevenfold increase in the incidence of in situ disease among all biopsies (9.6 percent) and a fourteenfold increase in incidence of in situ disease among all breast cancers (45 percent). Mammography has detected a predominance of DCIS over LCIS, averaging a 3:1 ratio in many series.

Lobular Carcinoma In Situ

Lobular elements of the breast from which LCIS originates are not noted in males; this form of noninvasive cancer is observed only in females. The average age at diagnosis is forty-four to forty-seven years, which is 15 years younger than the age at which invasive breast cancer is diagnosed. Over 90 percent of women with LCIS are premenopausal; this is distinctively different from the incidence (30 percent) for women with invasive cancer. This epidemiologic observation emphasizes the importance of estrogen influence on the biologic behavior of LCIS. Ninety percent of the invasive lobular cancers have estrogen receptor activity, compared to only 55 percent in duct carcinoma.

The frequency of LCIS in the base population cannot be reliably determined because it usually presents as an incidental finding. Published series suggest a wide frequency, ranging from 0.8 to 8 percent of all breast biopsies. LCIS has a distinct racial predilection, occurring twelve times more frequently in white women than in black women; black women, however, have a tenfold increase in the recurrence rate after therapy. A review of 1,455 nonpalpable breast malignancies in 18 recent series indicates that LCIS constitutes 2.3 percent of 6,287 biopsies and 9.8 percent of all malignancies.

Ductal Carcinoma In Situ

This histologic variant of in situ carcinoma of the breast is observed predominantly in the female but constitutes approximately 5 percent of all male breast cancers. Most patients present with DCIS in early menopausal years. A DCIS was found in nearly 7 percent of 6,287 breast biopsies and in nearly one-third of 1,455 nonpalpable breast malignancies. The predominance of this lesion among all in situ breast cancers is related to its mammographic definition and its presentation as a clinically palpable mass in over one-half of all cases.

Pathology of In Situ Disease

The original description of in situ carcinoma by Broders stressed the absence of invasion of cells into surrounding stroma and their confinement within the natural ductal or lobular boundaries of the cell membrane. The basement membrane is the crucial anatomic structure that defines the presence or absence of invasion. Diagnosis of an in situ lesion necessitates multiple sections to exclude invasion; frozen section is rarely relied on.

Evidence suggests that LCIS originates from the terminal duct–lobular apparatus. This explains its tendency to present as a nonpalpable mass and its diffuse distribution throughout the breast. The normal lobular anatomy undergoes a disorderly proliferation of epithelial cells to the point of filling and distending the terminal lobular lumina while the overall lobular architecture is maintained. Cells remain uniformly homogeneous, with a normal ratio of nuclear to cytoplasmic area and the absence of necrosis and mitoses. The cells are enlarged without loss of cohesion. Cytoplasmic mucoid globules are a distinctive cytologic feature of LCIS that distinguishes it from DCIS. The disease process frequently is observed in breast biopsy specimens that harbor microcalcifications; however, the process is not generally associated with the calcific sites. The process typically occurs in surrounding tissues that are clinically and radiologically normal. The “neighborhood calcification” is a feature unique to LCIS and contributes to its diagnosis.

The earliest phases of DCIS are characterized by proliferation of the inner cuboidal layer of the epithelial cells in major lactiferous ducts to form papillary ingrowths within the lumen. Cells in DCIS are well differentiated without evidence of significant pleomorphism, mitoses, or atypia. This may lead to difficulty in differentiating DCIS from benign hyperplasia (Fig. 14-26). With growth of the “papillary pattern” of DCIS, ingrowths coalesce to fill the ductal lumen until scattered rounded spaces remain interspersed among solid clumps of cells, which themselves tend to show atypia, hyperchromasia, and loss of polarity. This event was termed by Schultz- Brauns the “cribriform” growth pattern of DCIS. By contrast, a “solid” histologic pattern of DCIS is recognized when cellular growth obliterates these spaces and the ducts become distended with more anaplastic cells and mitotic figures.

With continued growth, these cells outstrip their blood supply, become necrotic, and lead to the classic “comedo” pattern that has been confused with benign inflammatory diseases. In the comedo variant, calcium deposition generally occurs in areas of necrosis, leading to typical DCIS radiographic manifestations. This latter pattern of DCIS has a significantly higher degree of nuclear grade, multicentricity, and microinvasion, suggesting that its biologic behavior is more aggressive than the papillary or solid types. Other indicators of aggressive biologic behavior and poor prognosis associated with comedo DCIS are high DNA proliferative activity, C-erbB-2 oncogene amplification, and overexpression of

HER-2-neu oncogene activity. Aneuploid DNA patterns and chromosome abnormalities that predominate in comedo DCIS also are correlated with a strong invasive potential and poor prognosis. Estrogen receptor activity is found as frequently in this variant as in invasive breast carcinoma. Consideration of these factors assists in determining management of the disease.

LCIS and DCIS may coexist, and their cytologic similarities may lead to diagnostic and therapeutic confusion. Histochemical and ultrastructural studies as well as monoclonal antibody technology have been used to distinguish the two pathologic entities. The term *intraductal carcinoma* is commonly applied to DCIS and denotes the basic pathologic features of ductal elements and their containment within the basement membrane.

Natural History of In Situ Carcinoma

Between 10 and 37 percent of women with LCIS will develop a breast malignancy, which represents a risk ratio six to twelve times higher than that of the base population. The majority of cancers that develop subsequent to LCIS occur more than 15 years after diagnosis, and over one-third occur more than 20 years later. Malignancies that develop later are recognized in either or both breasts, regardless of which breast harbors the focus of LCIS. Invasive cancers are discovered synchronously with LCIS in approximately 5 percent of cases.

A confounding variable is the evidence that 50 to 65 percent of future *invasive* malignancies are not lobular carcinoma but of ductal origin. This raises speculation about the validity of the transition theory. Invasive lobular carcinoma also occurs in this setting, however, at eighteen times the expected rate, and it is presumed that this entity does develop from LCIS. The distinctive pathologic and behavioral characteristics of LCIS are regarded as a “marker” of increased risk rather than an anatomic precursor that develops into an invasive lesion.

Since DCIS has been recognized as a distinct entity for a shorter period than LCIS, less evidence is available for the natural history of DCIS. The risk for invasive cancer from DCIS is considered to be in the range of 30 to 50 percent over 10 years. The risk for a subsequent malignancy is increased elevenfold after the diagnosis of DCIS. The future cancers are observed in the ipsilateral breast, usually in the same quadrant as the original biopsy, suggesting that DCIS is a true precursor of its invasive counterpart. Table 14-7 lists the salient clinical and pathologic characteristics of DCIS and LCIS. The report of the American College of Surgeons indicates a lower survival rate for DCIS than for LCIS, suggesting the need for distinct management of the two entities.

Studies of mastectomy specimens from patients with a diagnosis of DCIS confirm that residual disease in the biopsy site exists in as many as three- quarters of patients. These data suggest that a more complete excision of the primary lesion may reduce the risk of recurrent disease. By contrast, resection of smaller, nonpalpable specimens of DCIS for diagnosis has been observed to eliminate the risk completely.

Data suggest the need to distinguish grossly palpable and microscopically nonpalpable variants of DCIS to plan appropriate therapy more rationally. In comparison to nonpalpable or microscopic presentation, large palpable forms of DCIS have been noted to have occult invasive rates as high as 46 percent, higher rates of local recurrence, multicentricity, axillary nodal metastases, and evidence of poor survival rates. A more cautiously optimistic view of DCIS suggests that an occult microscopic presentation is important, but if it is left unresected, invasive carcinoma may develop.

Bilaterality and Multicentricity of In Situ Cancer

The frequency of synchronous bilaterality depends on the extent to which it is sought, suggesting that the published rates probably underestimate the true incidence. LCIS has a known statistically significant rate of bilaterality that has been reported to be as great as 90 percent. In contrast, DCIS is associated with only a 10 to 15 percent incidence of bilaterality, with an occasional series reporting an incidence as high as 30 percent.

Cancer of the breast originates and develops from multiple foci diffusely scattered throughout the breast. This explains both the heterogeneity of histologic forms found within individual tumors and the presence of other foci of malignancy in breasts that harbor noninvasive cancer. This frequency has been known to range from 10 to 90 percent. These foci of cancer consist largely of the in situ disease identified within the index lesion, and the frequency is not dependent on histology.

Multicentricity refers to occult malignancies found outside the quadrant of the primary (index) tumor, whereas *multifocality* and *residual disease* are appropriate terms for sites within the same quadrant as the index lesion. Studies that adhere to the true definition of multicentricity report that this phenomenon occurs in approximately one-third of patients with DCIS; some series note that LCIS has a much higher rate of true multicentricity that may approach 100 percent. A lower incidence of multicentricity is associated with invasive cancer as compared to in situ disease. This supports the theory that breast malignancies develop from a coalescence of multiple sites of origin. The small number of valid long-term studies of treatment of DCIS and the greater frequency of multicentricity for the lesion suggest caution in recommending conservation therapy that has been designed and implemented for invasive disease.

Infiltrating Malignancies General Considerations

Cancers of the mammary ducts may be classified according to histogenesis (duct, lobule, acini), histologic characteristics (adenocarcinoma, epidermoid carcinoma, sarcoma, etc.), gross characteristics (scirrhous, colloid, medullary), and invasive criteria (infiltrating, in situ). Approximately three- quarters of infiltrating carcinomas of the breast have been included in the imprecise characterization of “infiltrating ductal” or “adenocarcinoma, not otherwise specified” (NOS) category. The term “adenocarcinoma NOS” is preferred to “ductal carcinoma” because the site of origin of most breast adenocarcinomas remains indeterminate. The terminal ductal lobular unit is the most probable site for origin of the majority of breast adenocarcinomas. On the basis solely of morphologic features, no clinically significant differences have been observed between the less differentiated “unspecified” breast carcinomas and mixed variants, unless qualified by the objective assessment of nuclear and architectural degrees of differentiation, i.e., grade.

Current terminology describes histology that is based on the dominant architecture of the lesion, but many patterns may be observed in any one breast cancer. The following classification was originally proposed by Foote and Stewart:

Paget's disease of the nipple	
Carcinoma of duct origin	
Noninfiltrating (in situ, intraductal)	Infiltrating
1	Adenocarcinoma with productive fibrosis (scirrhous, simplex)
1	Medullary
1	Comedo
1	Colloid
1	Papillary
1	Tubular

Carcinoma of mammary lobulesNoninfiltrating (in situ) Infiltrating Relatively rare carcinomas Sarcoma of the breast The rarely encountered histologic patterns include melanoma, adenoid cystic carcinoma, squamous cell carcinoma, sweat gland carcinoma, and carcinoma with mesenchymal metaplasia of chondromatous or osseous types.

Approximately 40 to 50 percent of breast carcinomas are located in the upper outer quadrant, owing to the relatively larger volume of breast tissue in this sector. Almost one-quarter occur in the juxtaareolar area; the remainder are randomly distributed throughout medial and lower outer quadrants of the breast.

Paget's Disease of the Nipple

Described by Sir James Paget in 1874, this lesion presents as a chronic, eczematoid eruption of the nipple. Paget's disease constitutes approximately 2 percent of histologic types, and it is almost always associated with an underlying intraductal or invasive carcinoma. It presents as an encrusted, scaly, hyperemic, and enlarged tumor that occupies the surface of the nipple-areola complex.

Symptoms include tenderness, itching, burning, and intermittent hemorrhage. Intraductal adenocarcinomas often involve the epidermis of the nipple and areola by intraepithelial dissemination. Physical findings in the nipple-areola complex precede the identification of a palpable mass in the subareolar area. One-quarter to one-third of patients have axillary node metastasis at diagnosis. In general, this breast cancer has a better prognosis than the majority of lesions, because the nipple-areola changes promote early consultation, biopsy, and diagnosis.

Microscopically, Paget's disease presents as an intraepithelial tumor composed of single or small groups of clear cells with large vesicular and prominent nuclei. The intraductal lesion often is multifocal; ducts throughout the entire breast may be dilated as a result of obstruction of central collecting ducts at the ampulla of the nipple. Pathognomonic of this disease is the presence of very large, pale, vacuolated cells (Paget's cells) in the rete pegs of the epithelium. The lesion may be confused with superficial melanoma; differentiation between pagetoid intraepithelial malignant melanoma and Paget's disease of the nipple is difficult. The diagnosis is differentiated by demonstration of S-100 protein or melanoma-specific antigen immunoreactivity in malignant melanoma. The application of immunohistochemistry, specifically demonstrating carcinoembryonic antigen (CEA) within the Paget cells, has greatly facilitated diagnosis of the lesion. Melanoma does not contain CEA.

The origin of the Paget cell remains controversial, and two hypotheses are considered: (1) *epidermotrophism* of underlying tumor cells, and (2) *intraepithelial carcinomatous metaplasia*. The presence of typical Paget cells and the associated findings are diagnostic of Paget's disease of the nipple even in the absence of a subareolar mass. The ductal malignancy is most commonly invasive; but Paget's disease may be associated with carcinoma in situ of ductal origin.

Infiltrating Ductal Carcinoma with Productive Fibrosis

The 78 percent frequency of adenocarcinoma of the breast (ductal carcinoma) with productive fibrosis (*scirrhous, simplex, NOS*) is shown in Table 14-8. One-third of these tumors have recognizable elements of a specific histologic type, but the presence of specific tumor types in small volumes does not appear to affect prognosis. The prototypical common adenocarcinoma of the breast presents in a perimenopausal or postmenopausal woman in the sixth decade as a solitary, nontender, firm, ill-defined mass.

The tumor characteristically possesses a poorly defined border that is typically better defined by palpation than inspection. Cut surfaces suggest a central radiating stellate tumor

with a chalky-white or yellow streak extending into surrounding parenchyma. The histologic picture may reveal variable cellular and nuclear grade. A broad spectrum of variants is observed, from in situ to highly anaplastic, suggesting significant heterogeneity (see Fig. 14-26). Other lesions can possess bland homogeneity of cellular differentiation throughout the specimen. Neoplastic cells are arranged in small clusters or stacked in single rows (to produce “Indian filing”) that occupy irregular cleft spaces between collagen bundles (Fig. 14-27).

With profound desmoplastic response of tumor growth, the resultant fibrosis and tumor infiltration can shorten Cooper's ligaments as they course from the deep layer of clavicopectoral fascia to the superficial fascia of the corium. With hyalinization, these ligaments become entrapped within the expanding desmoplastic border of the tumor. With progressive growth, Cooper's ligaments are further shortened to initiate the classic physical finding of skin dimpling directly over the tumor and to initiate advanced local and regional presentations. This physical characteristic is exaggerated when the patient's arms are elevated above her head. This variant of skin dimpling and fixation does not represent a grave sign because it does not indicate direct involvement of the skin by the tumor. With progressive diffuse skin infiltration in the subdermal plexus and the characteristic involvement of Cooper's ligaments, there is extensive edema of the skin, referred to as peau d'orange.

Medullary Carcinoma

This cancer represents 2 to 15 percent of the histopathologic types and originates in large ducts. Grossly, the tumor is characterized by its soft, hemorrhagic bulky presentation. Commonly, the lesion is positioned deep within the breast and is mobile. The skin is often stretched over a bulky, spherical mass that exceeds 3 cm in diameter. There is usually delay in its initial progression, although rapid growth may occur secondary to tumor necrosis or hemorrhage. Bilaterality is reported in fewer than 20 percent of cases; fewer than 10 percent of these neoplasms contain detectable estrogen or progesterone receptors.

Microscopically, medullary carcinoma is characterized by: (1) a dense lymphoreticular infiltrate composed predominantly of lymphocytes and a variable number of plasma cells; (2) large pleomorphic nuclei that are poorly differentiated and accompanied by active cellular mitosis; and (3) a syncytial sheetlike growth pattern with minimal or absence of tubuloacinar differentiation (Fig. 14-28). Approximately one-half of these tumors are associated with intraductal cancer, with the intraductal component characteristically present at the periphery of the tumor mass. In rare circumstances, mesenchymal metaplasia or transformational anaplasia is noted.

Diagnosis of this lesion connotes a better 5-year survival than pure invasive ductal or lobular carcinoma. The most important prognostic determinant of medullary carcinoma is the presence or absence of axillary node metastasis. Because of the intense lymphohistiocytic response in and about the tumor, benign or hyperplastic enlargement of the nodes of the axilla may contribute to erroneous clinical staging. Metastases to axillary lymphatics are reported in more than 40 percent of patients.

Mucinous Carcinoma (Colloid Carcinoma)

This adenocarcinoma of ductal origin constitutes approximately 2 percent of all breast cancers and typically presents as a bulky, mucinous (colloid) tumor that is largely confined to the elderly population. The pathologic features of mucinous carcinoma are quite distinctive: the cut surface is glistening, glaring, and gelatinous. Fibrosis is variable and, when abundant, imparts a firm consistency to the tumor. Approximately one-third of patients have axillary metastases, and 5-year and 10-year survival rates are reported at 73 and 59 percent, respectively.

Characteristic microscopic features that are identifiable include large pools of mucin that surround variable groups of tumor cells. Tumor cells may not be evident in all sections. Signet-ring cells generally are not seen in mucin- producing adenocarcinomas of the breast. Approximately two-thirds of pure mucin-producing breast adenocarcinomas contain detectable estrogen receptors.

The lesion should be distinguished from benign *granular cell myoblastoma*. To confirm the malignant features of colloid carcinoma, multiple microscopic sections are essential. Frozen-section analyses are seldom diagnostic; relying on this technique is inadvisable.

Tubular Carcinoma

This lesion is a well-differentiated variant of breast carcinoma with an incidence of approximately 2 percent. Increasingly diagnosed mammographically, this tumor is reported in as many as one-fifth of women whose cancers are diagnosed by screening. Microscopically, tubular differentiation is distinctive. Under low magnification, a haphazard array of small, randomly arranged tubular elements are identifiable. The small glandular (tubular) pattern and single-cell lining of neoplastic tubules are important histologic characteristics of the tumor. Absence of myoepithelial cells and a well-defined basement membrane serve to distinguish common proliferative, microglandular, and sclerosing adenosis lesions from tubular carcinoma. Most commonly, the lesion is diagnosed in the perimenopausal or early menopausal population. These lesions are typically discovered mammographically when small (i.e., 1 cm maximum dimension).

Approximately 10 percent of patients with typical lesions develop axillary metastasis. Long-term survival approaches 100 percent if the carcinoma contains 90 percent or more of the tubular components. Metastases generally are confined to small numbers in low axillary nodes (Level I). Rosen and associates confirmed lower recurrences (3.5 percent) in patients treated for this disease.

Papillary Carcinoma

Papillary carcinoma accounts for less than 2 percent of all breast carcinomas and generally presents in the seventh decade. The lesion has been observed in a disproportionate number of non-Caucasian patients. Typically papillary cancer is small and rarely attains sizes greater than 2 to 3 cm in diameter. Morphologically, these cancers are well circumscribed; papillary differentiation in the form of papillae with well-defined fibrovascular stalks and multilayered epithelium may harbor moderately pleomorphic cells. McDivitt and colleagues noted that this tumor had the lowest frequency of axillary nodal involvement and the best 5-year and 10-year survival rates. Disease-free survival is similar to that for mucinous and tubular carcinoma. Despite the presence of axillary metastases, which may occur in up to one- third of patients, papillary carcinoma is a more indolent, slowly progressive disease than the common adenocarcinoma.

Adenoid Cystic Carcinoma

This lesion is very rare, accounting for less than 0.1 percent of breast cancers. It is typically indistinguishable from the more common adenoid cystic carcinoma that occurs in salivary glands. The age distribution is similar to that for typical adenocarcinoma. These cancers present as small lesions, 1 to 3 cm in diameter, characteristically well circumscribed with well- defined margins. On close inspection the tumors are found to contain dense mucoid material within glandular spaces that ultrastructurally mimics the lamina densa of the basement membrane. Axillary metastases are rare with adenoid cystic carcinoma. Only seven deaths from pulmonary metastases from this tumor have been confirmed.

Apocrine Carcinoma

These lesions present a ductal or acinar growth pattern with the unusual tendency to involve the lobular epithelium and are well-differentiated with rounded vesicular nuclei and prominent nucleoli. There is a very low mitotic rate and little variance in cytomorphologic features. These lesions can contain potentially aggressive biologic behavior; low to absent levels of estrogen and progesterone receptors are frequent.

Carcinoma of Lobular Origin

The histopathologic features include characteristic small cells with rounded nuclei, inconspicuous nucleoli, and scant, indistinct cytoplasm (Fig. 14-29). Special stains confirm the infrequent presence of intracytoplasmic mucin. Similar to colloid carcinoma, mucin may displace the nucleus, resembling signet-ring carcinoma of the gastrointestinal tract. These carcinomas originate in terminal ductules of the lobule and possess characteristic features that distinguish them from lesions of the larger, lactiferous ducts. The noninvasive variant is referred to as lobular carcinoma in situ (LCIS). In LCIS, lobules are packed with small hyperplastic cells of significant uniformity, arranged in rows or beads with few mitoses. Hyperchromatism, nuclear anaplasia, and other variants of invasive breast cancer are characteristic of the malignancy. The incidence of the in situ variant is approximately 3 percent of breast cancers; infiltrating lobular carcinoma constitutes approximately 10 percent of breast cancers.

Grossly, the infiltrating lobular variant deserves consideration, as these lesions vary from clinically inapparent microscopic tumors to those that replace the entire breast with a poorly defined, somewhat firm mass. Occasionally this cancer mimics inflammatory or benign lesions. Because the lesions have a high propensity for bilaterality, multicentricity, and multifocality, they sometimes present perplexing problems.

Squamous Cell (Epidermoid) Carcinoma

This infrequently observed cancer of epithelial origin arises from metaplasia within the lactiferous duct system. These cancers are typically devoid of distinctive clinical or radiographic characteristics. Similar to epidermoid carcinoma of the skin, metastases occur almost exclusively via the lymphatic route and are evident in approximately one-quarter of patients.

Sarcomas

Sarcomas of breast origin are a heterogeneous group of lesions. These tumors include *fibromatosis (low-grade fibrosarcoma or desmoid tumor)*, *fibrosarcoma*, *malignant fibrous histiocytoma*, *liposarcoma*, *leiomyosarcoma*, *osteogenic sarcoma*, and *chondrosarcoma*. *Stromal sarcoma* is a term that describes the diverse array of tumors of this type that are histologically identical with comparable soft-tissue tumors arising in extramammary sites.

The clinical presentation is typically that of a large, painless breast mass with rapid growth. Routine mammography is not a useful diagnostic aid; false-negative rates are high.

Morphologically, the tumors are predominantly of a solid type, although small cysts in degenerative areas may be observed. The typical sarcoma lacks the “cut cabbage” or leafy laminated surface configuration of the benign cystosarcoma phyllodes. Some sarcomas are well circumscribed, while others have infiltrative, ill-defined margins. Histologically, these lesions assume cellular features identical to those of malignancies of other body parts. These spindle-cell neoplasms grow as expansile, solid masses with microscopic margins that are sharp, pushing, or infiltrative. As a consequence, the lesions invade fat and tend to intervene between glandular aspects of the breast parenchyma to expand the lobules and intralobular spaces. Tumors are graded on the basis of cellularity, degree of cellular pleomorphism and nuclear atypia, evidence of differentiation, and mitotic activity.

Angiosarcoma

In 1948 Stewart and Treves described the syndrome of lymphangiosarcoma in patients with ipsilateral lymphedema following radical mastectomy. Angiosarcoma is the preferred term. It develops in a lymphedematous extremity that locally initiates an impaired immune mechanism. The average interval between the mastectomy and onset of the angiosarcoma is 10.5 years; 60 percent of patients have a history of postoperative radiotherapy to the operative site. Irradiation is considered a cofactor in the development of angiosarcoma only in the respect that it contributes to the development of lymphedema. The overall incidence of lymphedema following radical mastectomy is 15 to 25 percent, compared to 5.5 percent after modified radical mastectomy.

Poorly differentiated variants grow as solid nests and masses of spindle- shaped or epithelioid cells, the former mimicking Kaposi's sarcoma and the latter carcinoma. Exuberant mitotic activity, necrosis, and hemorrhage are evident in high-grade tumors. Less well-differentiated tumors grow as complex papillary proliferations of malignant cells forming anastomotic vascular channels. The typical presentation is a spectrum of differentiation with small capillary-sized vessels formed by atypical endothelial cells.

Ultrastructural features of postmastectomy angiosarcoma are identical with those of other types of angiosarcoma. Factor VIII–related antigen, a protein produced by endothelial cells, has been identified in this tumor and constitutes a reliable marker. This marker is not useful for distinguishing benign and malignant vascular proliferations; however, demonstration of factor VIII in an anaplastic cutaneous neoplasm excludes the diagnosis of carcinoma and melanoma.

The prognosis for patients with angiosarcoma is dismal; median survival is 19 months. No correlation has been observed between histologic features and survival. Radical forequarter amputation of the involved extremity has been proposed to manage the ulcerative complications of the arm and axilla and to palliate the massive progressive lymphedema. Five-year survivals are extremely rare.

Lymphomas

Primary lymphomas of the breast are rare. Presentation is that of a large lesion (mean size 4 cm) in the postmenopausal patient. DeCosse and associates noted a high incidence of tumor-positive axillary nodes. An occult breast lesion may be diagnosed after detection of palpable axillary lymphadenopathy.

Mammary lymphomas are identical to other malignant lymphomas, with tumor cells that are densely infiltrative throughout the breast parenchyma. There is a predominance of diffuse histiocytic lymphomas. Total mastectomy and axillary node sampling are advocated for large lymphomas of the breast. Recurrent or progressive local disease and/or regional disease is best managed by radiotherapy and multimodal systemic chemotherapy using protocols standard for non-Hodgkin's lymphoma. Prognosis is favorable, with 5-year and 10-year survival rates of 74 and 51 percent, respectively.

Inflammatory Carcinoma

The presence of lymphatic or vascular invasion portends a reduction in survival rate and a shorter disease-free interval. In *inflammatory carcinoma*, characteristic clinical features of erythema, peau d'orange, and skin ridging with or without the presence of a palpable mass are evident. This relatively rare entity constitutes approximately 1.5 to 3 percent of breast cancers. No specific histologic type predominates.

Typically the skin over the lesion is warm, diffusely scaly, and indurated with ridging. It may present with the characteristics of a cellulitis. An interval of treatment with antibiotics by the physician who mistakes this for a breast abscess is common. The tumor mass may be diffuse or nondefinable. The breast is diffusely “brawny” and the nipple is often retracted when the index lesion is subareolar. Diagnosis is established by generous biopsy of skin, subcutaneous tissue, and parenchyma.

Pathologically, subdermal lymphatics and vascular channels are permeated with microscopic foci of highly differentiated tumor. As many as 15 percent of patients free of axillary metastases have microscopic tumor emboli in tissues that surround the primary neoplasm. Inflammatory carcinoma refers to a clinicopathologic entity with characteristic absence of polymorphonuclear leukocytes and lymphocytes near the tumor.

This disease progresses rapidly, and more than three-quarters of patients have palpable axillary metastases at the time of presentation. It is important to distinguish inflammatory carcinoma from the contiguous extension of a scirrhou carcinoma that invades subdermal lymphatic spaces and skin to produce characteristic peau d'orange and lymphangitis of locally advanced disease (Fig. 14-30). Patients with inflammatory carcinoma have distant metastatic disease evident at a much higher frequency than that for more common breast cancers. Taylor and Meltzer found bone and visceral metastases in 36 percent of their patients. The extensive report of the Surveillance, Epidemiology, and End Results (SEER) Program by Levine and associates revealed metastatic disease at diagnosis in one-quarter of 3,171 white patients with inflammatory carcinoma.

Treatment

Historical Perspectives

The Edwin Smith Surgical Papyrus (3000–2500 b.c.) was the first document that referred to carcinoma of the breast. The lesion was in a man, but the description encompassed most of the clinical features of breast carcinoma. The author of the papyrus concluded, “there is no treatment [for cancer of the breast].” Few writings referred to tumors of the breast until the first century a.d. Direct reference to treatment of breast cancer is conspicuously absent in the Corpus Hippocraticum.

Celsus recognized the value of operations for early breast cancer in his early Roman writings of the first century a.d. A translation notes: “None of these can be removed but the cacoethes [early lesion], the rest are irritated by every method of cure. The more violent the operations are, the more angry they grow.” In the second century a.d., Galen inscribed one of the classic clinical observations:

We have often seen in the breast a tumor exactly resembling the animal the crab. Just as the crab has legs on both sides of his body, so in this disease the veins extending out from the unnatural growth take the shape of a crab's legs. We have often cured this disease in its early stages, but after it has reached a large size no one has cured it without operation. In all operations we attempt to excise a pathological tumor in a circle in the region where it borders on the healthy tissue.

The Galenic system of medicine ascribed neoplasms to an excess of “black bile” and concluded that excision of a local outbreak could not cure the systemic imbalance. Theories espoused by Galen dominated medicine until the Renaissance. Operative intervention was considered a misdirected, futile, ill-advised approach by the majority of established and respected physicians.

Beginning with Morgagni's systematic approaches, modalities that varied from those espoused by Galen became acceptable. More radical approaches for treatment of the breast became acceptable, including some early and primitive attempts at total mastectomy and axillary dissection. The procedure evolved slowly from simple amputation of the breast. LeDran repudiated Galen's humoral theory in the eighteenth century and stated that cancer of the breast was a local disease that spread by way of the lymphatics to regional nodes. He removed large axillary nodes in his operations on patients with cancer.

In the nineteenth century, Moore, of the Middlesex Hospital of London, emphasized wide removal of the breast and felt that the axillary contents should be removed en bloc, together with the breast, when neoplasm was evident in the axilla. In a presentation before the British Medical Association in 1877, Banks supported Moore's concepts and also advocated en bloc resection of axillary contents with the breast even when palpable nodes were not evident. Banks recognized that occult involvement of axillary nodes could be present.

In 1894 Halsted and Meyer simultaneously reported their operations for treatment of cancer of the breast. By demonstrating superior local and regional control rates after en bloc radical resection, these eminent surgeons established radical mastectomy as “state of the art” for that era. Both Halsted and Meyer advocated complete axillary dissection of all nodal levels from the latissimus dorsi muscle laterally to the thoracic outlet medially. Both routinely resected the long thoracic nerve and the thoracodorsal neurovascular bundle en bloc with the axillary contents.

D. H. Patey of Middlesex Hospital, London, is credited with the demonstration of the worth of the “modified radical mastectomy” technique. In the 1930s Patey was able to refute the unproved postulates on which the original radical operations were based for cases in which advanced local disease was not evident. Thereafter, Patey and colleagues developed the technique for in-continuity removal of the breast and axillary contents with preservation of the pectoralis major muscle. Removal of the pectoralis minor with retraction of the pectoralis major allowed access and clearance of the axillary contents. Madden and Auchincloss advocated the modified radical approach with preservation of both the pectoralis major and minor muscles. This restricts the dissection of the apical (Level III) nodes, and nodal recovery is less than with the Patey modified technique.

Patient Selection

As late as the 1960s, radical mastectomy was the only procedure used for the treatment of breast cancer. Surgeons attempted to exclude from operation patients who would almost certainly develop distant metastasis later. These concepts led to the adoption of the generally accepted principles espoused by Haagensen, which he referred to as “criteria of inoperability.” These general criteria included fixation of the local breast cancer to the chest wall, fixation of the involved lymph nodes of the axilla, and inflammatory carcinoma. This detailed list of criteria included:

- (1) Extensive edema of the skin over the breast (Fig. 14-31)
- (2) Satellite nodules in the skin over the breast
- (3) Carcinoma of the inflammatory type (see Fig. 14-30)
- (4) Parasternal tumor nodules
- (5) Proved supraclavicular metastases
- (6) Edema of the arm
- (7) Distant metastases
- (8) Any two or more of the following grave signs of locally advanced carcinoma:
 - (a) Ulceration of the skin
 - (b) Edema of the skin of limited extent (less than one-third of breast skin involved)

- (c) Solid fixation of tumor to the chest wall
- (d) Axillary lymph nodes measuring 2.5 cm or more in transverse diameter
- (e) Fixation of the axillary nodes to the skin or deep structures of the axilla

At the time these criteria were developed, more than one-quarter of patients were excluded from surgical therapy. Today, more than 10 percent of patients would be found to have such advanced tumors, and the utility of combined modality therapy would perhaps revert the majority to a simple extended procedure. The success of modern adjuvant chemotherapy and radiotherapy has greatly altered the approach to therapy; the majority of patients (80 percent) can at least expect local-regional control despite systemic metastases.

Current Therapy

Both patient and physician should have a clear perspective on the planned course of therapy. The physician should discuss with the patient the possibility that the suspicious lesion may be a cancer that necessitates a therapeutic regimen, including surgical options and the proposed multimodal therapy. The duration of therapy and the issue of irradiation also must be addressed.

Biopsy

The morbidity and mortality related to breast biopsy procedures are acceptably low. Local anesthesia can be used. A 1980 study on the cost- effectiveness of breast cancer management demonstrated that the most effective measure for containing economic morbidity of the illness is via targeted selection of high-risk patients for biopsy under local anesthesia. Although most (60 to 80 percent) biopsies of “suspicious” breast lesions prove to be benign, specific clinical and mammographic characteristics are associated with a high probability of malignancy.

Medical history, physical examination, and results of clinical staging each influence the timing and method of breast biopsy. Properly done, the biopsy is of immense value to determine subsequent work-up and definitive therapy. By contrast, inconclusive data derived from inadequately sampled tissue or a skin biopsy incision placed in the inappropriate skin contour or quadrant may limit therapeutic options and alter subsequent management.

Nonpalpable Lesions

The mammographically detected nonpalpable lesion may present in the “normal” breast without physical signs of an underlying cancer. In recent decades the wide application of screening mammography has resulted in the detection of increasing numbers of nonpalpable lesions. Specific criteria that commonly lead to the diagnosis of the nonpalpable breast mass include: (1) localized soft tissue mass within the breast parenchyma; (2) architectural distortion, including contracture of trabeculae, which produces stellate alterations, and asymmetry with thickening of the lobular or periductal architecture; and (3) clustered microcalcifications.

Despite the simplicity of mammographic techniques using craniocaudal and mediolateral views, intraoperative localization with adequate excision presents challenges that have led to the development of several methods, including noninvasive and invasive localization. *Noninvasive techniques for localization* include visual estimation, external breast markers, stereomammograms, plotted coordinates on a breast diagram, and grid compression devices. *Invasive localization methods* have improved remarkably over the past decade with the use of small radiopaque needles that may be radiographically guided into the suspicious lesion. After insertion of the localization needle, subsequent mammograms will demonstrate orientation of the needle tip to the suspect mass. This technique requires cooperation and communication between the radiologist and the surgeon, and specimen radiography is necessary. Figure [14-32](#) demonstrates the operative technique for needle localization biopsy.

Stereotactic core needle biopsy has become increasingly accepted as an alternative to needle localization biopsy for mammographically detected nonpalpable breast lesions. The advantages of this technique include a lower complication rate, decreased trauma to the patient, avoidance of scarring and disfigurement of the breast, and lower cost. The accuracy of stereotactic core needle biopsy is higher than that of stereotactic fine- needle aspiration and has improved significantly with the use of larger needles and a larger number of cores per sample. The incidence of insufficient sample is negligible. The immediate establishment of a diagnosis of breast cancer enables definitive surgical management of the disease with only one visit to the operating room.

Palpable Lesions

The biopsy technique for a palpable lesion often is influenced by the physical characteristics, the size, and the location of the suspicious lesion, the type of anesthesia desired by the patient, and the therapy planned if a malignancy is confirmed. An *incisional biopsy* of a large breast mass can be performed under local anesthesia if the patient presents with bony metastasis. This technique provides histologic confirmation of the malignancy and adequate tissue for hormonal receptor analysis before initiation of radiation or chemotherapy. *Fine-needle aspiration* of a small, suspicious palpable lesion is appropriate in an outpatient setting for the patient with clinical stage I breast cancer. Regardless of the method, it is essential that the biopsy specimen be handled expeditiously and appropriately to render a valid specimen for histologic and hormone receptor analyses.

Fine-Needle Aspiration (FNA)

This technique usually is performed when a palpable mass is evident. The combination of physical examination, mammography, and FNA provides a diagnostic accuracy that approaches 100 percent. A negative FNA cytology in the presence of a palpable mass, however, does not conclusively exclude carcinoma. When the mass is clinically and mammographically suspicious, the sensitivity (true-positive) of FNA is 80 to 98 percent. The false- negative rate of FNA is 2 to 10 percent. Sensitivity and efficacy are influenced primarily by false-negative results. The specificity and predictive value of FNA approach 100 percent because false-positive results are rare. Fine-needle aspiration of nonpalpable, mammographically detected breast lesions can be performed with stereotactic technique. However, the stereotactic fine-needle aspiration is less accurate and reliable than the stereotactic core needle biopsy, and therefore the latter is preferable for nonpalpable breast lesions.

Cutting Needle Biopsy

The standard Tru-Cut needle (Travenol, Deerfield, IL) is the most commonly used cutting needle for biopsy of breast masses. False-positive diagnostic rates are lower with tissue procured by cutting needles than with FNA specimens because more tissue is submitted for analysis. But a core biopsy specimen without malignant tissue cannot conclusively be considered a “negative” biopsy, as it might reflect a sampling error.

Incisional and Excisional Biopsies

Both techniques procure suspicious breast tissue to be submitted for microscopic examination. The *incisional technique* is indicated for patients with large (4 cm or larger) primary lesions for whom preoperative chemotherapy and/or radiation therapy is desirable. The surgeon should carefully incise tissues that are not necrotic to permit histologic and hormonal receptor analyses. Tissue procured from both incisional and excisional techniques should be obtained with the cold scalpel, because electrocautery may distort histologic features of the tumor and invalidate tissue levels of hormonal receptors.

Excisional biopsy implies removal of the entire lesion and generally a margin of normal breast parenchyma surrounding the suspicious lesion. The surgeon should avoid transection or disruption of the lesion for fear of tumor implantation. When the volume of tissue excised is small (<1 cm³) permanent histologic sections should be planned, as it may be difficult pathologically to differentiate an invasive carcinoma from severe atypia or in situ disease on frozen-section specimens. Both incisional and excisional biopsies can be closed in layers with absorbable sutures.

Planning Incisions

Figure [14-33](#) illustrates nonradial approaches for cosmetically acceptable scars of the breast. Radial incisions in the upper half of the breast are ill- advised because of scar contracture and asymmetric displacement of the nipple-areola and parenchyma. Incisions should be cosmetically designed, since approximately 70 percent of the biopsies confirm benign (proliferative and nonproliferative) disease. Lines of tension in the skin of the breast (Langer’s lines) are generally concentric with the nipple. Incisions that parallel these lines generally result in thin, cosmetically acceptable scars. It is important to keep incisions within the boundaries of potential incisions for future mastectomy or wide-local excision that may be required for definitive treatment (Fig. [14-34](#)). The most cosmetically acceptable scars result from circumareolar (curvilinear) incisions. Centrally located subareolar lesions are best approached in this manner.

Biopsy is best performed with a scalpel rather than electrocautery. Hormonal receptor profiles should be obtained from index tumor tissue. Use of residual tumor from the mastectomy specimen for estrogen and progesterone receptor studies may provide invalid hormone receptors, especially when warm ischemia time is prolonged in the course of the procedure.

After scalpel removal of the lesion, electrocautery of bleeding sites or absorbable suture ligatures are used to achieve hemostasis. Wound drainage with soft rubber Penrose drains (¼-inch) is optional. Although closure of the breast tissue defect is not mandatory, we recommend closure with interrupted 2-0 or 3-0 absorbable chromic gut or polyglycolic sutures. Subcutaneous tissues can be closed with 3-0 or 4-0 absorbable sutures. A running subcuticular suture of the skin using 5-0 synthetic suture is performed, followed by approximation of the defect with adhesive tape strips (Steri-Strips). A light occlusive dressing is applied.

For most palpable and nonpalpable breast masses, local anesthesia and sedation incur minimal morbidity and no mortality. When general anesthesia is required for biopsy of a suspicious breast mass, a full work- up with clinical staging and plans to implement comprehensive therapy should be completed before the procedure to avoid a secondary operation. If needle localization is required, the operating room personnel must arrange, preoperatively, for *specimen radiography* to be performed as soon as the tissue is procured. In the case of a suspicious lesion, an informed consent for the previously agreed treatment should be obtained; if frozen section confirms an invasive neoplasm, this allows the surgeon to proceed with definitive therapy. After biopsy excision of breast tissue, three dimensions of the tumor should be carefully marked with suture or clips and recorded; the surgeon should orient the pathologist to these findings if subsequent margins are questioned on final pathologic review.

Therapeutic Options

The past three decades have witnessed significant progress in multimodality therapy for the treatment of breast cancer and the integration of these modalities to enhance survival and, in appropriate patients, to employ conservation surgical principles. In addition, large breast cancers (>3 cm) with matted axillary metastases usually are treated with preoperative chemotherapy to initiate a cytoreductive effect for the index tumor and the metastases. This approach allows the surgeon to complete a planned mastectomy without the use of skin grafts. After mastectomy, irradiation of the chest wall and the internal mammary and supraclavicular nodes eradicates residual microscopic disease in the skin flap or regional nodes outside the operative field. This multimodal approach enhances local-regional control of the advanced primary tumor and has the additional benefit of treating

potential systemic metastases with the preoperative chemotherapy.

The therapeutic objective of the surgeon and the radiation therapist is local-regional control; the objective of the medical oncologist is control of systemic disease. While cytotoxic agents, especially in combination, are effective for breast cancer metastases, *complete eradication* of documented metastasis is theoretically impossible because of the log-kill cytokinetics of chemotherapeutics. A small fraction of cells that enter the G₀ phase outside the cell cycle and are nonreplicating will potentially develop resistance or become refractory when exposed to these cytotoxic agents. Prospective trials in North America and Europe have allowed the clinician to predict control rates, survival rates, and prevailing toxicities. It is the integration of surgery, radiation therapy, and chemotherapy that has achieved the unprecedented response rates afforded to patients with this disease.

Therapy of Early Breast Cancer and In Situ Disease

Adenocarcinomas of the breast in which the diameter is less than 5 cm, limited to the lateral aspect of the breast, and with involvement of the pectoral fascial or skin fixation (T1a, T2a) often are treated by surgery alone, provided that lymph node metastases are absent in the pathology specimen. Ductal and lobular carcinoma in situ are not invasive lesions and therefore do not have nodal metastases. These too are treatable by surgery alone, and in most clinics axillary node dissections are not performed. By contrast, when lymphatic metastases are evident pathologically and when the adenocarcinoma is medially or centrally positioned in the breast, the combination of surgery and postoperative radiation therapy is often used to ensure local and regional chest wall control.

Lobular Carcinoma In Situ (LCIS)

LCIS is considered a *marker* for increased risk rather than an inevitable *precursor* of invasive disease. The goal of observation is to detect subsequent invasive cancers that develop in a minority of these patients. If subsequent invasive cancers do develop, bilateral mastectomy will have a high probability of cure. There is no demonstrable benefit to widely excising LCIS and obtaining clear margins if nonoperative observation is chosen, because the disease is assumed to diffusely involve all breast tissue as well as the contralateral breast.

A 5 percent rate of associated invasive carcinoma and a high rate of multicentricity and bilaterality are the major arguments that support operative therapy of the disease. Routine bilateral mastectomy for LCIS appears to be an aggressive radical approach for a lesion that has a low risk potential. Routine contralateral biopsy in the absence of standard indications is not justified, because the likelihood of identifying a lesion requiring therapy (i.e., invasive carcinoma or DCIS) is minimal and the clinical significance of other foci of LCIS is negligible. If operation is chosen, anything less than total mastectomy is inappropriate, because the disease process is diffuse and often bilateral. In some instances bilateral mastectomy and reconstruction are applicable. The incidence of axillary node metastasis is generally less than 1 percent; routine dissection is not advisable, but sampling of Level I nodes in conjunction with the mastectomy adds virtually no morbidity to the procedure.

Ductal Carcinoma In Situ (DCIS)

For many decades unilateral mastectomy has been used for this lesion. Mastectomy is still considered the “gold standard” against which lesser procedures must be evaluated. In combined data from 14 series, a total of 1,061 women with DCIS were treated with mastectomy; a local recurrence rate of only 0.75 percent and a mortality of 1.7 percent were demonstrated. Ipsilateral therapy is adequate because the overall incidence of occult disease (10 to 15 percent) is essentially equivalent to that for invasive carcinoma. Breast reconstruction can be performed at the time of the ipsilateral mastectomy (Fig. [14-35](#)).

The excellent results achieved with breast-sparing therapy of invasive disease have led to its use for DCIS. Rosner and colleagues showed that wedge resection of DCIS was equivalent to mastectomy with regard to overall survival. Follow-up intervals of up to 14 years for DCIS treated by local excision alone suggest local recurrence rates that range from 10 to 63 percent. Lagios and associates and Gump and associates note that recurrence is greatest for palpable tumors of large size (>25 mm), when the criteria for confirmation of pathologically clear margins are less rigorously applied, and when the histology is the comedo type. Recurrences are noted most often within the original biopsy site, implicating inadequate marginal clearance rather than intrinsic biologic behavior of DCIS. Combined data from 14 studies of conservative surgery couple with postoperative radiation therapy in 1,098 women with DCIS showed an overall recurrence of 9.1 percent with 45 percent of the recurrent lesions being invasive carcinomas.

Results of prospective randomized trials assessing the value of radiation therapy in the treatment of DCIS are relatively limited. The first published trial containing such results was the report on Protocol 6 of the National Surgical Adjuvant Breast and Bowel Project (NSABP). Although the trial was designed to study the value of radiation therapy in addition to lumpectomy for invasive breast cancer, 51 patients included in the study were later identified as having only DCIS. Of these 51 patients, 22 had lumpectomy alone and 29 had lumpectomy followed by breast irradiation. The recurrence rate in the lumpectomy-alone group was 23 percent, compared to 7 percent in the lumpectomy-plus-radiation group. The short follow-up period of only 39 months combined with the relatively large size of the tumors and some uncertainty regarding the assurance of negative tumor margins, create some doubt about the validity of these results. The results of Protocol 17 of the NSABP, which was designed to compare lumpectomy alone and lumpectomy plus radiation therapy for the treatment of DCIS, suggested an enhanced 5-year event-free survival in the women who had lumpectomy followed by breast irradiation. The 5-year cumulative incidence of ipsilateral breast cancer was reduced by breast irradiation from 10.4 percent to 7.5 percent for noninvasive cancers ($p < .05$) and from 10.5 percent to 2.9 percent for invasive cancers ($p < .001$). The mean duration of follow-up was 43 months. This is a relatively short follow-up period for patients with DCIS, and a longer period of assessment will be necessary before definitive conclusions can be drawn. An additional limitation of this study is the fact that 42 to 45 percent of the tumors were less than 0.1cm, 30 to 31 percent were 0.1–1.0 cm, and only 8 percent were more than 2 cm. Since the majority of the tumors in this study were smaller than 1 cm or microscopic, extrapolating the results of the treatment to larger tumors should be done with caution. Protocol 17 also did not address the histopathology or grade of the DCIS, which are considered predictors of recurrence in other studies. Whether or not the results of breast-sparing treatments are comparable to the excellent results achieved by mastectomy has not been addressed.

An additionally important issue with the use of breast-sparing treatment for DCIS is that over one-half of all recurrences are invasive. Studies suggest that local recurrence after conservation treatment may be successfully treated with “salvage mastectomy,” a technique that does not carry the ominous prognosis documented after recurrence following mastectomy. Other studies suggest that local/regional recurrence in this setting may result in diminished survival. In the absence of conclusive evidence, caution is warranted, as the safety and efficacy of breast-sparing therapy for DCIS are less certain. Until data are available from ongoing prospective trials, it would be prudent to offer mastectomy for lesions that suggest a substantial risk of local/regional recurrence and reduced survival (palpable mass > 25 mm, comedo histology, extensive multicentricity, multifocality, high nuclear grade, negative estrogen and progesterone receptor studies, aneuploid DNA pattern, high proliferative index, etc.). Breast-sparing therapy may be offered to women with DCIS when uncertainties and risks are fully discussed. Mastectomy is recommended when attempts at wide local excision reveal extensive foci of residual DCIS and when margins cannot be cleared pathologically. We continue to recommend postoperative radiotherapy after conservation treatment. No role currently exists for use of cytotoxic chemotherapy in this disease. Axillary nodal dissection beyond Level I generally is not recommended in view of the low yield of positive nodes (<2 percent). Comprehensive lifelong surveillance is indicated for the contralateral breast in women previously treated for DCIS.

Stage I and Stage II Breast Cancer

In the United States in 1972 45.3 percent of patients were reported to have had a Halsted-type radical mastectomy. In 1981 3.4 percent of patients underwent the procedure, and in 1990, only 0.4 percent. Conversely, partial mastectomy was performed in only 3.4 percent of patients in 1972, 7.2 percent in 1981, and 25.4 percent in 1990. These changes in the distribution of patients by the type of operation performed are shown in Table [14-9](#). Although breast conservation surgery has been used with increasing frequency, modified radical mastectomy remains the most commonly used surgical treatment for carcinoma of the breast. The proportion of patients receiving adjuvant radiation therapy has remained around one-fifth or one-sixth over the past three decades, while the proportion of those receiving cytotoxic chemotherapy, tamoxifen, or both climbed steadily, from 17.6 percent in 1976 to 46.6 percent in 1990 (Table [14-10](#)).

Evaluation of Modified Radical Mastectomy

In the 1982 American College of Surgeons Survey, 5-year survival rates by stage, type of treatment, and type of adjuvant therapy were evaluated. Similar survival rates for patients with localized disease were observed for treatment by partial mastectomy alone and by partial mastectomy plus irradiation of the breast, the axilla, or both. The five-year survival rates for patients treated by modified radical mastectomy were equivalent to those of patients treated by the Halsted radical mastectomy. Wilson and associates noted that survival rates were similar for those who received additional radiotherapy or chemotherapy with either of the two procedures.

There has been a transition in curative surgical procedures used by American surgeons from the Halsted radical to the modified radical mastectomy procedure. The transition was apparent at the time of the 1977 survey reported by Nemoto and colleagues, and a 1981 analysis confirmed that the vast majority of patients treated had a modified rather than a radical mastectomy (77 percent versus 3 percent). This change was based on the conclusion that extirpation of the pectoralis major muscle is not essential to provide local/regional control for stage I and stage II disease. Also, either the modified radical mastectomy or the Halsted procedure *alone* is inadequate procedure for achieving local/regional control of TNM stage III and Columbia Clinical Classification C and D tumors.

Subsequent prospective trials for modified radical mastectomy as compared to the radical procedure have included the Manchester Trial, reported by Turner and associates, and the University of Alabama Trial, reported by Maddox and associates. In both studies, recurrence rates for stage I and stage II patients were comparable at 5 years. Disease-free survival was different at 10 years in the analysis by Maddox and colleagues, and trends favored the more radical procedure.

Fisher, Safer, and Fisher confirm that biologic rather than anatomic factors are responsible for metastatic dissemination. They demonstrated that hematogenously carried tumor cells enter the lymph nodes, concluding that hematopoietic and lymphatic systems are unified as routes of tumor cell dissemination. Because total (simple) mastectomy is designed to treat local or regional disease, some authors have proposed that the addition of the regional node dissection should *not* influence survival. These series have made comparisons of total mastectomy with and without radiation.

Five-year survival rates for clinical TNM stage I tumors range from 51 to 78 percent; for clinical TNM stage II cancers the range was 33.7 to 71 percent. Radical radiotherapy administered to the peripheral lymphatics in these nine series appeared to have had little overall benefit at 5 years. At 10 years the absolute survival appeared to be improved for patients who underwent radical irradiation of peripheral lymphatics. Survival rates achieved with total mastectomy (with or without radiotherapy) are comparable to those obtained with radical mastectomy.

In the original report of the Cancer Research Campaign of the United Kingdom, Kyle and associates compared results of a “radical” therapeutic regimen (total mastectomy plus radiotherapy) with those of a conservative policy (total mastectomy alone) in a prospectively controlled study of 2,268 patients. At 5-year follow-up, although there was no evidence that routine postoperative radiation therapy was detrimental to wound repair, this modality was found to confer no additional benefit for survival or distant recurrence. Radiotherapy did, however, significantly reduce the incidence of local/regional recurrence. Further, a fourfold reduction in chest wall recurrence and a threefold reduction in supraclavicular recurrence was evident at 5 years in the treatment group. Similar trends were observed for recurrence in the operative site.

An identical trial was conducted by Berstock and associates with follow-up periods ranging from 9 to 14 years (median 11.4 years). Analysis confirmed no significant difference in survival and distant recurrence between the two treatment groups. Prophylactic postoperative radiotherapy reduced the risk for development of local recurrence.

In the randomized trial conducted by Langlands, Prescott, and Hamilton, simple mastectomy and radiotherapy had an overall survival equivalent to radical mastectomy. At 12-year follow-up they confirmed that survival in the radical mastectomy treatment group was significantly better, but only for those with clinical stage I disease. There was a significant prolongation of survival after detection of recurrence in the radical mastectomy group; this was greatest when local recurrence and distant metastases coincided.

The National Surgical Adjuvant Breast and Bowel Project B-04 trial conducted by Fisher and collaborators compared local and regional treatments of breast cancer. Life table estimates were obtained for 1,665 women enrolled for a mean of 120 months. This NSABP trial randomized patients with *clinically negative* axillae into three groups: (1) Halsted radical mastectomy (RM); (2) total (simple) mastectomy plus local/regional radiotherapy (TM + RT); and (3) total mastectomy alone (TM). Removal of axillary regional nodes was to be completed only when nodes became clinically positive. *Clinically node-positive* patients were treated with RM or TM + RT. Adjunctive chemotherapy was not given to patients in any of the three randomization groups.

For patients treated by total mastectomy and regional radiotherapy versus those treated by total mastectomy alone, no differences were observed between treatment groups for patients with clinically positive nodes or clinically negative nodes with respect to disease-free, distant-disease-free, or overall survival at 10-year follow-up. Ten-year survival was approximately 57 percent for node-negative and 38 percent for node-positive patients. These investigators conclude that *variations of local and regional therapy were not important in determining survival of patients with breast cancer*. Further, results obtained at 5 years accurately predicted outcome at 10 years. Despite similarity in survival, chest wall recurrence was significantly greater at 10-year follow-up for stage I patients treated with mastectomy alone (5.2 percent) than those treated with total mastectomy and radical irradiation (0.9 percent).

Figure 14-36 confirms that there was no significant difference in disease-free survival during the entire period of follow-up among groups of patients with *clinically negative nodes* treated by RM, TM + RT, or TM (panel A of Fig. 14-36). When disease-free survival was evaluated in the first and second 5-year periods of follow-up, Fisher and colleagues observed no differences among groups within the first 5 years after surgery (panel B). Panel C of Fig. 14-36 confirms no statistical differences in the probability of failure among the three groups during the *second* 5 years of follow-up. For each group, approximately 75 percent of patients who were free of disease at the end of 5 years remained so at the end of the tenth year. Patients undergoing TM + RT also had a lower incidence of local and regional recurrence than did those in the other two treatment groups.

Fig. 14-36 further confirms no significant differences in disease-free survival among patients treated with RM or TM + RT for individuals who presented with *clinically positive nodes*. These data were consistent for the first and second 5-year follow-up intervals. In addition, little difference between the two groups was observed in occurrence of distant, local, or regional disease (Fig. 14-37).

Figure 14-38 illustrates the probability of survival for node-negative and node-positive patients. For node-negative patients among the three treatment groups, no significant differences were evident for distant-disease-free or overall survival. These data also were confirmed for the two treatment groups with positive nodes. Approximately 75 percent of patients with negative nodes who were alive at 5-year follow-up remained alive at 10 years, and approximately 65 percent of those with positive nodes who lived 5 years survived another five years.

Figure 14-39 further confirms the relationship of treatment to survival according to tumor *location* in the NSABP B-04 study. For patients with clinically negative nodes in medial-central or laterally located tumors, no differences in outcome were observed among the three treatment groups. Similarly, for patients with clinically positive nodes, treatment was not observed to affect survival in those with lateral or medial-central tumors. Thus, location of breast tumor does not influence prognosis, and irradiation of the internal mammary chain in patients with inner quadrant lesions does not improve survival. This study served to reiterate the important principle that variations of local and regional treatment parameters have less importance in determining survival of the patient with breast cancer than originally presumed.

Mastectomy

Both the Halsted radical mastectomy and the Patey modified radical mastectomy necessitate en bloc resection of the breast, the axillary lymphatics, and overlying skin near the tumor with a 3-cm to 5-cm margin that ensures histologic clearance of the tumor. The Patey mastectomy acknowledges the importance of the complete axillary dissection and the anatomic necessity for preservation of the medial and lateral pectoral (anterior thoracic) nerves, which may provide dual innervation to the pectoralis major muscle. The Halsted mastectomy necessitates resection of the pectoralis major by virtue of size of the lesions (T2, T3, T4) that present with gross infiltration (fixation) of the skin or pectoralis major and for peripheral (high-lying) lesions near the clavicle in patients who are otherwise not candidates for radiotherapy. Major considerations for operations less extensive than the classic Halsted mastectomy are based on tissue preservation to enhance the cosmetic result. The modified radical mastectomy, with removal of the pectoralis minor muscle (Patey dissection), allows access to Level III nodes. The Patey modified technique is intended for lesions that cannot be removed with clear margins by segmental mastectomy and for lesions of large size (>T2, >5 cm) in which cosmetic reconstruction and regional control cannot be accomplished. The modified radical technique is not intended for large tumors with evidence of skin or pectoral muscle fixation, for which resection of the muscle is necessary to achieve adequate margins.

The Madden and Auchincloss mastectomies advocate preservation of both the pectoralis major and minor muscles, thus allowing adequate access to Level II lymphatics with incomplete dissection (or preservation) of apical (Level III) nodes. These approaches (Figs. 14-40, 14-41, 14-42, 14-43) require total mastectomy with at least partial axillary lymph node dissection. With limitation for dissection of the apical (subclavicular) nodal group, the Auchincloss and Madden procedures allow higher probability for preservation of the medial (anterior thoracic) pectoral nerve, which courses in the lateral neurovascular bundle of the axilla and commonly penetrates the pectoralis minor to supply the lateral border of the pectoralis major.

Regardless of the skin incisions chosen, the limits of the modified radical mastectomy are delineated *laterally* by the anterior margin of the latissimus dorsi muscle, *medially* by the midline of the sternum, *superiorly* by the subclavius muscle, and *inferiorly* by the caudal extension of the breast some 2 to 3 cm inferior to the inframammary fold (see Fig. 14-40, *inset*). The surgeon should be cognizant of the thoracodorsal nerve, whose origin is medial to the thoracodorsal artery and vein en route to innervation of the latissimus dorsi. With medial dissection, the surgeon encounters the chest wall deep in the medial axillary space and is able to identify the long thoracic nerve (Bell's respiratory nerve) in the deep investing fascia of the serratus anterior muscle. This nerve is constant in its location anterior to the subscapularis muscle and is closely applied to this fascial compartment. Every effort should be made to preserve the long thoracic nerve; otherwise, permanent disability with a "winged" scapula and shoulder apraxia will follow denervation of the serratus anterior.

After completion of the extirpation of breast tissue from the chest wall, the entire mastectomy specimen and axillary contents are submitted en bloc for pathologic analysis. *Estrogen receptor (ER)* and *progesterone receptor (PR)* activity studies should be obtained on all pathologic breast cancer specimens to aid therapeutic planning of endocrine replacement treatment should metastatic disease occur. The results of these studies will guide future management for neoadjuvant therapy as well. Despite the importance of ER and PR activity to guide future therapies, processing of neoplastic tissue for pathologic examination, in all cases, must take precedence over determination of steroid receptor activity. Procurement of tissues for pathologic diagnosis and determination of qualitative and quantitative steroid receptor activity is best accomplished with the cold scalpel. This technique avoids the possibility with electrocautery of heat-induction artifact, tissue necrosis, cellular death, and temperature-dependent inactivation in steroid receptor activity and in procured tissues.

The responsibility of the surgeon and the radiation therapist is to provide the patient with the greatest probability of control of chest wall disease and to ensure minimal morbidity and mortality related to the therapy. After complete dissection of the axilla for Levels I, II, and III nodes, axillary irradiation should *not* be used, as the incidence of lymphedema to the ipsilateral extremity is six to eight times higher with this combination of modalities. Major lymphatics are removed surgically, and residual lymphatic collaterals may be destroyed by irradiation. In addition, the axilla dissected for operable disease should not require irradiation after radical or modified radical mastectomy unless extracapsular involvement of the lymphatics or tumor implantation in soft tissues of the axilla is evident.

Conservation Surgery

Conservation surgery of the breast implies the resection of minimal volumes of diseased breast tissue to achieve control rates equivalent to those accomplished by mastectomy. It has the goal of preservation of cosmesis and function. These procedures are variously termed *segmental resection*, *lumpectomy*, or *tylectomy*.

The breast may be preserved when adequate removal of all primary breast cancer can be accomplished without incision into cancerous tissue in appropriately selected patients. In all circumstances, frozen-section evaluation and permanent-section analyses of resected margins should be performed to ensure that all breast cancer has been removed en bloc with the specimen. Margins that harbor residual breast cancer warrant further excision. If clearance of tumor margins is not possible, or if multicentric disease is evident, total mastectomy is appropriate.

After reconstruction of the peripheral breast tissues in the operative site, sampling of ipsilateral axillary lymphatics is completed. To determine the necessity for adjuvant chemotherapy, the status of the axillary lymphatics must be determined. Adequate sampling is accomplished via a curvilinear incision between the lateral border of the pectoralis major and latissimus dorsi muscles 4 to 6 cm below the apex of the axilla. Lateral axillary contents that would be removed with an extended simple mastectomy (Level I) are taken with approximately 10 to 15 lymph nodes in the sampling. This volume of lymph nodes assures adequate sampling that is indicative of the regional nodal status. Some clinics demand complete axillary dissection of Level I through Level III. Subsequent irradiation of the axilla should not be performed, in order to avoid lymphedema of the ipsilateral extremity.

Indications for lumpectomy, axillary sampling, and comprehensive irradiation of the ipsilateral breast include: (1) a small breast cancer (<4 cm in transverse diameter); (2) clinically negative axillary lymphatics; (3) breast volume of adequate size to allow a uniform dosage of radiation; and (4) a radiation therapist experienced with the technique. Excessive radiation doses or nonhomogeneous distribution of the radiotherapeutic field may initiate painful, edematous, ulcerative, and/or fibrotic residual breast tissue. As experience with this treatment modality has increased, the indications have been extended successfully to larger-breasted women and to women with small but clinically positive axillary lymph nodes.

It is the surgeon's responsibility to ensure complete removal of the cancer within the breast. If viable cancer cells remain within the breast parenchyma at the periphery of the resection, they will be incorporated into the desmoplastic response of scarring and become poorly oxygenated. Marginally or poorly oxygenated anoxic cells entrapped within scar tissue may not be eradicated by irradiation; recurrence of breast cancer in the scar would be anticipated. Data confirm that clearance of the surgical margins of the index lesion is required to minimize the chances of local recurrence and to enhance cure and control rates. It is the practice of most North American and European clinics to reexcise scar in such patients and complete the axillary sampling procedure. If reexcision with histologically negative margins is not obtainable, these patients are best treated by total mastectomy. Approximately one-half of patients who have had scars reexcised were found to have viable cancer cells present in the wound margins after what was originally deemed an adequate segmental mastectomy. For patients in whom reexcision of the scar has not been advocated, external beam radiation boosted by implantation of iridium (¹⁹²Ir) needles in the area of the scar has been used.

Conservation surgery for patients who meet the above criteria results in long-term disease control and survival data that are equivalent to those achieved in patients treated by

modified radical mastectomy. Protocol B-06 of the National Surgical Adjuvant Breast and Bowel Project compared total mastectomy to lumpectomy with or without radiotherapy in the treatment of stage I or stage II breast cancer. The results of this study after 5 and 8 years of follow-up showed that lumpectomy with or without irradiation of the breast resulted in rates of disease-free, distant-disease-free, and overall survival that were not significantly different from the rates observed after total mastectomy. The results also showed that there was no statistically significant difference in the rates of survival with or without radiotherapy among the women who underwent lumpectomy, although the incidence of ipsilateral breast tumor recurrence was higher in the nonirradiated group. These findings support the use of lumpectomy in the treatment of stage I and stage II breast cancer and also indicate that irradiation of the breast reduces the probability of local recurrence after treatment of breast cancer by lumpectomy.

Reanalysis of this study after 12 years of follow-up was performed after the discovery of falsified information on patients enrolled in the study by one of the participating institutions. Separate audits were performed, and the results were recently reported. Again, no statistically significant differences were found in overall disease-free and distant-disease-free survival after mastectomy and lumpectomy alone or with radiotherapy. However, the cumulative incidence of ipsilateral tumor recurrence was significantly higher in the lumpectomy-alone group (35 percent) as compared to the lumpectomy-plus-radiotherapy group (10 percent, $p < .001$). These findings suggest that lumpectomy followed by breast irradiation is an appropriate treatment for patients with breast cancer 4 cm or less in diameter with negative or positive axillary lymph nodes. These findings are detailed in Table [14-11](#) and Fig. [14-44](#).

The long-term effects of irradiating the breast are not yet known, and patients wishing conservation surgery should be apprised of the uncertainty of the prolonged effects of radiobiologic injury. Properly done, lumpectomy, axillary sampling, and comprehensive irradiation of the remaining breast can provide a very satisfactory functional and cosmetic result. Breast cancer cannot be considered cured, however, by lumpectomy alone. Several studies have shown the disease to be potentially multicentric within the ipsilateral breast, requiring irradiation for sterilization of residual foci of invasive microscopic disease.

If lymphatics removed at the time of axillary sampling confirm histologic metastases, *adjuvant chemotherapy* should be considered in the postoperative period. For approximately 20 to 30 percent of patients, clinically negative axillary lymph nodes will be proved pathologically positive. In many clinics, the concomitant administration of adjuvant therapy (CMF—cyclophosphamide, methotrexate, and 5-fluorouracil) with comprehensive irradiation is being used with minimal toxic systemic effects.

QU.A.R.T. Procedure (Quadrantectomy, Axillary Dissection, and Radiation Therapy)

Quadrantectomy implies that a quadrant of the breast that harbors carcinoma is resected. Resection of an entire quadrant in a small- or medium-sized breast can produce an unacceptable cosmetic result. This procedure has yielded excellent local control and survival results when followed by radiation therapy and axillary dissection. The technique aims to remove an entire quadrant of the breast, including the skin and superficial pectoralis fascia. The objective is radical removal of the primary tumor and potential foci of infiltration via en bloc excision of one-fourth of the entire breast. Veronesi notes that it is difficult to do an appropriate operation for tumors whose diameter exceeds 2 to 3 cm unless the breast is large. The segmental mastectomy, however, has been applied in moderate-size breasts for lesions as great as 4 cm, so long as 1-cm margins are obtained. The QU.A.R.T. procedure provides a more radical resection (≥ 2 cm from the biopsy incision) of the tumor.

Veronesi suggests that the axillary dissection be performed in continuity; excision of a previously made biopsy incision allows adequate exposure of the axilla. The en bloc operation is generally performed when the primary tumor is situated in the upper outer quadrant close to the axilla. For index lesions in other quadrants, quadrantectomy is performed separately from the axillary dissection, which incorporates nodes of Levels I through III (Figs. [14-45](#) and [14-46](#)). Comprehensive irradiation of the intact breast is an important component of therapy. A dose of 50 Gy is delivered through two opposing tangential fields with high-energy photons (cobalt unit or a 6 MeV linear accelerator), and another dose of 10 Gy is given with orthovoltage radiotherapy as a booster to the skin surrounding the scar.

Figure [14-47](#) depicts equivalent disease-free survival curves for the QU.A.R.T. procedure and the classic Halsted radical mastectomy. These data apply to node-negative and node-positive disease confirmed at axillary dissection (Fig. [14-48](#)). An algorithm depicting treatment options for early stage breast cancer is presented in Fig. [14-49](#).

Future Developments

Prospective trials conducted by Veronesi for the QU.A.R.T. procedure and Fisher and colleagues of the NSABP for segmental mastectomy indicate that conservation surgery results in equivalent disease-free and overall survival compared to more radical procedures. Veronesi makes two important conclusions about the value of these procedures: (1) with specific reference to QU.A.R.T., the operation appears to be safe and allows preservation of the majority of breast substance and form; and (2) the patient treated with *inadequate* local-regional surgery or *inadequate* radiotherapy are at greater risk for local-regional recurrences and thus of overall and disease-free survival.

International trends favor a reduction in radical procedures, with increasing selection of breast conservation. An increasing realization has emerged that lumpectomy *without* radiation may be suitable for an undefined proportion of patients with early breast cancer. At 12-year follow-up, the B-06 protocol of the NSABP demonstrated no statistically significant reduction in survival (distant-disease-free or overall) for patients who had local excision *alone* compared to those who underwent local excision with radiation therapy for cancers 4 cm or less in transverse diameter. The trend for management of this disease over the past decade has been toward selective breast-sparing procedures with restriction of radiation therapy (i.e., elimination of irradiation of axillary, supraclavicular, and internal mammary node sites), and more liberal application of systemic adjuvant therapy.

We can expect the subset of patients treated by local excision *without* radiotherapy to increase. These patients will be the beneficiaries of early detection, definition of risk for local recurrence, pathologic analysis, and the emerging application of the adjuvant antiestrogen agent tamoxifen. Expanded therapeutic regimens will invoke the application of sophisticated genetic, biochemical, and pathologic prognostic indicators to verify and predict recurrence following conservative management parameters.

The role of axillary lymphadenectomy in the management of early breast cancer has been questioned in recent years, though it remains a required component of the surgical management of invasive breast cancer. Lymphatic mapping and sentinel lymphadenectomy has been shown in a single-institution trial to provide accurate staging of breast cancer without the morbidity associated with axillary lymphadenectomy. A multi-institution trial for the assessment of this technique is under way.

Limitations

Kurtz and associates and Recht and associates identified patients at risk for failure after breast-preserving techniques. There is ample reason to expect that recurrence after conservation surgery might be reduced to approximately 3 percent for patients who do not have an *extensive intraductal component (EIC)* and who are older than 35 years (Fig. [14-50](#)). Certain morphologic and histochemical features allow the selection of patients in whom breast conservation can be performed with increasing confidence: (1) mammographically detected lesions; (2) decreasing size of the primary invasive cancer; and (3) low S-phase component of DNA flow cytometry.

Despite the importance of breast preservation to enhance cosmesis and allow control and survival rates equivalent to radical procedures, certain women will desire total mastectomy for a variety of economic and psychosocial reasons. Patients less concerned about the cosmetic or functional importance of the breast may view total mastectomy as the most expeditious and desirable therapeutic option, especially with the economic morbidity and inconvenience of radiotherapy. Women who have EIC within and surrounding the index lesion should undergo total mastectomy because of the very high local failure rates in the remaining irradiated breast. This high local recurrence rate for EIC was observed despite extensive lumpectomy and evidence of pathologically negative margins with frozen-section control of the inked specimen.

For large lesions that occupy the central, subareolar portion of the breast, margins sufficient to achieve local control require sacrifice of large volumes of breast tissue, which may yield an unsatisfactory cosmetic deformity. These patients are best treated by total mastectomy and autogenous tissue reconstruction. Patients with two or more primary lesions in the same breast have a higher probability of local recurrence after local excision and irradiation. Patients with synchronous, multiple primary tumors have a higher likelihood of EIC. Very young patients (under 35 years of age) also have a higher incidence of recurrence in the presence of the EIC component after local excision and radiotherapy (see Fig. [14-50](#)).

Advanced Local Disease (Stage IIIA, IIIB, and Inflammatory Carcinoma)

Inflammatory breast carcinoma (see Fig. [14-30](#)) is an ominous clinicopathologic variant, with 5-year survival rates of 3 to 5 percent. Combination chemotherapeutic regimens (e.g., CAF—cyclophosphamide, doxorubicin, and 5-fluorouracil) have effected dramatic regressions of the breast lesion in approximately 60 to 75 percent of these patients. The index lesion and the associated breast changes related to subdermal lymphatic infiltration, as well as any axillary metastases, may disappear. With induction responses following two to six drug cycles of CAF, an extended simple mastectomy (inclusive of Level I nodes) is performed to remove residual malignant disease from the chest wall. Thereafter, peripheral lymphatics, skin flaps, and the central-apical axilla (Levels II and III) are treated with comprehensive radiation therapy. This multimodal approach may result in 5-year survival rates with inflammatory breast cancer that approximate 30 percent.

Polychemotherapy has been valuable in the therapy of stage III disease. In patients with large, matted axillary metastases and grave signs (edema, ulceration, peau d'orange, and skin or pectoralis major muscle fixation), extended simple mastectomy may not be technically possible. Preoperative chemotherapy allows a regression in size of the index lesion and of axillary metastasis. Sites of tumor infiltration and fixation to skin with ulceration also may undergo regression. Subsequently, an extended simple mastectomy might be feasible. Comprehensive irradiation of the chest wall defect and peripheral lymphatics is important to enhance local and regional control. These multimodal approaches may reduce chest wall recurrence to 4 to 10 percent; 5-year and 10-year survival rates are reported as 45 and 28 percent, respectively.

Breast Reconstruction

The use of immediate chest wall reconstruction at the time of mastectomy for invasive carcinoma has increased. In most instances, when radiation therapy or chemotherapy is planned, breast reconstruction can be delayed until these treatments have been completed. Increasingly, chest wall irradiation is being used in patients with implants, although planning and implementation of radiation physics are less precise. Optimally, reconstruction should be deferred until radiation therapy has been completed, because capsular scarring around the breast prosthesis may be stimulated by irradiation and various types of chemotherapy, particularly with doxorubicin. In 1992 the Food and Drug Administration allowed the placement of gel prostheses for reconstruction purposes only in the patient with neoplastic disease. The increasing use of autogenous tissue transfers for reconstruction does not appear deleterious to the radiation therapy.

Immediate breast reconstruction also can be considered in patients having total mastectomies for ductal carcinoma in situ or lobular carcinoma in situ, as well as individuals who, because of high risk, undergo prophylactic mastectomy. The use of autogenous tissues for reconstruction is highly desirable in these clinical settings.

The mastectomy is ideally performed via a transverse or oblique incision (see Fig. [14-34](#)). If the oblique incision is used, off-shoulder gowns may be worn without the medial portion of the scar visible. Laterally, however, the oblique scar should not extend into the apex of the axilla, as scarring may limit mobility of the arm and shoulder.

The major criticism of breast reconstruction has been the potential for delay in diagnosis of recurrent chest wall disease. For stage I breast cancer, chest wall recurrence as the first sign of failure is unusual. When proper local therapy of breast cancer has been completed, local chest wall recurrence rates of stage I and early stage II disease are 0 to 2 percent.

As the breast prosthesis is placed in the subpectoral position, superficial recurrence of the skin and subdermal connective tissues usually is palpable and is not obscured clinically or radiographically by the prosthetic implant.

Adjuvant Therapy

No solid tumor has been as extensively studied to determine the effects of systemic therapy as has carcinoma of the breast. Clinical trials indicate that *adjuvant cytotoxic therapy* and possibly *hormonal therapy*, when used in patients with axillary metastasis but without established distant metastasis, prolong the disease-free interval and may enhance survival rates. For patients with established distant metastasis (stage IV), therapy with several drugs that are less effective as single agents has resulted in response rates upwards of 50 percent when used in combination (polychemotherapy). The most prevalent and most studied polychemotherapy combinations are (1) cyclophosphamide, methotrexate, and 5-fluorouracil (CMF), and (2) cyclophosphamide, doxorubicin, and 5- fluorouracil (CAF). Prednisone and vincristine have sometimes been added to these regimens. Liberal use of vincristine, however, is not justified because of its high neurotoxicity.

Response rates for cytotoxic combinations vary from 20 to 70 percent. Complete responses (patients in whom all evidence of disease resolves) are rare with rates consistently below 20 percent. Complete responses with combination cytotoxic therapy are rare because heterogeneity of the breast cancer cell population often denies response by cells that are in a resting (G₀) phase of the cell cycle. With reentry into the cell cycle, neoplastic cell growth and mitosis are evident. Heterogeneous cell populations have variable response rates to the administered agents. This heterogeneity of cell population may explain why multiple drug combinations, with different sites of cytotoxic action within the cell, have a better overall response rate than is associated with single-agent therapy.

The toxicity noted with cytotoxic agents for breast cancer is similar to that observed with chemotherapy of other malignancies, and includes nausea, vomiting, myelosuppression, alopecia, thrombocytopenia, and exercise intolerance. These toxic events may be reversible with discontinuance of the cytotoxic agents. Doxorubicin initiates a profound and predictable cardiomyopathy with cumulative, dose-limiting side effects. Only 550 mg/m² may be given to a patient because cardiomyopathy, if it occurs, is irreversible.

Hormonal Receptors

Within the cytosol of breast cancer cells are specific proteins that bind and transfer steroid moieties into the cell nucleus to exert specific hormonal effects. The most widely studied and available receptor proteins are the estrogen receptor (ER) and progesterone (PR) receptor proteins. To obtain a quantitative hormonal assay of either hormone receptor, 1 g of fresh tissue obtained from the tumor is essential; the receptors are thermal and ischemia labile. Use of the electrocautery current near the fresh tumor at the time of excision should be avoided, as ER and PR activity will be invalidated. The cold scalpel should be used for obtaining tissue useful for valid analyses.

Specimens must be rapidly frozen (-70°C) for ER and PR assay, because decay in activity is evident within 20 to 30 min after extirpation of the neoplasm. Tissue cytosol is obtained by homogenization and centrifugation of the prepared specimen, which is then incubated with ³H-tritium-labeled estradiol-17 β . Labeled unbound hormone is removed from the incubation mixture, and the bound estrogen sediment is measured by multipoint titration with Scatchard plot analysis. Binding capacity is expressed in femtomoles (fmol) of ³H-estradiol-bound tissue per milligram cytosol protein.

Values of 10 fmol/mg or higher are considered *receptor-positive*; values below 3 to 4 fmol/mg are *receptor-negative*. Intermediate values are considered *borderline*. In all cases the laboratory analysis values should be reviewed to ensure appropriate interpretation.

The degree of positivity is proportional to the differentiation and histologic subtype of the lesion. Ninety percent or more of well-differentiated ductal and lobular carcinomas are ER-positive. Sequential studies of ER activity in the same patient usually reveal no significant difference between lesions of the primary and metastatic sites. There also appears to be no evolution or change of activity in metastatic sites from that of the index lesion.

Clinical response to various forms of endocrine manipulation is evident in patients who have ER activity. Less than 10 percent of ER-negative patients are responders; more than 60 percent of ER-positive patients respond to exogenous estrogens or endocrine ablative measures.

In the past, oophorectomy, adrenalectomy, and/or hypophysectomy were the primary *endocrine ablative procedures* used to treat metastatic foci. *Oophorectomy* was primarily used for premenopausal patients who presented with skin or bony metastasis with a prolonged disease-free interval that exceeded 18 months between treatment of the primary tumor and the discovery of metastases. Visceral metastases (e.g., lung, liver) were infrequently observed to respond to any form of hormonal manipulation. Pharmacologic doses of exogenous estrogens were provided for postmenopausal women who were observed to have an 18-month disease- free interval and metastasis primarily to bone or skin. Response rates for each of these subgroups approximated 30 percent. *Adrenalectomy* and *hypophysectomy* were effective in individuals who had previously responded to either oophorectomy or exogenous estrogen therapy. The response rates of these additional ablative techniques were also seen in one-third of the treated population.

Receptor activity is the most commonly used measure for determining the applicability and selection of additive hormonal or ablative endocrine procedures. There are correlations between tumor differentiation characteristics and reactivity of ER. In one review, only 8 percent of patients with ER-positive tumors were observed to have relapse. Ninety- one percent of patients with ER-positive tumors were free of disease at 24 months, compared to only 62 percent of ER-negative patients.

Other prognostic variables potentially account for differences in recurrence rates according to ER activity. Younger patients were observed to have trends toward positive nodes and greater need for adjuvant chemotherapy and more commonly had ER-negative tumors.

PR activity in the cytosol is also a measure of hormonal responsiveness of the index tumor or metastatic foci of disease. This receptor is measured concomitantly with ER from the primary tumor. Premenopausal patients have a lower incidence of ER-positive activity (30 percent) than postmenopausal patients (60 percent). These data suggest that premenopausal patients have a lower responsiveness to hormonal manipulation. However, response rates of premenopausal and postmenopausal patients are similar, and PR activity may be more indicative of an opportunity for hormonal manipulation in the premenopausal patient. Commonly, the premenopausal patient may have a tumor that is strongly PR-positive, yet may be ER-negative. This profile may indicate a high clinical correlation for response of the malignancy to hormonal manipulative therapy.

Premenopausal patients with undetectable ER have a threefold increase in PR as compared to postmenopausal groups. Since high endogenous estrogens in premenopausal patients may mask ER in tumor biopsies, it appears advantageous to perform PR determinations to identify an additional 15 percent of women with metastatic breast cancer who may benefit from endocrine therapy (Table 14-12). McGuire observed a correlation of the level of ER (fmol/mg cytosol protein) in breast neoplasms with the response rate to endocrine therapy. He observed that synthesis of PR is strictly estrogen-dependent and is the end product of estradiol- stimulated pathways in breast cancer tissues. An 80 percent objective response was observed in patients whose ER was 100 fmol/mg cytosol protein or more. A response rate of 46 percent was observed in women with lower values. This objective response rate to endocrine therapy as a function of content of ER has been confirmed by others. Studies also indicate a trend toward higher quantitative values of ER and PR in tumors that are histologically well differentiated. These correlations have been confirmed as high mean ER and PR values in tissues harboring low-grade (grade 1) neoplasms when both receptors are positive.

Antiestrogen Therapy

The antifertility drug tamoxifen was originally observed to have antiestrogen activity and initiate regression of breast cancer. Approximately one-third of patients initially treated with the drug showed objective regression of metastatic disease. Antitumor activity was closely correlated with the reactivity of ER and/or PR. Antiestrogens block the uptake of estrogen by the target tissue after cytosol binding to the ER. Diminished responsiveness at one dose level may be reversed by escalation of the dose.

The most striking advantage of tamoxifen over chemotherapy is the absence of toxicity and severe side effects. There may be, however, a “flare” of bone pain with induction of hypercalcemia when therapy is initiated; this effect usually is short-lived. In addition, nausea, vomiting, and fluid retention may be induced. An important long-term risk of tamoxifen use is the development of endometrial cancer. Thrombotic events occur rather infrequently, in 1 to 3 percent of treated patients.

The overview analysis of adjuvant systemic therapy trials for early breast cancer by the Early Breast Cancer Trialists' Collaborative Group showed that adjuvant therapy with tamoxifen produced highly significant reductions in the annual rates of recurrence and death (25 percent reduction in annual risk of recurrence and 17 percent reduction in annual mortality). The analysis also noted a reduction in the risk of development of contralateral breast cancer by 39 percent. Tamoxifen therapy usually is discontinued after 5 years.

Adrenalectomy

The initial application of adrenalectomy was in postmenopausal females after ablation of all other sources of estrogen, particularly in individuals who initially responded to exogenous estrogens. After menopause the adrenal glands are the major site for production of endogenous estrogens. Aminoglutethimide blocks enzymatic conversion of cholesterol to g-5- pregnenolone and inhibits the conversion of androstenedione to estrogen in peripheral tissues. After treatment with this agent, adrenal suppression is evident, with a reduction of cortisol secretion and feedback increase in ACTH that may override the aminoglutethimide blockade. Thereafter, glucocorticoid therapy is required for suppression of ACTH secretion by the adrenal cortex. This therapy amounts to a “medical adrenalectomy” and has been compared prospectively with surgical adrenalectomy and hypophysectomy. Medical therapy is equivalent to surgical ablation and represents an alternative. Neither permanent adrenal insufficiency nor acute crises were observed. Side effects included ataxia, dizziness, and lethargy; these effects were dose-dependent and transient.

Applications

Fisher and associates and Bonadonna and associates suggested that disease-free and overall survival may be improved when additive therapy is initiated before clinically detectable distant disease. The goal of therapy is eradication of well-established but as yet unidentified micrometastases. Original recommendations were for adjuvant chemotherapy using multiple combinations in premenopausal women with three or more positive axillary lymph nodes. Data suggest that this approach also may be applicable for women with one to three positive nodes regardless of menopausal status. The addition of the antiestrogen agent tamoxifen to the chemotherapeutic regimen for ER-positive patients appears to provide even greater protection against the development of distant disease.

An improvement in survival of at least 5 to 20 percent over that anticipated for untreated patients with either stage II or stage III disease is being realized in most clinical trials.

The overview analysis of adjuvant systemic therapy trials for early breast cancer by the Early Breast Cancer Trialists' Collaborative Group showed that combination chemotherapy produced a 28 percent reduction in the annual rate of recurrence and a 16 percent reduction in mortality. These reductions in the risk of recurrence and mortality were observed in both node-positive and node-negative patients. The risk reductions produced by chemotherapy were highly significant in patients of all ages, but in younger patients there was a significantly higher efficacy (36 percent annual reduction in risk of recurrent and 24 percent reduction in annual mortality in women younger than 50 years of age compared to 24 percent and 13 percent, respectively, for women older than 50 years of age). Although long-term (12 months) polychemotherapy was not shown to be better than short-term (6 month) treatment by both direct and indirect randomized comparisons, polychemotherapy was found to be significantly better than single-agent chemotherapy. No significant

differences were found between different polychemotherapy regimens or between different tamoxifen doses. However, long-term tamoxifen treatment was shown to be significantly more effective than treatment of shorter duration.

Node-Negative Breast Cancer

Data from the NIH Consensus Conference in 1991 indicate that (1) the majority of patients with node-negative cancers are cured by breast conservation treatment or total mastectomy and axillary dissection; and (2) the prevailing evidence suggests that the rate of local and distant recurrence is decreased by *both* adjuvant combination cytotoxic chemotherapy and adjuvant tamoxifen. Ten randomized trials confirm that adjuvant systemic therapy reduces the observed rate of recurrence by approximately one-third.

At present, prospective randomized trials are too immature and often lack sufficient numbers to estimate with acceptable precision the correlation between menopausal status or steroid reactivity and the effects of adjuvant therapy in these node-negative patients. Few patients with ER- negative tumors have been included in tamoxifen studies. Reduced mortality, however, is seen in nearly all trials, although this has not reached statistical significance in most trials. The rate of death in patients with node- negative disease is low; thus, a clinically important reduction in mortality will require prolonged follow-up with large numbers of patients to achieve statistical significance.

The major benefits of chemotherapy are seen when the antimetabolites (5- fluorouracil and methotrexate) are administered intravenously, rather than given orally. Trials with tamoxifen suggest that the use of this drug for more than 2 years (usually 5 years) results in greater reduction in the risk of recurrence.

In all prospective-study patients who are node negative, tamoxifen reduces the clinical incidence of contralateral primary breast cancer. Overall benefits from tamoxifen in postmenopausal patients clearly outweigh the toxic side effects encountered. For premenopausal patients, the administration of tamoxifen may initiate endocrine abnormalities that have not been defined by long-term analysis (e.g., endometrial carcinoma, effect on the developing fetus). There are no data on the effects of combination cytotoxic agents with tamoxifen for treatment of node-negative breast cancer patients.

The NIH Consensus Conference recommended that patients who are not candidates for prospective trials or who are noncompliant for participation in these trials should be made aware of the benefits and risks of adjuvant systemic therapy. Adjuvant therapy should consist of either combination chemotherapy in these patients or tamoxifen (20 mg/day for at least 2 years). Comprehensive prospective studies have not directly compared tamoxifen and chemotherapy (with or without tamoxifen) in the node- negative subset.

Prognostic Factors

The majority of node-negative patients should be cured after local-regional therapy. Factors considered important to the risk for recurrence include tumor size, ER and PR status, tumor grade, histologic type, proliferative rate (thymidine labeling indices, S-phase fraction), and other incompletely defined risk parameters (protease, cathepsin, HER-2/neu, EGF receptors, stress-response proteins). Despite the proliferation of definable risk factors and biologic markers, tumor size and the axillary nodal status remain the most important of these risk variables (Table [14-13](#)).

The incorporation of such prognostic parameters into equations that mathematically estimate risk proportion are gaining attention and may have theoretical and clinical investigational value. With the exception of clinical trials, it is not reasonable to treat patients with tumors 1 cm or less in diameter, because the chance of recurrence in 10 years is less than 10 percent. With increasing tumor diameter with or without positive nodes, other prognostic variables must be considered in deciding whether to use adjuvant therapy.

Systemic Therapy Trials for Early Breast Cancer

Surgery for early breast cancer allows all clinically apparent (macroscopic) disease to be removed. Various forms of systemic “adjuvant” therapy should be considered postoperatively, namely, antiestrogen therapy (tamoxifen) and those that involve a cytotoxic agent, or a combination of the two drugs. Analysis of collected data by the Early Breast Cancer Trialists' Collaborative Group confirmed significant reductions in annual rates of recurrence and of death with tamoxifen-treated patients, in patients who had ovarian ablation before the age of fifty, and in patients treated with chemotherapy, but no improvement in survival or reduction in recurrence rates for patients treated by immunotherapy.

Tamoxifen also was shown to reduce the risk for developing contralateral breast cancer by 39 percent. The salient benefits of reduction in *recurrence* by both polychemotherapy and tamoxifen were seen chiefly during years 0 to 4 postoperatively; the reduction of *mortality* was highly significant both during and after years 0 to 4 in these relatively brief treatments. The Cancer Trial Collaborative Group provided little information beyond year 10, except for ovarian ablation, which produced significant mortality reductions during and after years 0 to 9 postoperatively. These collaborators verified that long-term (12 months) polychemotherapy was no better than shorter (6 months) regimens. Polychemotherapy provided reduction of recurrences and overall survival that was superior to single-agent chemotherapy. There was no significant difference between various forms of polychemotherapy or different tamoxifen doses, but long-term tamoxifen (e.g., 2 years, or even 5 years) was significantly more effective than short-term regimens.

Tamoxifen was effective in older patients (over 70 years of age); chemotherapy has not been properly evaluated in this geriatric group. In patients aged 50 to 69 years direct comparisons confirm that chemotherapy *plus* tamoxifen is superior to chemotherapy alone or tamoxifen alone, for both recurrence and survival. In younger women (under 50 years), chemotherapy and ovarian ablation have comparable effects. Trends suggest that the combination of chemotherapy and ovarian ablation might be superior to either alone.

A 30 to 40 percent proportional reduction in risk was achieved with combination chemoendocrine therapy for middle-aged patients. This risk reduction was evident for node-positive and for node-negative patients. The improvement in absolute 10-year survival was *twice* as great for the node-positive patients as for the node-negative groups (see Table [14-13](#)). An algorithm of treatment options for adjuvant systemic therapy is shown in Fig. [14-51](#).

Metastatic Disease

Polychemotherapy was designed for therapy of metastasis to bone, liver, soft tissue, lung, and occasionally brain. The combinations of cytotoxic agents most commonly used were 5-fluorouracil, cyclophosphamide, methotrexate, vincristine, and doxorubicin. Randomized trials comparing cytotoxic agents indicated an increase in response rates from approximately 25 percent with single agents to 50 to 60 percent with combination therapy. Further, median survival for combination therapy in those individuals who do not respond is longer than that obtained with single-agent therapy. While relationships between responsiveness to chemotherapy and the ER-PR status have been controversial, more recent studies confirm that hormonal receptor data properly guide anticipated response rates. The heterogeneity of the cellular population within the breast cancer primary and metastatic sites probably determines the therapeutic response cytokinetics and cell kill relative to the cell cycle. No reproducible parameters to evaluate heterogeneity of the cell population are as yet available. The majority of trials identify significant prolongation of chemotherapy-induced responses for patients who previously were responders to hormone therapy and who have ER-positive tumors.

Age, menstrual status, family history, number of positive nodes, tumor size, and type of surgery have been poor predictors of response to chemotherapy. A prolonged disease-free interval usually does not indicate a response advantage. The median duration of response to combination chemotherapy ranges from 12 to 18 months. Once failure has occurred, the use of an additional combination of agents may initiate a remission (partial or complete). Stage IV patients who ultimately achieve complete remissions have a median survival of 32 months.

Patients who experience relapses from combination therapy remain eligible for hormonal manipulation, particularly if their tumors are hormone- receptor positive and they have not previously been treated by hormonal manipulation. Patients who have rapidly progressive disease and a short disease-free interval should be treated initially with combination cytotoxic agents before therapy with hormonal manipulation. As tamoxifen has shown therapeutic advantage when combined with chemotherapy in the age group 50 to 69 years, it may prolong survival in advanced disease as well.

A relationship exists between *response* to chemotherapy and *dose* of the cytotoxic agent used, but there is dose-limiting toxicity. For most chemotherapeutic agents this toxicity factor is myelosuppression. Recent trials using transplantation of normal autologous bone marrow cells have allowed dose-intensive chemotherapy regimens to overcome this limitation.

In the case of advanced local disease (stage III), the cytotoxic dose may be escalated as great as tenfold, depending on the toxicities encountered. Anteman and Gale reviewed 27 trials of high-dose therapy in which 172 patients received single-agent or multiagent therapy, radiation, or both. Many had been treated extensively with multiple agents before receiving high-dose intensive therapy after marrow transplantation. The multiple alkylating agents offer the best response rate (76 percent). Although response rates are high, duration of response may be short and is often less than 6 months.

In a trial with high-dose cyclophosphamide, cisplatin, carmustine, and melphalan along with bone marrow support as initial therapy, a *complete response* was evident in 55 percent with an *overall response* rate of 73 percent. The median duration of response for patients who had complete remission was 9 months. These studies suggest that a large cell kill can be obtained with single intensive therapy using autologous marrow rescue. However, this therapy appears to be inadequate to eliminate enough cell populations in order to provide durable remission responses. The use of hematopoietic growth factors (GM-CSF—granulocyte-macrophage-colony- stimulating factor) may allow applications of multiple-dose intensive regimens to obtain an enhanced cell kill with autologous marrow rescue. The future of successful therapeutic interventions for stage IV disease depends on innovative approaches that provide high cell kill with reduced myelosuppression and systemic toxicities.

New agents that produce high response rates have been evaluated in the treatment of metastatic breast cancer. They include spindle poisons such as paclitaxel, docetaxel, and vinorelbine, topoisomerase inhibitors, and new antifolates. New hormonal treatments include the use of new aromatase inhibitors, GnRH agonists, antiprogestins, and new antiestrogens. Finally, biologic therapies targeting growth factors and growth-factor receptors such as HER-2/neu and epidermal growth factor receptors (EGFR) have been developed and trials using these approaches are under way.

Carcinoma of the Male Breast

Less than 1 percent of all breast cancers occur in men. The incidence appears to be highest among North Americans and the British, in whom it constitutes 0.4 to 1.5 percent of all male cancers. Jewish and black males have a higher incidence. Gynecomastia precedes approximately one-fifth of these malignancies. Male breast cancer has been associated with Klinefelter's syndrome (XXY), estrogen therapy, high endogenous estrogen levels related to testicular feminizing syndromes, irradiation, and trauma.

This tumor is rarely seen in young males; the incidence peaks between 60 and 69 years of age. Hormonal dependence of the neoplasm is typical, and the tumor is commonly estrogen-receptor positive. Clinical presentations of the disease are similar to those for women except that the diagnosis is delayed owing to infrequent recognition in the male patient.

Clinical characteristics include breast mass, nipple retraction, discharge, skin fixation, ulceration, and pain. Stage for stage, men with this neoplasm appear to have the same survival rate as women, but the overall prognosis is poor because of the advanced stage of disease (stages III, IV) at the time of diagnosis. Overall survival rates for node-negative

patients correspond favorably with those for women; survival in node-positive males is poor, suggesting the need for adjuvant therapy in this group.

The preferred treatment is modified radical mastectomy and use of postoperative radiotherapy for ulcerative and/or high-grade anaplastic tumors to reduce local recurrence. Orchiectomy and administration of estrogenic steroids may induce remissions of metastatic disease. Hormonal manipulation, by medication or by ablation, often provides objective responses in the management of metastatic disease. Cytotoxic chemotherapeutic agents have been used infrequently in the therapy of male cancer. Early trials suggest response rates similar to those for female breast cancer patients.

Breast Cancer During Pregnancy and Lactation

From the time of Billroth until Halsted's pioneering work, carcinoma of the breast diagnosed during pregnancy was considered incurable. White and White in 1956 reported an incidence of approximately 2.8 percent for cases occurring during pregnancy. Recent reviews suggest an incidence of 3 cancers per 10,000 pregnancies, or a range from 0.4 to 3.8 percent of reported breast cancers. The average age of the pregnant patient with concomitant breast cancer is 34 years.

In the past, the association of cancer with pregnancy was considered ominous. The profound estrogen and progesterone stimulation of breast cancer cells from the placenta and corpus luteum reportedly increases the risk of distant disease with provision of an excellent hormonal milieu to support cellular growth of the neoplasm. More recent data indicate that, stage for stage, carcinoma of the breast in pregnancy is associated with a prognosis similar to that of the nonpregnant female. There are, however, proportionally more patients with stage II and stage III breast cancers diagnosed in pregnancy than in the general population. Whether this late stage at diagnosis is secondary to the hormonal stimulation of pregnancy or to delay because of the coincident physiologic changes expected with pregnancy has not been determined.

Diagnosis

A careful breast examination should be performed at the initial obstetric visit and, at least, in each trimester of the pregnancy. Diagnostic work-up in pregnancy and lactation is similar to that in the nonpregnant patient, although breast mammography tends to be less reliable because of the extensive parenchymal changes associated with gestation. Radiation exposure of the fetus should be negligible with modern techniques for proper shielding of the abdomen. Regardless of the mammographic findings, any dominant mass should be evaluated promptly in the pregnant or lactating patient. Evaluation may begin with fine-needle aspiration to distinguish cysts from solid lesions. Any solid, discrete mass requires biopsy, which usually can be completed under local anesthesia. Risk of spontaneous abortion during mastectomy is approximately 1 percent and is correlated with stage of gestation.

Treatment

Therapy is identical to that for the nonpregnant patient. Patients who have advanced cancer require appropriate chemotherapy and radiotherapy. Modified radical mastectomy is optimal therapy for patients with stage I or stage II disease. When segmental mastectomy is selected, it must be followed by whole-breast irradiation, after delivery if the diagnosis is established late in the third trimester. In patients with positive axillary lymph nodes, chemotherapy should be delayed until the second trimester of pregnancy to diminish fetal toxicity and spontaneous abortion.

Termination of pregnancy has no role in the management of stage I or stage II disease. There is no evidence that oophorectomy influences the course of breast cancer during pregnancy and lactation. With mastectomy, normal pregnancy is allowed to continue, with minimal risk to the mother or the fetus. Modern series do not provide evidence that abortion benefits control or survival rates for patients with the disease. For stage I and stage II disease some patients with early disease will elect breast conservation. Segmental mastectomy should be strongly discouraged except in the third trimester, when radiotherapy could be reasonably delayed (4 to 6 weeks) until delivery.

Risks associated with chemotherapy during pregnancy have not been established. Schapira and Chudley found the incidence for teratogenicity of chemotherapeutics given to humans in the first trimester to be 12.7 percent, whereas Sweet and Kinzie noted an 11.5 percent incidence. There was no evidence of teratogenicity from administration of chemotherapeutic agents in the second and third trimesters. Little data exist with regard to combination regimens, as most of the reports considered single-agent usage. Long-term consequences of fetal exposure to chemotherapeutic agents are unknown.

In general, the use of cytotoxic agents during the first trimester should be discouraged; use during the second and third trimesters probably induces very few fetal abnormalities. For patients with positive lymph nodes at mastectomy, chemotherapy may be delayed until the second trimester. In the third trimester, after determination of fetal age and maturity, consideration should be given to early cesarean section to minimize delay in initiating cytotoxic therapy for stage II and stage III disease.

Lactation should be suppressed promptly in the postpartum state, even if the biopsy identifies a benign lesion, as milk from transected lactiferous ducts will drain via the biopsy site. If the infant is breast feeding, rapid weaning is desirable.

During postoperative radiotherapy or chemotherapy to control an aggressive primary lesion (stage III, inflammatory cancer), the patient who becomes pregnant should consider therapeutic abortion. In the first trimester, both radiotherapy and chemotherapy are potentially teratogenic, particularly in the first 9 weeks of gestation. Radiation in doses greater than 500 cGy, by itself, administered in early fetal development may be teratogenic.

Recurrence During Pregnancy

Data do not convincingly establish that survival is diminished nor that recurrence is enhanced for women who become pregnant after treatment of a breast cancer. In contrast, studies suggest an improved survival among breast cancer patients who later become pregnant. These data document no detrimental effect of subsequent pregnancy even among patients with positive nodes or of pregnancies that occur less than 2 years after mastectomy. Abortion does not appear to provide an improvement in the survival rate.

While no therapeutic grounds exist for recommending avoidance or termination of pregnancy among patients without documented recurrence, theoretically the disease-free interval may be shortened, particularly in ER- positive patients in whom the enhanced estrogen milieu will support growth of tumor cells. Thus, child bearing or estrogen-containing compounds must be considered cautiously before either is recommended to the patient at high risk for recurrent disease (e.g., stage II, III, inflammatory cancer). For patients at high risk for recurrent disease and in whom estrogen antagonists may be useful as an antineoplastic agent, the use of oral contraceptives and estrogen-containing compounds should be avoided.

CHAPTER 15 - Tumors of the Head and Neck

John J. Coleman III
Mark R. Sultan

CONGENITAL LESIONS

Thyroglossal Duct Cysts

The thyroid gland originates from the pharyngeal floor at the foramen cecum during the fourth week of gestation. It enlarges, becomes bilobed, and descends ventrally in the midline of the neck in close approximation to the developing hyoid bone. During this descent the patent diverticulum is called the thyroglossal duct. The duct normally resorbs by the tenth week of gestation. When all or a portion of this duct persists, thyroglossal duct cysts or sinuses are formed.

Classically these cysts present as midline masses in childhood, although they have been reported to be as much as 2 cm from the midline and may present for the first time in adults. Eighty percent occur at or just below the hyoid bone. A maneuver to differentiate them from Delphian lymph nodes or other central masses is to have the patient protrude the tongue. The level of the cyst is elevated by protrusion, demonstrating its embryologic origin from the base of the tongue. Unlike branchial cleft remnants, thyroglossal duct cysts generally do not have external sinuses. A significant proportion do become infected, however, usually during the course of an upper respiratory tract infection. Approximately 5 percent of the cysts contain functional thyroid tissue, and rare cases of thyroglossal duct carcinoma have been reported.

The differential diagnosis for midline neck masses about the hyoid bone includes lingual thyroid tissue. In rare cases this is the patient's only active thyroid gland. Therefore, the presence of thyroid tissue in its normal anatomic location must be confirmed either clinically or by radioactive scan before any midline neck mass is excised, and careful postoperative observation for hypothyroidism is imperative.

Sistrunk is credited with the development of a technique for excising thyroglossal duct cysts and sinuses that minimizes the risk of recurrence. He described resection of the cyst with the central portion of the hyoid bone, following the sinus superiorly to its presumed site of origin, the foramen cecum, and excising it in its entirety.

Branchial Cleft Anomalies

Branchial cleft cysts, sinuses, and cartilaginous remnants result from the incomplete fusion of the branchial clefts. The branchial clefts, appearing in week 4 of embryonic life and normally involuting fully by week 7, contribute to the formation of various head and neck structures in the developing embryo. When a portion of a cleft persists, epithelium-lined cysts or sinuses, with or without cutaneous openings and cartilaginous rests, may result. These anomalies usually present in the first decade of life but may go undetected until adulthood. The majority of branchial cleft cysts and sinuses are lined by squamous epithelium, although ciliated columnar epithelium has been reported as well. Branchial cleft carcinoma occurs rarely when there is a history of a branchial cleft cyst, the subsequent development of epidermoid cancer at that site, and no other primary lesion. Branchial cleft cysts also contain lymphoid tissue and may enlarge in response to upper respiratory tract infections.

The most common types of branchial cleft anomalies are those of the second cleft and are found at the middle and lower thirds of the sternocleidomastoid muscle. Cartilaginous rests from the first branchial cleft typically are subcutaneous, usually appear medial to the tragus, and may be managed by simple excision. Cysts and sinuses often extend more deeply into the neck. The fistulous tract courses superiorly along the carotid sheath and then medially over the hypoglossal nerve between the internal and external carotid arteries to end at the pharynx adjacent to the tonsillar fossa. A stairstep incision is sometimes needed to follow this circuitous route. First branchial cleft cysts and sinuses are located above the level of the hyoid bone just below the body of the mandible and extend superolaterally through the parotid gland to end within the membranous external auditory canal. Excision of these cysts and sinuses is recommended to avoid the complications associated with recurrent infection. Dissection must be meticulous to avoid injury to the facial, hypoglossal, vagus, and lingual nerves and to the carotid vessels. Anomalies of the third branchial cleft are rare. Like second cleft anomalies, they arise anterior to the middle and lower thirds of the sternocleidomastoid muscle. However, they course behind the carotid artery to end at the pyriform sinus.

Hemangiomas and Vascular Malformations

Congenital vascular lesions must be clearly classified as hemangiomas or vascular malformations in order to assess their prognosis and establish appropriate management plans. The distinctions between the two have been clarified on the basis of cellular and clinical characteristics. Hemangiomas have an increased mitotic activity and as such may be considered true neoplasms. They are typically absent at birth or may be present as a faint vascular blush. During the first several months of life they may undergo a rapid proliferative phase, during which they sometimes grow to large size. Although the majority of hemangiomas undergo spontaneous involution by the age of seven, complications such as ulceration and bleeding, obstruction of the eye with subsequent amblyopia, nasal airway obstruction, and rarely thrombocytopenia (Kasabach-Merritt syndrome) may mandate early surgical resection. Systemic dexamethasone therapy, or the intravenous administration of interferon- α , for a short course has been found to arrest the growth of large lesions during their proliferative phase. The use of intralesional steroid injections or sclerosing agents may be successful in achieving temporary control of smaller hemangiomas in certain locations such as the lip or eyelid. Photodynamic laser therapy may be helpful in preventing the onset of the proliferative phase of hemangiomas.

Vascular malformations, unlike hemangiomas, have a normal rate of endothelial cell turnover. They result from congenital errors in vascular morphogenesis and are classified by their vessel of involvement—capillary, venous, arterial, lymphatic, or combined. High-flow lesions result from gross abnormalities connecting the arterial and venous systems and may cause catastrophic problems of massive hemorrhage, high-output congestive heart failure, and hemolytic anemia. Chronic increased blood flow may be associated with skeletal abnormalities such as bone hypertrophy and distortion. Capillary, venous, and arterial malformations may occur anywhere in the head and neck. Lymphatic malformations (cystic hygromas) classically occur in the neck or the floor of the mouth. All malformations are present at birth, although they may not be clinically evident until the ectatic vessels suddenly dilate under hormonal or other physiologic influences. They normally grow proportionally with the child and do not regress spontaneously, unlike hemangiomas. Therefore, the management of malformations often is surgical. Indications for early surgical resection include recurrent infections, obstructive symptoms (e.g., respiratory distress), hemorrhage, and significant aesthetic deformities.

Because vascular malformations of the head and neck often are highly infiltrative, a complete preoperative evaluation of the extent of the lesion and its vascularity must be obtained. Angiography usually is necessary, sometimes for diagnosis, but usually to determine the contributory vessels. When technically possible, complete extirpation of the malformation should be performed while preserving normal anatomic structures. Preoperative embolization by arteriographic technique may decrease blood flow temporarily, making surgical resection safer and more practical.

Vascular birthmarks, in the past descriptively named “strawberry” or “capillary” hemangioma, “port-wine stains,” “cavernous hemangiomas,” and “cystic hygromas,” are now classified by their major vessel of involvement—capillary, venous, or lymphatic malformation. Accurate description is crucial, since the prognosis and management of vascular birthmarks depend directly on their correct classification as hemangiomas or malformations.

In deep-seated subcutaneous vascular malformations such as those sometimes occurring in the cheek or pharynx, physical examination may be inadequate for accurate delineation. Further evaluation often is necessary and may include computed tomography (CT) or magnetic resonance imaging (MRI), angiography, or technetium-labeled red blood cell scintigraphy. Definitive diagnosis in any patient with a vascular mass may require open biopsy to rule out a malignancy, which may occasionally have similar radiographic characteristics.

BENIGN LESIONS

Lip

The lower lip may be subject to chronic irritants such as pipe smoking or lip biting and, more important, to the damaging effects of chronic actinic exposure. In affected individuals the epidermis of the vermilion becomes atrophic and the dermis reveals elastosis. The basal layer of the epidermis then develops dysplasia, creating thickening of the superficial mucosal layer, the stratum corneum. This thickening or hyperkeratosis is clinically visible and palpable. With progression, the dysplasia extends upward into the epithelium, producing parakeratosis, the accumulation of nucleated cells, near the epithelial surface. This is manifested clinically by scaling of the lip. A proliferation and abnormal orientation of epithelial cells, *dyskeratosis*, may then follow, ultimately leading to *carcinoma in situ*. With penetration of the basement membrane, an invasive squamous cell carcinoma develops. When dyskeratosis or carcinoma in situ is present over a large extent of the surface of the lower lip, excision of the entire vermilion (“lip shave”) should be considered. The lip is then resurfaced by advancing the labial and buccal mucosa to the mucocutaneous junction.

Oral Cavity

A variety of benign lesions arise in the oral cavity. They may be grouped by location into those affecting the buccal mucosa, gingiva, or tongue or by their causation, such as inflammatory or ulcerative. For many, their significance lies in their possible premalignant potential or in their mimicking of true malignancies.

The oral lining contains countless mucous glands, the minor salivary glands. A submucosal accumulation of mucus results in a mucous retention cyst. Since the majority of these cysts have no epithelial lining, it is believed that they are most often caused by rupture of the duct system, with extravasation of mucus, and not by ductal obstruction, as was previously thought. The most common location for a mucous cyst or mucocele is the labial mucosa of the lower lip (Fig. 15-1). These lesions are typically less than 1 cm in diameter, smooth, rounded, and have a bluish hue. The treatment of choice is excision. Marsupialization alone is reserved for extensive lesions. A *ranula* is a type of mucous retention cyst that arises from major salivary glands, most commonly the sublingual glands. This too is managed by excision, but given its location in the floor of the mouth and, in some cases, its large size, it may require a meticulous dissection to avoid nerve injury and postoperative hemorrhage. It is frequently necessary to resect the affected sublingual gland in-continuity to prevent recurrence.

An *epulis* is a granulomatous lesion of the gingiva; as elsewhere in the body, it represents an exaggerated inflammatory response to minor injury. Two subtypes exist: *congenital epulis* is typically found in the anterior maxilla of newborns; *epulis gravidarum* occurs in approximately 1 percent of pregnant women and normally resolves spontaneously when the pregnancy is concluded. Only symptomatic epulides need be excised.

Peripheral giant cell reparative granulomas also occur most commonly on the gingiva. The “giant” cell of origin resembles an osteoclast. These granulomas are polypoid, submucosal, and fibrous. They can create ulceration and hemorrhage of the overlying mucosa. Radiographs may reveal erosion of the underlying bone. Excision must be complete to prevent recurrence. The term “peripheral” refers to the soft-tissue origin of these tumors as opposed to the *central giant cell reparative granulomas*, which, although similar histologically, arise within bone. The peripheral giant cell reparative granulomas are four times more common than the central type. The latter are expansile endosteal lesions that typically present in the mandible of young adults. They also have been reported in the paranasal sinuses, orbit, cranial vault, and temporal bone. They must be distinguished from true giant cell tumors of bone (which have malignant potential), brown tumors of hyperparathyroidism, traumatic bone cysts, and fibrous dysplasia. Thorough curettage is generally

curative.

The tongue and the larynx are common locations for the development of *papillomas*. They are caused by the human papillomavirus, which induces squamous epithelial proliferation into soft, irregular, pedunculated lesions that may recur and cause obstruction of the airway. Eradication may be accomplished by excision or cauterization using a carbon dioxide laser. Other common benign masses of the tongue include fibromas, neurofibromas, and lingual thyroid nodules. The latter may lie dormant through childhood and then rapidly enlarge during puberty.

In 1926 Abrikossoff described rare benign tumors involving the tongue, which he named *granular cell myoblastoma* because of their presumed embryonal muscle cell of origin. They are now believed to derive from Schwann cells and have been found to arise throughout the aerodigestive tract, particularly in the larynx. In the tongue they typically occur as firm, submucosal swellings in the middle one-third and may therefore mimic squamous cell carcinoma. Wedge excision is curative.

The oral lining is subject to a number of ulcerative conditions. The *idiopathic aphthous ulcer* is the most common type. The cycle of painful ulceration and spontaneous healing may occur several times a year and persist for many years. Other similar ulcers have identifiable causative factors, including viral infection with herpes simplex, nutritional deficiencies including vitamin B, folate, or iron, and emotional stress. These ulcers often respond to topical steroids. Multiple painful oral ulcerations may be a manifestation of *pemphigus vulgaris*. This may be accompanied by severe, generalized toxicity. The disease typically occurs in the fifth to seventh decade of life in patients of Mediterranean descent. The ulcers begin as intraepithelial bullae that subsequently rupture and ulcerate. The overlying epithelium may be rubbed off easily (Nikolsky's sign). In *erythema multiforme*, persistent or recurrent painful oral ulcerations arise within a background of diffuse oral erythema. Biopsy examination reveals a perivascular lymphocytic cellular infiltrate. Separate skin involvement may or may not be present. A variety of causes have been proposed. Management with systemic steroids and antimetabolites is often necessary.

Discrete, painful ulcers are also present in *necrotizing sialometaplasia*. This is a benign inflammatory disease of minor salivary glands that usually occurs on the hard palate. It is believed that local trauma leads to progressive local ischemia and ulceration. The histologic differentiation from squamous cell cancer or mucoepidermoid carcinoma can be extremely difficult by incisional biopsy. Therefore, although these ulcers will ordinarily heal spontaneously in 6 to 10 weeks without specific treatment, in cases where the correct diagnosis remains unclear after incisional biopsy, complete excision of the ulcer is prudent.

The description and significance of leukoplakia and erythroplasia will be reviewed later in this chapter. Other white plaquelike lesions of the oral cavity include *white sponge nevus*, *lichen planus*, and *oral hairy leukoplakia*. Histologically, all reveal parakeratosis. White sponge nevus is a rare familial ectodermal disease that diffusely involves the oral cavity in a benign, self-limited manner. Lichen planus is a degenerative mucocutaneous disease with a probable autoimmune basis. Oral lesions may appear with or without cutaneous manifestations and may at times become erosive. Oral squamous cell carcinoma has been found in association with lichen planus with an incidence varying between 0.09 and 10 percent in different series. Therefore, as in oral leukoplakia, systemic and topical retinoids are being evaluated in the treatment of oral lichen planus to reverse the condition itself and, more important, to suppress the presumed heightened potential of the oral mucosa toward degeneration into invasive carcinomas in these conditions. Oral hairy leukoplakia is a form of parakeratosis recently described in patients with AIDS or other forms of immunosuppression such as in patients with renal transplants or leukemia. Thick, shaggy plaques typically appear on the lateral surface of the tongue and become symptomatic when superinfected with *Candida*. Management includes antifungal medication, antiviral agents, or surgical excision.

Nose

Polyps arise commonly within the nasal cavity and paranasal sinuses. They occur with equal frequency in males and females and in all age groups after adolescence. Ten percent of children with cystic fibrosis may also develop nasal polyps. The polyps are often multiple, involving both sides of the nasal cavity and the paranasal sinuses. They may present with nasal obstruction, mucoid nasal discharge, or anosmia. Those that arise in the region of the turbinates and ethmoids are mainly allergic in origin, while those of the posterior nasal cavity are most often infectious. Medical management should include an evaluation for allergies. Aspirin should be stopped or avoided, since an association exists between aspirin use and the formation of nasal polyps. If the allergic evaluation is negative, an empiric trial of antimicrobials is begun. Steroid nasal sprays may be helpful. When medical management fails, surgical intervention may be necessary. Simple polypectomy carries a high rate of recurrence, and more extensive endoscopic or open excision may be necessary.

Papillomatous growths may occur on the nasal skin or within the nasal cavity. The *squamous papilloma* is an exophytic verrucous lesion caused by the papillomavirus and is present on the skin of the nasal sills, columella, or alae. It is managed as are other cutaneous warts. The *inverted papilloma* (also called schneiderian papilloma, squamous papilloma, or papillomatosis) is a polypoid mass occurring on the lateral nasal wall, typically in middle-aged men. The name is derived from its histologic appearance of an “inverted” proliferative growth pattern. The significance of this lesion lies in its presentation with symptoms of nasal obstruction, its recurrence rate of 50 percent with polypectomy alone, and its association with concurrent (8 percent) and subsequent (4 percent) invasive squamous cell carcinoma. More extensive resection and close follow-up are therefore indicated and can lower the recurrence rate to 6 percent.

Juvenile nasopharyngeal angiofibromas are benign but highly expansible and destructive fibrovascular neoplasms that typically arise in adolescent males between 10 and 20 years of age. Originating in the superior nasal cavity, they can erode widely into the paranasal sinuses, orbit, pterygomaxillary fossa, and middle cranial fossa. Early symptoms include nasal obstruction and epistaxis, and more advanced lesions can produce anosmia, proptosis, or cranial nerve dysfunction. Management commonly requires preliminary angiographic embolization followed by surgical extirpation. Approximately 10 percent require a combined intracranial/extracranial approach. Radiation therapy is generally reserved for residual or recurrent disease, although its successful use as a primary modality has also been reported.

Paranasal Sinuses

Although the terms are often used interchangeably, mucous retention cysts and mucocèles of the paranasal sinuses are different entities with distinct pathogeneses, natural histories, and connotations. *Mucous retention cysts* arise as a result of blockage of secretion from *microscopic* secretory ducts of mucous glands within the lining of the paranasal sinus cavity, possibly as a sequela of sinusitis. The fluid mass that results remains separate from the bony wall of the sinus and so continues to be surrounded by air within the sinus, except at its base. Rarely, they can enlarge to occupy the entire sinus, at which point it would be difficult to distinguish them from the more virulent mucocèles. Radiographically they appear as discrete masses that are profiled by sinus air. The most common location for mucous retention cysts of the paranasal sinuses is in the maxillary sinus, where they usually present as an asymptomatic incidental finding on x-ray. Ten percent of routine sinus radiographs reveal evidence of these cysts in the maxillary sinus. They are considered the most common benign lesions of the maxilla. Treatment is rarely necessary.

As opposed to the indolent mucous cyst, *mucocèles* of the paranasal sinuses, although benign, can be expansile, highly destructive lesions. These result from *macroscopic* blockage of a sinus ostium by epithelial or osseous neoplasms or inflammatory processes, or as a result of trauma (e.g., facial bone fractures). Mucinous secretions then accumulate within the entire sinus. With persistent secretion a pressure effect on the entire sinus wall is produced, displacing both the epithelial lining and the bony wall. This ultimately can result in thinning and destruction of the wall such that the mucocèle can “invade” adjacent vital structures. CT or MRI scanning is needed to delineate the complete extent of the process, but clinical distinction from a carcinoma can be difficult. Mucocèles most commonly arise within the frontal sinuses, followed, in order of frequency, by the ethmoidal, maxillary, and sphenoidal sinuses. In the frontal sinus location they most often present with frontal headaches. Sixty percent of frontal sinus mucocèles erode through the floor of the sinus (the orbital roof) causing proptosis and frontal swelling. Left untreated, diplopia and even blindness can result. Symptoms resulting from mucocèles of the other sinuses depend on their direction of spread. Fortunately, intracranial extension is rare. Mucocèles that become infected are called *pyocèles* and present with the additional signs and symptoms of sinusitis. The most definitive treatment of a mucocèle includes the evacuation of the contents of the sinus through an open approach. The entire mucosal lining of the sinus must then be removed and the sinus duct occluded with muscle or bone. The question remains controversial as to whether or not the remaining sinus itself should then be obliterated, and if so, with what material (e.g., muscle, fat, cancellous bone).

Larynx

The most common benign neoplasm of the larynx is the *papilloma*, accounting for more than 90 percent of laryngeal tumors. Papillomas, probably caused by the human papillomavirus, usually arise on the vocal cords and usually present with hoarseness. They may be found at any site in the larynx as well as on the hypopharyngeal or pharyngeal walls and present as pedunculated exophytic masses. Laryngeal papillomas may be grouped into juvenile or adult types, depending on the age at onset. In the juvenile group there is a 2:1 female predominance, and ratio is reversed in the adult group. The typical course of each type is also distinctly different. In adults the masses are most often solitary and rarely recur after excision. In the juvenile group the lesions tend to be multiple and may recur and spread rapidly after excision. The reason for these differences is not known. Laryngeal papillomas are usually treated with laser obliteration.

Other, less common benign tumors of the larynx include oncocytic tumors and granular cell myoblastomas. The former present as a smooth submucosal mass, and the latter as a sessile mucosal mass. The most common location for both is the vocal cords, and so they too typically present with hoarseness. Chondromas of the larynx are rare benign cartilaginous neoplasms most commonly occurring on the cricoid cartilage. They can cause hoarseness, respiratory obstruction, or dysphagia. All of these benign neoplasms are managed by conservative excision.

A *laryngocele* is a herniation of the laryngeal ventricle. Three forms exist, categorized by their site of presentation. An *internal laryngocele* remains confined to the larynx and presents as an enlargement of the false cord. An *external laryngocele* protrudes through the thyrohyoid membrane, causing swelling in the anterior neck. Combinations of these two types, called *mixed laryngoceles*, occur as well. The pathogenesis is believed to be associated with chronic increases in intralaryngeal pressure. Corroborative evidence for this theory includes the fact that singers and musicians have a propensity for their development. Symptoms depend on the site of presentation, with the internal variety often causing hoarseness and the external most commonly remaining asymptomatic. Treatment includes ligation of the stalk of the laryngocele and repair of the ventricular weakness.

Odontogenic and Bone Tumors

Odontogenic Tumors

A variety of cysts and tumors of the mandible and maxilla may arise from the progenitor cells of tooth development. The majority of these odontogenic lesions are benign and may be treated conservatively. Ameloblastomas (adamantinomas) arise from dental lamina and often are associated with impacted teeth in young patients. Their usual presentation is that of a painless mass of the jaw with a multilocular, radiolucent appearance on x-ray. They occur four times more frequently in the mandible than in the maxilla. Although slow-growing, they may grow to large size and erode adjacent bone (Fig. 15-2). Treatment consists of resection of the entire lesion with a margin of bone to prevent local recurrence. Myxomas and Pindborg tumors (calcifying epithelial odontogenic tumors) are similar in their presentation and management, and they too require an en bloc resection for cure.

A second group of odontogenic tumors, including calcifying odontogenic cysts (Gorlin's cysts), ameloblastic fibromas, cementomas, and keratocysts, are generally less aggressive

than those discussed above and are treated effectively by enucleation and excision of the entire lining of the lesion.

Nonodontogenic Tumors

The tumors in this group arise from bone that is not involved in tooth development. Torus is a benign, slow-growing projection from the surface of bone. The torus palatinus occurs in the midline of the hard palate, and the torus mandibularis usually develops on the lingual surface of the mandible opposite the premolars, often bilaterally. They are both common lesions. In the United States 20 percent of the population have a torus palatinus and 8 percent a torus mandibularis. There is evidence that they are genetically inherited by autosomal dominant genes with incomplete penetrance. Tori often begin around puberty and are slow-growing. They can induce ulceration of the overlying mucosa, thus mimicking a mucosal neoplasm. No therapy is needed unless they interfere with speech, mastication, or the use of dentures, at which time simple excision is performed.

Exostoses are similar to tori and also commonly occur in the jaws. There are localized overgrowths of bone that may be nodular, pedunculated, or flat and are often multiple. They most often present in the maxilla at the canine fossa as a hard, discrete, submucosal mass. Only symptomatic masses require excision.

Osteomas are slow-growing tumors of mature bone that arise within (intraosseous) or at the periphery of the involved bone. The peripheral lesions often are attached to the cortical bone by a dense pedicle. Involvement of the bones outside of the face and skull is rare. They most commonly arise on the mandible on the lingual aspect of the ramus or on the lower border of the angle of the mandible. Osteomas also may occur in the paranasal sinuses, where they may grow to a large size. Excision is advised when continued growth encroaches upon vital structures or becomes cosmetically unacceptable. Multiple osteomas are one of the manifestations of Gardner's syndrome, the others being multiple inclusion cysts of the skin, supernumerary teeth, and familial polyposis.

Fibrous dysplasia is a benign bone disorder of unknown cause in which cortical bone is replaced by immature fibrous tissue. The fibrous tissue often proliferates and extends beyond normal boundaries, distorting and compressing vital structures. Seventy percent of patients have involvement of a single bone—monostotic—and 30 percent have the polyostotic form. In the head and neck, the mandible or maxilla is most often involved. Albright's syndrome includes polyostotic fibrous dysplasia, precocious puberty, café- au-lait spots, and several endocrine abnormalities. The management of the patient with fibrous dysplasia is dictated by the aggressiveness of the disease and ranges from observation only to extensive local resection and reconstruction. Malignant degeneration occurs in 1 percent of the patients and may be related to prior radiation therapy. Malignant degeneration should be suspected in any lesion that undergoes rapid growth or produces significant pain.

CARCINOMAS

General Considerations

Malignant neoplasms that arise in the head and neck area or upper aerodigestive tract share the general behavior of most solid tumors: local growth, locoregional spread, and distant metastasis. Their effect, however, before therapy and as a consequence of therapy, depends much more than most other neoplasms' on local disruption of function. The two main vegetative functions of the human being—alimentation and respiration—are effected by the intricate synergy of the bone, nerve, muscle, and mucosa-lined cavities that make up the head and neck. Invasive carcinoma disrupts this fine balance, resulting not only in the proliferation of abnormal cells but also in the derangement of feeding, breathing, and speaking, which may present as malnutrition, upper airway obstruction, and recurrent aspiration pneumonia. Thus unlike the case of adenocarcinoma of the breast, colon, and stomach, malignant melanoma, squamous cell carcinoma of the lung, and most other solid tumors, in which the fatal event is almost always disseminated malignancy, as many as 60 percent of patients with a fatal head and neck malignancy die without clinical evidence of metastasis beyond the local/regional disease. Central nervous system invasion, rupture of the great vessels, airway obstruction, and invasive local infection are common causes of death in these patients (Fig. 15-3). Because of the predominant local and locoregional natural history of this disease, significant attention must be paid to local diagnosis and therapy.

Most malignant tumors that develop above the clavicles are squamous cell carcinomas (epidermoid carcinomas) originating from the respiratory and stratified squamous epithelium of the upper aerodigestive tract. Although there are some differences in the natural history of tumors arising at the various sites of the upper aerodigestive tract, probably dependent on characteristics of blood supply, lymphatic drainage, or histologic variation specific to that area, most squamous cell carcinomas of the head and neck behave similarly. Their unique clinical expression then depends on the interruption of normal activity inherent in their epicenter and those areas to which they spread (Fig. 15-4). So nasopharyngeal carcinoma may present with nasal stuffiness and progress to cranial nerve dysfunction and central nervous system invasion as well as neck metastasis; and carcinoma of the floor of the mouth may present with pain, tethering of the tongue, and dysphagia, resulting in malnutrition and, sometimes, aspiration.

Moreover, the therapeutic approach to the malignancy may interfere with normal function. Laryngectomy and glossectomy obviously impair speech and swallowing tremendously. Radiotherapy, used alone or in combination with surgery, may result in deficiencies of olfaction, salivation, and infection control in the upper aerodigestive tract. Hence the survival of the patient with head and neck cancer requires consideration of both tumor growth and residual local function in formulating the therapeutic plan. The appropriate selection of radiotherapy, extirpative surgery, chemotherapy, and reconstructive surgery is crucial in the physician's attempt to prolong life and restore reasonable function and appearance. A multidisciplinary approach to this group of tumors is essential.

In both children and adults neoplasms other than squamous cell carcinoma, benign and malignant, and other clinically important masses arise in the head and neck area (Fig. 15-5). Although some of these are more likely to progress to early metastatic disease, most have significant local effect in both their clinical expression and therapy. In adults salivary neoplasms are the next most important group of lesions in the head and neck.

Epidemiology

Squamous cell carcinoma of the head and neck is not a major public health problem in the United States. Combined upper aerodigestive tract sites account for approximately 23 new cases per 100,000 males and 8 per 100,000 females, or roughly 6 percent of new cancers in males and 2 percent in females. There are 30,000 to 40,000 new cancers of the head and neck and 10,000 to 15,000 deaths per year. Approximately one-third of patients who develop a squamous cell carcinoma of the upper aerodigestive tract will die from it. Incidence and mortality rates in the United States have remained relatively stable over the past 40 years in white males but have increased dramatically for most sites in nonwhite males and in females of both groups (Fig. 15-6). Like many solid tumors, the incidence of disease increases with age in both sexes, being very rare below age thirty except in immunocompromised patients. In the United States there seems to be a clear-cut relationship between squamous cell carcinoma of the upper aerodigestive tract and the chronic use of tobacco and alcohol together. Although the use of either tobacco or alcohol alone increases the likelihood of squamous cell carcinoma of the upper aerodigestive tract, the cumulative abuse greatly increases the risk (Fig. 15-7). Previously noted increases in the incidence of squamous cell carcinoma in females were probably a result of the more widespread acceptance of cigarette smoking among women over the past 30 years. In the Western world the combination of tobacco and alcohol of various forms seems to be the predominant cause of this disease; and though there is some slight variation, the mortality rate is similar from country to country. Cigarette, cigar, and pipe smoking, chewing tobacco, and snuff have all been implicated, as have distilled beverages, beer, wine, and even mouthwash, which in many forms has a high content of alcohol. The previously demonstrated relationship of asbestos and tobacco in the carcinogenesis of lung cancer is probably operant in squamous cell carcinoma of the upper aerodigestive tract as well.

Squamous cell carcinoma of the head and neck is endemic in other parts of the world, with incidences reaching as high as 50 percent of new cancers in Bombay, India, where chewing of *pan*, a combination of tobacco, betel nut, and lime (CaOH 2), causes buccal carcinoma. Throughout southeast Asia the use of betel nut and tobacco combinations similarly results in a high frequency of oral cancers. In cultures such as those of South Asia and Southeast Asia, where alcohol is not commonly used, the prevalence of vitamin deficiency and local submucosal fibrosis of the oral mucosa may play an important adjuvant role. Reverse smoking (smoking of cigarettes and cigars with the lighted end inside the mouth) similarly contributes to the high incidence of palate and oral cancers seen in India and some parts of Central and South America. In South Africa unusually high rates of nasal and paranasal cancers have been discovered, where nickel contaminates the tobacco inhaled as snuff, and where it and other substances are industrial contaminants among workers in the nickel, furniture, and shoe industries.

In southern China and the Pacific Rim countries, carcinoma of the nasopharynx is extremely common in both men and women, up to twenty times more common than in the United States. The causative factors are unclear, although inhaled fumes, cooking smoke, chemical pollutants, or others have been proposed, as has the ingestion of salted fish. The role of the Epstein-Barr virus (EBV) in the causation and natural history of nasopharyngeal carcinoma is unclear. Infection with EBV is prevalent in this group, and there seems to be a close relationship between elevated serum EBV titers and risk. Despite the differences in proposed causative agents throughout the world, it appears clear that an important factor in the origin of squamous cell carcinoma is a chemical carcinogen and that a linear dose- time risk ratio is likely. Prevention should be possible.

Carcinogenesis

The simplest explanation of the causation of squamous cell carcinoma falls within the accepted principles of chemical carcinogenesis, more specifically cocarcinogenesis, where an *initiating* agent (perhaps some contaminant or metabolite of tobacco) induces an irreversible change in the DNA of the affected cell. A *promoting* agent (perhaps alcohol, vitamin deficiency, local inflammation secondary to trauma, poor hygiene, or submucosal fibrosis) allows that irreversible change to manifest itself as a histologically and clinically identifiable malignancy. Initiation involves alteration of the DNA by addition through covalent bonding, replacement, deletion, or other mechanism. Promotion theoretically involves facilitation of expression of the abnormal DNA via activation of cell surface and cytoplasmic protein receptors or other reactions with the epithelial cell. This theory is consistent with many of the epidemiologic and clinical characteristics of squamous cell carcinoma of the upper aerodigestive tract. The indictment of chronic use implies that initiation alone is not sufficient for malignancy. In addition to the sites in the nasopharynx and larynx where inhaled and exhaled tobacco smoke contact, high-dose exposure is possible to the mouth, tongue, and buccal mucosa as metabolites of tobacco are secreted into saliva and sit pooled in the lingual and buccal sulci. The chronic inflammation attendant to frequent alcohol use may stimulate local proliferation of epithelial cells and react with reproducing cells to allow expression of the previously altered DNA.

The role of viral carcinogenesis via initiation or promotion is unclear but certainly suspicious. Patients with papillomatosis caused by human papillomavirus of the nasal cavity and larynx have been noted to be at higher risk for development of invasive squamous cell carcinoma. Recent studies of DNA from squamous cell carcinoma of the nasal cavity and paranasal sinuses using the polymerase chain reaction have identified human papillomavirus (HPV) types 16 and 18, whereas they were not identified in tumors of other histologic type (adenocarcinoma, adenoid cystic, etc.). HPV 16 genomes also have been found in squamous cell carcinoma of the larynx, buccal mucosa, tongue, and cervical lymph node metastases. Elevated antibody to Epstein-Barr virus is associated with the presence of nasopharyngeal carcinoma but is not specific enough to be of clinical use, since viral infection is common. That the virus plays either an initiating or a promoting role in carcinogenesis is suggested by the presence of the Epstein-Barr viral genome in cervical metastases as well as in the primary tumor arising in the nasopharynx but its absence in lymph nodes of Epstein-Barr-antibody-seropositive patients that did not contain tumor and its absence in metastatic tumors of other histology.

Although malignancy of the head and neck is not commonly associated with familial syndromes, benign tumors such as exostoses, sebaceous cysts, and sebaceous adenomas may be seen in the genetic alteration that causes Gardner's syndrome and Muir-Torre's syndrome. Of the identified oncogenes, several have been discovered in squamous cell carcinoma. The *int-2* oncogene related to fibroblast growth factor and the *C-myc* gene that codes for a DNA-binding protein concerned with regulation of cell growth have been demonstrated in 11 of 21 and 2 of 21 squamous cell carcinoma tumors studied. Improved methods of DNA characterization will clarify the role of viral transformation, heredity, and increased susceptibility in the pathogenesis of squamous cell carcinoma.

Current molecular biologic and genetic investigations of squamous cell carcinoma of the head and neck have not yet produced useful mechanisms of therapy. Overexpression of oncogenes and increased levels of oncoproteins, such as the a6b4 integrins (cell surface adhesion molecules and receptors for extracellular matrix proteins), and the HER2/neu oncoproteins have been associated with rapid locoregional spread and metastasis. Inactivation of tumor suppressor genes by deletion or other mutations seems to be a common mechanism of tumor initiation and subsequent progression. It has been theorized and partially demonstrated that the formation of a head and neck tumor requires many genetic events. In vitro analysis of several lines of squamous cell carcinoma have demonstrated common allelotypes with deletions at the 9p21, ep, and 17p chromosome sites. The level of p53 mutations may predict the responsiveness of tumor to radiotherapy and chemotherapy. Another potential therapeutic mechanism being investigated is the elaboration of humorally and cellularly mediated antibodies to these overexpressed tumor cell proteins. The further delineation of the genetic identity of squamous cell carcinoma and the manipulation of protein synthesis will have a major role in future treatment.

The protean manifestations of AIDS include a number of abnormalities in the head and neck. Proliferative lymphocyte deposits in the nasopharynx have been noted to cause eustachian tube dysfunction and may be precursors of the commonly seen extranodal lymphomas. Squamous cell carcinomas of the upper aerodigestive tract appear to be disproportionately common and unusually aggressive in patients with AIDS, as in other immunodeficient states such as chronic lymphocytic leukemia. Oral and pharyngeal presentations of Kaposi's sarcoma are common in HIV-positive patients and occasionally require surgical or radiotherapeutic intervention (Fig. 15-8). Cystic degeneration of lymph nodes in the parotid and submandibular glands also occurs, and in one series this was the presenting symptom of newly diagnosed HIV infection.

Natural History

Malignancy in the head and neck follows a relatively predictable course along the continuum of histologic changes from early evidence of hyperplasia with atypia to poorly differentiated invasive malignancy. The sequential presentation of these abnormalities fits well with a theory of chronic exposure to one or several chemical carcinogens. The normal oral and oropharyngeal cavities are lined with stratified squamous epithelium similar to the skin but without the characteristic keratinization. Another difference between the skin and oral mucosa is the lack of distinct rete ridges in the mouth in normal states. Immediately subjacent is the basement membrane, beneath which lies the submucosa, containing lymphoid aggregates and lymphatic channels, blood vessels, and mucous and serous glands. In most areas of the oral cavity and oropharynx, mucosa and submucosa cover muscle. Within the epithelial layer are terminations of the nerves mediating the special senses of olfaction and taste as well as other nerve fibers. The larynx, nasal cavity, and paranasal sinuses are lined by pseudostratified columnar ciliated epithelium, which overlies a similar arrangement of minor salivary glands, nerves, and blood vessels.

Viral infection, chronic irritation by ill-fitting dentures, trauma, or infection from poor dental hygiene may elicit a response from the epithelium known as hyperplasia or papillomatosis, in which cells with normal DNA configuration and organelle structure proliferate, resulting in more prominent intraluminal projection as well as extension of the mucosa deeper into the submucosa. Despite these changes there are none of the cellular manifestations of malignancy (mitoses, pyknotic nuclei, prominent nucleoli, etc.), and the basement membrane beneath the mucosa remains intact.

Most of the clinical changes that reflect these histologic alterations, including hyperplasia, hyperkeratosis, and pseudoepitheliomatous hyperplasia (the aggressive end of this spectrum, which may be confused clinically with malignancy), have been grouped under the term *leukoplakia* (white patch). Histologic analysis shows hyperkeratosis and parakeratosis or orthokeratosis (appearance of nuclei in the most superficial layers of the mucosa with or without inflammatory cell infiltrate and acanthosis). Earlier approaches required the removal of all leukoplakia, which was believed to be a precursor of invasive malignancy. More recent thinking, however, suggests that this change is not in itself premalignant but simply evidence of chronic irritation.

Cellular manifestations of malignancy result in the diagnosis of epithelial dysplasia. Lack of a normal cellular progression to maturation characterizes dysplastic epithelium. Nuclei are larger, are hyperchromatic, and show mitotic activity. Cells may be pleomorphic with basophilic cytoplasm. Cell layers become disorganized, with loss of the gradual ascent to the epithelial surface and the presence of immature cells at the basement membrane as well as the epithelial surface. The extent of the individual cellular changes and loss of normal polarity determines whether the entity is termed dysplasia, severe dysplasia, or carcinoma in situ. All of these changes, however, overlie an intact basement membrane. The change from hyperplasia to dysplasia is thought to be irreversible and the initial step in carcinogenesis. The clinical manifestation of these histologic changes has been termed *erythroplasia* or *erythroplakia*, or red patch. These lesions appear reddish, are frequently exudative, and may have associated leukoplakia. Biopsy or excision is mandatory, because they are premalignant and may also indicate the presence of another adjacent malignancy.

The cellular changes of carcinoma in situ with loss of the integrity of the basement membrane become invasive squamous cell carcinoma. Deranged cellular function results in intracellular keratinization or keratin pearl formation (Fig. 15-9). Growth into the oral cavity may be manifested grossly as an exophytic carcinoma, whereas invasion into the adjacent muscle or bone produces ulcerative lesions.

In addition to the continuum of changes from hyperkeratosis to invasive carcinoma, patients with squamous cell carcinoma frequently demonstrate another phenomenon consistent with the theory of chemical carcinogenesis. Field *cancerization* or the *condemned mucosa* phenomenon is the finding of epithelial abnormalities throughout the entire upper aerodigestive tract in a patient with squamous cell carcinoma at one site (Fig. 15-10). Erythroplakia in the oral cavity increases the risk of invasive carcinoma in the pharynx, larynx, esophagus, and lung. The incidence of synchronous malignancies in the upper aerodigestive tract has been reported to range from 4.4 to more than 10 percent, with lung, esophagus, and other head and neck sites being most common.

Other anatomic abnormalities and functional disorders are also more frequent in patients with upper aerodigestive tract malignancy. Barrett's esophagus and esophagitis have been reported to occur in 33 percent of patients undergoing laryngoesophagectomy for advanced laryngeal carcinoma. An overall incidence of esophageal disease of 54 percent was found, with synchronous esophageal cancer in 25 percent of these patients. Metachronous or subsequent malignancies also appear at a higher frequencies in patients with squamous cell carcinoma of the upper aerodigestive tract than in the general public. Lung, esophagus, and other head and neck sites are more common, with a risk of up to 27 percent. Cessation of smoking and alcohol intake may or may not be protective.

The phenomenon of field cancerization and the high frequency of synchronous and metachronous malignancies in patients with squamous cell carcinoma of the head and neck fit nicely with the current theories of oncogenesis. Within the condemned mucosa there may be multiple subpopulations of neoplastic cells, each the clonal expression of a common initial abnormality. Different environmental conditions, subsequent mutations caused by the chronic insult of chemical carcinogens, and amplification of genetic abnormalities at one site more than another may explain the simultaneous appearance of erythroplasia, well-differentiated local carcinoma, and poorly differentiated lymph node metastasis as the disease progresses clinically and histologically. The application of the theory of *tumor heterogeneity* to the entire mucosal surface explains many of the characteristics of individual tumors such as resistance to chemotherapy and radiotherapy as well as the patient's systemic response to disease.

Although theories of malignancy that espouse a stepwise progression from local to locoregional to metastatic disease have been shown to be inaccurate for breast and gastrointestinal solid tumors, squamous cell carcinoma of the head and neck does seem to spend a considerable portion of its natural history in the local or locoregional stages. After passage through the basement membrane, malignancy invades the surrounding mesenchymal tissue, be it muscle, cartilage, or bone. Proteases and collagenolytic and osteoclastic enzymes facilitate the destruction of the adjacent tissues. Invasion of subjacent nerves opens the perineural spaces, and tumor emboli may pass in the perineural lymphatics. The usual spread of tumor is from the primary site via the subjacent lymphatics (Fig. 15-11) to the neck or by continued local invasion through nerve and bone to the base of the skull. The virulence of the primary tumor and its likelihood of metastasis or ability to cause the death of the host have been estimated by a number of methods. The size of the primary tumor is the main parameter determining its clinical stage in the TNM (tumor-node- metastasis) staging system adopted by the American Joint Committee on Cancer (AJCC) and other worldwide organizations (Fig. 15-12). Although it is a crude method, it is fairly reliable in suggesting the prognosis of the patient and the appropriate form of therapy.

Histologic characteristics such as degree of differentiation (primarily a function of nuclear morphology), pattern of invasion (blunt pushing borders vs. noncohesive jagged borders), microvascular invasion, perineural invasion, and tumor thickness have been used to predict the likelihood of lymph node metastasis and overall prognosis. The amount of tumor angiogenesis within the cancer as measured by the intensity of staining of the endothelium is a cogent predictor of aggressiveness. Advances in biochemical and molecular investigation have allowed more careful consideration of the primary tumors. Flow cytometric analysis of tumor suspensions shows that aneuploidy is common in primary tumors (68 percent) and in cervical metastases (82 percent). Aneuploid tumors are more likely to metastasize than are diploid tumors. Correlation also has been found between thymidine labeling index and the T stage of squamous cell carcinomas, with T3 lesions having significantly more activity than T1. Further subcellular analysis of squamous cell carcinoma has attempted to correlate abnormalities and thus predict behavior.

Expression of histocompatibility antigens HLA-1 and HLA-2 on squamous cell carcinoma demonstrates marked tumor heterogeneity, particularly in poorly differentiated tumors. The relationship of growth factors to primary tumor development and progression is unclear, but, as in other tumors, such as breast and brain, growth factor receptors have been identified on squamous cell carcinoma of the head and neck. Higher absolute levels of epithelial growth factor receptor and demonstration of amplification of the gene for epithelial growth factor receptor in squamous cell carcinoma of the upper aerodigestive tract may indicate that epithelial growth factor plays an important role in local tumor behavior. The histologic, biochemical, and genetic characteristics of head and neck tumors also have been used in an attempt to predict response to radiotherapy and chemotherapy.

As with most solid tumors, the most cogent prognosticator of head and neck cancer is the presence or absence of lymph node metastases. In the unoperated patient, passage of tumor emboli through the lymphatics follows an orderly pattern, with the anatomic triangles of the neck reflecting the site of primary disease. In the patient who has undergone previous surgical therapy or radiotherapy or who has extensive tumor that blocks normal lymphatic flow, metastasis from a primary tumor may not follow the usual pathways, and a neck mass may not predict accurately the site of recurrence or new primary disease (see Fig. 15-3 B). Clinical and ultimately pathologic staging of the neck according to the AJCC system depends on number of lymph nodes, size of lymph nodes, fixation to the skin or subjacent neck muscles, and laterality with respect to the primary tumor (ipsilateral, contralateral, and bilateral). Although there are many determinants of primary tumor behavior, size and differentiation are useful predictors of the risk of metastasis. Increasing T stage is generally reflected by increasing N stage. Distant metastasis, however, is more closely related to N stage than to T stage. In a study of 160 patients with extensive disease in the neck, N3a, only 63 completed combined therapy with surgery and radiation and, of these, only 13 showed no evidence of disease at 2 years. Disseminated disease was the most common cause of death, followed by failure at the primary site and in the neck.

Lymph node metastases appear to behave in some ways similarly to primary disease in that micrometastases are not as poor a prognostic indicator as clinically palpable metastatic disease. Spread of the tumor outside the capsule of the lymph node may occur in clinically negative and positive lymph nodes and is a poor prognostic sign, indicating a more aggressive tumor. In a study of stage III carcinoma of the oral cavity, the 2-year survival rate of patients with no lymph node metastases was 87 percent; with intracapsular lymph node metastases, 75 percent; and with cervical metastases with extracapsular spread, only 39 percent. The incidence of extracapsular spread of cervical disease increases with the size of the lymph node. Proportional to increase in extracapsular spread is the likelihood of recurrent disease, and thus of death.

Uncontrolled growth of squamous cell carcinoma in the neck results in carotid artery hemorrhage, invasion of the sympathetic ganglia resulting in Horner's syndrome, erosion of the

cervical vertebrae, invasion of cranial nerves IX, X, and XI (jugular foramen syndrome) and of cranial nerve XII at the base of the skull, airway obstruction, and brachial plexus palsy. The site of the primary tumor dictates not only the site of cervical metastasis but the frequency as well. Although the size of the primary lesion at presentation is important, it seems that independent of size, squamous cell carcinomas of the tonsil and the base of the tongue have high rates of metastasis to the neck, and lesions of the buccal mucosa and palate have low rates.

Distant metastases from squamous cell carcinoma have been reported to range from 31 percent of patients with no evidence of cervical metastases to 59 percent of those with extensive neck disease. Despite this relatively high incidence, they are not uniformly the cause of death. Although any site is possible, lung, bone, skin, and liver are the most common metastases. Systemic effects of both local and systemic disseminated tumors include hypercalcemia from bone metastasis and elaboration of parathormonelike peptides as well as syndrome of inappropriate antidiuretic hormone secretion (SIADH) from vasopressinlike substances. There is some evidence that the widespread use of chemotherapy has changed the natural history of metastatic squamous cell carcinoma, increasing the frequency of patients dying with disseminated disease.

Diagnosis and Evaluation

History and physical examination are the most important considerations in the diagnosis of carcinoma of the upper aerodigestive tract. A history of chronic tobacco and alcohol abuse places the patient in the high-risk category. Males over forty with such a history comprise 70 to 80 percent of most series of patients with head and neck cancer. A previous occurrence of lung cancer, esophageal cancer, or other head and neck malignancy, diseases causing immunodeficiency such as renal failure with its therapy by transplantation, malnutrition, and AIDS are also significant.

Symptoms referable to the tumor itself usually are mild and not commensurate with the size of the tumor, often because of the patient's generally stoic personality and denial. Late-stage presentation is common in these patients. Barkley noted that 36 percent of patients presenting with oropharyngeal lesions had local disease alone and that the remaining 64 percent already had cervical or disseminated metastases. Pain at the site of the tumor is not a frequent complaint. Because otitis media and externa are relatively rare problems in adults, pain in the ear in a patient over forty may be a manifestation of tumor in the oral cavity, oropharynx, or larynx via referred pain pathways, including the lingual to auriculotemporal nerves, glossopharyngeal to tympanic nerve, or vagus to auricular nerve. Prograde neural symptoms such as formication (the feeling of ants crawling along the lip or cheek) may represent mental or infraorbital nerve invasion by buccal, labial, or alveolar carcinoma. Family members or the patient may note changes in speech caused by tethering of the tongue (Fig. 15-13). Constant or variable hoarseness is the sign of vocal cord impairment by local growth of laryngeal or hypopharyngeal cancer or by paralysis in the neck of the recurrent laryngeal nerve. The sensation of scratchiness or tickling in the throat, gagging on food, or nocturnal choking secondary to aspiration may all represent interference with the synergistic mechanisms of swallowing and breathing. Airway compromise is usually a late symptom but occasionally may be the first presentation in an emergency setting. The typical American patient, then, is male, over forty, with a long history of tobacco and alcohol abuse, frequently with underlying psychologic or behavioral disorder such as depression or antisocial personality with withdrawal.

Visualization of the entire upper aerodigestive tract, using a systematic approach that includes inspection of the facial and cervical surface anatomy and contour, intraoral examination, and indirect (mirror) laryngoscopy with nasopharyngoscopy, is essential for diagnosis and staging (Fig. 15-14). In addition to size, shape, and projection into the cavity (exophytic or degree of ulceration), it is important to note the mobility of the tongue and its position relative to the midline (hypoglossal nerve function), any fixation of the tongue to the adjacent mandible, and any direct invasion of the mandible. Mirror examination of the oropharynx and hypopharynx and larynx should note the patency of the vallecula, the distensibility of the pyriform sinuses, and the normal adduction to the midline of the vocal cords. Interference with vocal cord function may result as hypopharyngeal lesions invade the medial wall of the pyriform sinus or by paralysis of the recurrent laryngeal nerve. By retracting the soft palate forward with a transnasal catheter, visualization of the nasopharynx is possible with the mirror. The vault of the nasopharynx, the choanae, and the eustachian tube should be examined. The condition of the teeth and gums should be evaluated and the presence of torus palatinus or torus mandibularis noted. Limited motion of the mandible may come from direct tumor invasion or, more frequently, from invasion of tumor through the retromolar trigone area or tonsillar fossa to the pterygoid muscles. Infiltration or inflammation of the internal and external pterygoids limits jaw motion and causes the uncomfortable symptom of trismus, an ominous clinical sign. Compilation of the appropriate information about the primary tumor allows clinical staging. The distinct anatomic site, size, pattern of growth, and invasion of adjacent structures are all necessary to assign the appropriate T stage.

Examination of the neck will reveal the presence or absence of lymph node metastases. The site of the primary tumor should predict the most likely site of metastatic disease (see Fig. 15-11). Enlargement or inflammation of the submandibular gland may interfere with evaluation of the neck. Careful palpation, preferably performed with the examiner standing behind the seated patient, allows systematic and sequential evaluation of the submental, submandibular, jugulodigastric, midjugular, juguloomohyoid, posterior triangle, and supraclavicular lymph node stations. The number of lymph nodes, lymph node size, and any fixation to the skin or subjacent muscle allows the examiner to assign an N stage. Tumors with no evident primary site are manifested as lymph node metastases in 3 to 4 percent of malignancies. Cervical metastases of squamous cell carcinoma comprise two-thirds of these cases. Furthermore, the initial manifestation of the subsequently discovered disease is a neck mass in 25 percent of the patients with carcinoma of the oral cavity, oropharynx, and thyroid, and in 50 percent of patients with carcinoma of the nasopharynx. Because of variable extension into the neck, parotid gland masses may present as a cervical lymph node. The characterization of masses in the neck can be guided largely by age. In children congenital and inflammatory masses predominate; in young adults, inflammation or proliferative disorders of the lymphatic system; and in adults, metastatic disease from the upper aerodigestive tract and skin.

Careful physical examination, including neurologic examination of the remainder of the head and neck area, may reveal evidence of more extensive disease such as cavernous sinus invasion, as documented by extraocular movement disorders, or invasion of the cervical sympathetics, as indicated by Horner's syndrome.

Distant metastases are evaluated by history, physical examination, laboratory procedures, and radiology. Pleuritic pain or shortness of breath may indicate lung involvement, and distinct pain at a specific site may indicate spread to distant bone.

Before treatment planning, definitive histologic confirmation of disease is necessary. If a primary site is visible, a wedge biopsy specimen should be taken at the edge of the tumor to include some adjacent normal tissue, fixed in formalin, and examined histologically. Touch preparations and other cytologic methods are occasionally helpful but suffer from lack of specificity and sensitivity. Although the extent of the tumor usually can be assessed by direct visualization, the use of vital dyes such as toluidine blue may help to delineate the extent of the disease, staining only the malignant and dysplastic epithelium and washing off the surrounding inflamed tissue. Hematoporphyrin dyes share this characteristic of differential uptake by tumor and normal cells and have occasionally been of use in demarcating index tumors and identifying and sometimes treating multicentric disease. Because of the significant incidence of synchronous primary tumors, evaluation of the rest of the upper aerodigestive tract may be useful. The value of triple endoscopy—bronchoscopy, esophagoscopy, and direct laryngoscopy—has been debated, but it is advisable for the ideal work-up of an advanced head and neck cancer in a patient with a long history of tobacco and alcohol use.

Since treatment planning depends a great deal on the clinical stage of disease, and since therapies vary greatly in morbidity to the patient, precise and accurate staging is essential. Extent of resection and volume of radiotherapy depend on a reliable assessment of the degree of invasion of the primary tumor. The use of adjuvant chemotherapy or radiotherapy or the inclusion of neck dissection in the surgical plan usually is determined after careful analysis of the neck. Various radiologic studies may help to define the extent of the disease.

Radiologic evaluation of intraoral disease usually involves assessment of the mandible. If tumor abuts the mandible in the lingual or buccal sulcus and is not easily mobile, it may penetrate the cortex. In edentulous patients, tumor descends through the cortical defects left by the previous teeth along the occlusal ridge. Once the medullary canal has been invaded, spread may occur locally or by way of the inferior alveolar nerve. In dentulous patients, direct invasion of the lingual plate occurs, and spread usually does not extend within the bone beyond the extent of the soft-tissue tumor. Dental films taken directly at the site of tumor contact show cortical invasion or widening of the periodontal membrane. Panoramic films and mandibular series show the extent of disease within the mandible by cortical disruption and widening of the inferior alveolar canal or mental foramen. Simple plain-film radiographic analysis of the mandible, however, may be inaccurate, with one series of 111 patients revealing a false-negative rate of 44 percent and a false-positive rate of 9 percent. Technetium-99m radionuclide bone scans have been advocated for diagnosis of mandibular invasion. Although their sensitivity is greater in general than plain films, their specificity is not great, with false-positive rates of 53 percent and false-negative rates of 12 percent. In large tumors bone scans are even more likely to be false-positive because of surrounding inflammation. CT is a highly sensitive method of diagnosing cortical invasion, but the presence of metal tooth fillings interferes with its accuracy (Fig. 15-15). MRI is probably the most accurate and useful method of evaluating the mandible in suspicious but not definitive cases, because it can accumulate and reformat data in any plane without repositioning the patient, it offers superior separation of cortical and marrow images, and it is unaffected by dental fillings.

Analysis of the extent of intraoral and paranasal sinus tumors in difficult-to-examine areas such as the parapharyngeal space, larynx, and nasopharynx is assisted by both CT and MRI. Correlation between extent of disease determined at operation and preoperative CT scanning was found in 78 percent of 26 patients evaluated by high-resolution CT, and 94 percent when MRI with contrast enhancement with gadolinium DTPA was used. Particular advantage is obtained in evaluation of muscle and bone invasion, but mucosal detail is difficult to assess with both CT and MRI (Fig. 15-16).

The administration of agents such as gadolinium with MRI provides better soft-tissue contrast and can suggest the differences between tumor and surrounding inflammation. By reformatting images in several planes, a three-dimensional characterization of the tumor is possible that can better demonstrate tumor relationships to nearby normal structures and can aid in more accurate staging. MRI-directed stereotactic surgical techniques have been used in neurosurgery and in the administration of radiotherapy and may have a role in surgical extirpation of carcinoma of the head and neck.

Since survival seems to depend on eradication of regional as well as local disease, evaluation of the neck for the risk of metastatic disease is crucial to the overall treatment plan. Surgery or radiotherapy may be used to remove regional disease in the lymph nodes if there is disease that is clinically apparent (palpable N+) or if there is high risk of disease in a clinically negative neck (N0). As has been discussed, the size of the primary tumor (T stage), its histologic parameters, and its site all may suggest an increased likelihood of subclinical disease in the neck. Unfortunately, physical examination of the neck may be faulty, with false-negative rates ranging from 16 to 60 percent. Although of some importance, the rates of false positivity are generally lower and usually not as clinically relevant. Lymphangiography has been unrewarding in the evaluation of the neck. CT has recently been evaluated and found in most studies to be slightly more sensitive than physical examination: 82 percent sensitivity versus 75 percent, 93 percent versus 70 percent, and 90 percent versus 82 percent in three studies. Implicit in this advantage is the ability of CT to upstage disease from N0 to N+ and suggest the need for neck dissection. Gadolinium-enhanced MRI appears even more sensitive—92 percent sensitivity versus 82 percent for CT scanning and 75 percent for physical examination—and is also useful in upstaging disease. Although these technologies are not necessary in every case of clinical staging, they are of significant value in decision-making when physical examination of the neck is difficult because of obesity, anatomic variation, or previous surgical or radiation therapy. Micrometastases of less than 3 mm, however, are still undetectable by any available technology, although position emission tomography using fluorine 18-labeled 2-deoxyglucose (PET-FDG) has demonstrated exquisite sensitivity in early studies of squamous cell carcinoma and melanoma metastatic lymphadenopathy.

Therapy

Decision-making on therapy is based almost completely on the clinical stage (TNM) of the tumor at the time of presentation. Although histologic characteristics may to a slight

degree influence the treatment, the size of the local tumor and the extent of invasion of adjacent structures (T stage); the presence or absence, the number, and the laterality of cervical metastases (N stage); and the presence or absence of distant metastatic disease (M stage) dictate therapy. Definitive or curative treatment methods all are oriented toward total extirpation of local and locoregional disease, with the expected subsequent decrease in disseminated disease. Palliative procedures, which may produce relief of pain, relief of airway obstruction, or improvement in local function and hygiene, similarly require complete macroscopic tumor removal at the primary site and in the neck and may occasionally be justifiable in the presence of distant metastases. Subtotal resection of local or locoregional disease is unlikely to be of any benefit in any situation.

Definitive therapy may consist of surgery alone, radiotherapy alone, surgery with radiotherapy as a preoperative or postoperative adjuvant, or chemotherapy delivered either systemically by intravenous route or locally by intraarterial infusion before either or both modalities as neoadjuvant therapy. For small tumors (less than 2 cm, T1), surgery or radiotherapy, well planned and appropriately executed, in most cases will have equivalent local control and survival rates (Fig. 15-17). The choice of the method, then, depends on patient compliance, volition, associated disease, expense, interference with normal function, and available facilities. As the size of the tumor increases to T2 stage or greater, the likelihood of local control and ultimate cure with radiotherapy alone decreases, so surgery or surgery with adjuvant radiotherapy becomes preferable (Fig. 15-18). In the larynx, where staging is more a function of invasion of adjacent structures than of tumor size, and where function is completely dependent on preservation of structure, radiotherapy is usually the first choice for T1 and T2 lesions and is occasionally used as definitive therapy for T3 lesions. Advanced disease has a poor prognosis even with combined treatments of surgery and radiotherapy.

Unfortunately, postoperative adjuvant chemotherapy has been unsuccessful in prolonging life in controlled randomized trials. Despite high response rates to preoperative administration of cisplatin and 5-fluorouracil there has not been the survival advantage that had been demonstrated with chemotherapy for breast disease. One possible role for chemotherapy, however, is as a predictor of successful therapy and thus an indicator of which patients may be treated with radiotherapy instead of surgery with better preservation of function. In several prospective studies patients with T3 or T4 laryngeal tumors were treated with cisplatin, 100 mg/m² body surface area, and 5-fluorouracil, 100 mg/m²/day × 4 for three courses. Patients with complete response (disappearance of all tumor) were then treated by either radiotherapy alone or the more conventional approach of surgery (laryngectomy) with postoperative adjuvant radiotherapy. Patients with less than complete responses were treated with surgery plus radiotherapy. Results show no difference in survival between patients who respond completely to chemotherapy whether they had been treated primarily with surgery, radiation therapy, or not. Patients with incomplete response to chemotherapy had much poorer survival than either group of complete responders. These findings may indicate that the natural history of tumors that respond completely was more benign and that they can be treated less aggressively, preserving function. Approximately 30 to 40 percent of patients treated with chemotherapy and radiotherapy can survive with a preserved larynx. Nonresponders probably demonstrate greater tumor heterogeneity or clonal resistance to therapy and thus are unlikely to have their tumor controlled by any therapy. The results of these trials on carcinoma of the larynx have stimulated investigators to study other head and neck sites for the possibility of organ preservation. Given a 40 to 50 percent complete response to chemotherapy, improved techniques in patient selection (genetic analysis of tumors), and radiotherapy, there is speculation that higher cure rates with preservation of function are possible. Salvage surgery in these previously irradiated patients, however, is difficult, with major complication rates approaching 40 to 50 percent.

The basic principle of solid tumor therapy is en bloc treatment, either resection or radiotherapy of the primary tumor and the regional disease in the neck. The decision of whether to treat the neck or not depends on the presence of clinically discernible metastatic disease or the risk of micrometastases to the neck. As primary tumor size increases, risk of neck disease increases at a greater rate for some primary sites than others (Fig. 15-19). When palpable lymph nodes are present in the neck, confirmation of metastatic disease may be obtained with fine-needle aspiration and cytologic examination, or the decision to proceed with therapy may be made on purely clinical grounds. Palpable or radiologically positive lymph node metastases require surgical therapy in the form of some type of neck dissection, usually performed in continuity with the resection of the primary tumor. Subclinical disease or micrometastases may be treated by a modification of neck dissection or radiotherapy, depending on the modality chosen for treatment of the primary site.

The lymph nodes draining the head and neck are contained in a fascial envelope, between the superficial and deep layers of the investing fascia of the neck. Within the layers of the investing fascia lie the sternocleidomastoid muscle and the spinal accessory nerve (CN XI). The cervical lymph nodes lie between the investing fascia and the deep cervical fascia (Fig. 15-20) or prevertebral fascia and can be removed in toto with the jugular vein, the sternocleidomastoid muscle, and the accessory nerve, as in the classical radical neck dissection described by Crile in 1906 (Fig. 15-21). The lymphatic connections between the tumor and the cervical metastases should remain intact with en bloc resection, and all the lymph- node-bearing tissue of the exposed side of the neck, including the anterior and posterior triangle, is removed.

The major morbidity of neck dissection is secondary to paralysis of the trapezius muscle by resection of the accessory nerve. Because of this, Bocca in 1967 suggested preservation of the nerve. Other surgeons have demonstrated techniques in which the jugular vein and the sternocleidomastoid muscle also can be left intact. These methods are particularly useful in prophylactic (elective) neck dissections when there is no clinical evidence of metastatic disease to the neck. Although there is some debate about the quality of function after modified neck dissection, it seems likely that long-term function is improved when the spinal accessory nerve is preserved, and the likelihood of survival is not significantly impaired by the lesser procedure.

Since the site of potential neck metastasis can be fairly accurately predicted by the location of the primary squamous cell carcinoma, and since the lymph-node-containing areas of the neck have been described as discrete anatomic areas demarcated by muscles, fascial condensations, and the triangles of the neck, it has been suggested that in addition to leaving the accessory nerve and the sternocleidomastoid muscle intact, only those lymph nodes at risk should be resected. The concept of *selective neck dissection*, customized to the site of primary disease, has gained support. Thus for carcinoma of the lip, anterior tongue, floor of the mouth, and buccal mucosa, *supraomohyoid neck dissection* might be used, removing the submental, submandibular, upper and midjugular lymph nodes (Levels I, II, and III). If a nasopharyngeal lesion or posterior scalp melanoma was the primary site, the suboccipital, retroauricular, upper and midjugular, and posterior triangle lymph nodes (Levels II, III, IV, and V) would be removed via a *posterolateral neck dissection*. In primary sites of the pharynx or larynx, a *lateral neck dissection* including upper, middle, and lower jugular nodes (Levels II, III and IV) might be appropriate. In thyroid disease, removal of the paratracheal, perithyroidal, and precricoid nodes in an *anterior compartment neck dissection* might be appropriate (Fig. 15-22). Although it seems obvious that control of disease in the neck by its surgical removal with some form of neck dissection should improve survival, there is no well-designed prospective study to prove the equivalency or superiority of neck dissection or radiotherapy for the clinically negative (N0) neck or to suggest which operation of the several described should be used.

Approximately 70 percent of patients in the United States who present with squamous cell carcinoma of the upper aerodigestive tract have advanced disease, stage III or stage IV. Even with aggressive therapy late- stage disease has a high recurrence rate. Recurrent disease may occur at the primary site in the previously treated neck and in the contralateral neck. Just as with primary disease, the therapy of recurrent disease is based on wide local resection and clearance of the involved or at-risk regional lymph nodes. The extent of resection depends on involvement by tumor and the proximity to the great vessels and the central nervous system. If tissue tolerance to ionizing radiation allows, postoperative adjuvant radiotherapy may be useful, even as a second course. For unresectable recurrent disease, combinations of chemotherapy and radiotherapy or chemotherapy alone as well as laser or other noninvasive surgical methods of tumor reduction may provide some palliation in reducing bulk, alleviating pain and airway compression, but long-term survival does not appear to be improved.

The therapy of distant metastases of squamous cell carcinoma of the upper aerodigestive tract has been unsuccessful. The lung is a common site of metastasis for head and neck cancer, but it must be realized that a solitary lesion in the lung of a patient with a previous squamous cell carcinoma of the head and neck is more likely to be a primary lung cancer than a metastatic deposit. The patient should be aggressively evaluated and treated for that primary cancer. Resection of metastatic disease to the lung, however, has not proved salutary in most cases. Second primary tumors or metachronous tumors are a significant problem in head and neck cancer. Prevention of recurrent disease and of new primary disease and reversion of possible premalignant entities may be possible with chemoprevention. Isotretinoin, a vitamin A analogue, and beta carotene have reduced concomitant premalignant changes, and have possibly reduced the incidence of second primary malignancies in patients with epidermoid carcinoma of the upper aerodigestive tract.

Immunotherapy

Because of prolonged alcohol abuse and coincident malnutrition, many patients with squamous cell carcinoma of the head and neck present with various manifestations of immunodeficiency. There is evidence that anergy and deficient cellular immunity result in poorer survival rates for squamous cell carcinoma of the head and neck as well as for other malignancies.

Cell-mediated immunity has been demonstrated to be depressed in head and neck cancer patients. The cause of this depression is uncertain, however, and surgery, radiotherapy, the malignancy itself, and suppression of natural killer cell function by circulating immune complexes all have been implicated. Natural killer cells have been shown to function as a recognition and defense mechanism against metastatic disease from primary squamous cell carcinoma. The effects of humoral or B-cell-mediated immunity on the progression of head and neck carcinoma are not as clear. Unlike some malignant cells, the squamous cell carcinoma tumor cultures have not been particularly immunogenic, and cell-specific immune manipulation has not yet been achieved.

Nonspecific cellular immunostimulation with various agents, such as levamisole, thymosin, and interferon, however, has shown some promise both as an adjuvant and as palliative method. Natural killer cells from patients with head and neck cancer treated in vitro with interleukin-2 (IL-2) show increased activity after therapy, suggesting that IL-2 negates some of the suppressive agents in the serum. The use of IL-2 has been extended to the clinical arena, with infusion of this agent with intramuscular interferon- α reversing in vivo depressed natural killer cell activity. Perilesional injection of IL-2 in recurrent inoperable head and neck carcinoma resulted in temporary but dramatic response in 65 percent of 20 patients treated. Systemic recombinant interferon- α given intramuscularly resulted in one complete response, one partial response, and two stabilizations of disease in 14 patients treated with a second cycle, with salutary effect being attributed to a rise in natural killer cell activity.

Although the benefit is as yet uncertain, it appears likely that more specific characterization of the antigenic identity of squamous cell carcinoma and more precise manipulation of effector cells through natural or synthetic lymphokines will ultimately help in the adjuvant therapy of head and neck cancer.

Reconstruction

In the treatment of head and neck cancer, as in any other disease, there is a hierarchy of priorities. *Survival* obviously is of first concern and depends a great deal on adequate surgical or radiotherapeutic ablation and possibly adjuvant chemotherapy or immunotherapy. *Freedom from pain* fortunately is accomplished in most cases of successful ablative therapy. Preservation or restoration of *function* as well as *appearance* is the next consideration and relies largely on the ability of the surgeon to repair the created defect with local, regional, or distant tissues. Finally, but perhaps most practically important to the patient, is the *efficiency* of the treatment regimen. Efficiency dictates that the therapy be delivered in a time period commensurate with the natural history of the disease.

Advanced squamous cell carcinoma has a high recurrence rate. Eighty-nine percent of patients whose local or regional disease recurs have their recurrence within 2 years of therapy. Thus restoration of function and appearance in this group of patients with a high failure rate and short disease-free intervals should be performed as quickly as possible. A multiple-stage method of reconstruction carried out over several months may prolong recovery. The most efficient methods are single-stage reconstructions performed at the time of the ablative surgery.

In the past there was considerable reluctance to perform immediate reconstruction after resection of malignancy. Fear of cloaking persistent or recurrent disease, coupled with realistic assessment of the poor results from multiple procedures, led to recommendations that the patient be observed for 1 to 5 years after surgery. The functional disability inherent in major oral or oropharyngeal resection usually mandated permanent gastrostomy for feeding and tracheostomy for safe maintenance of the airway. The attendant loss of taste, speech, swallowing, and other corollary functions made the postoperative state of the patient with head and neck cancer miserable.

Improved methods of reconstruction, better pathologic analysis at surgery, and a more comprehensive understanding of the natural history of the disease have made single-stage reconstruction at the time of the initial surgical resection the current standard of care in most instances. Resection of the primary disease and regional metastatic disease, confirmation of disease clearance by frozen-section examination of the margin of resection, and immediate reconstruction are usually possible for squamous cell carcinoma of the upper aerodigestive tract. In malignancies for which frozen-section analysis may be inaccurate, when bone is involved, in recurrent disease with previous radiotherapy, or when there is uncertainty about other aspects of the resection, secondary reconstruction may be more appropriate.

The upper aerodigestive tract is a complex mixture of cutaneous cover, epithelial lining, bone, and cartilaginous framework all joined in a complex arrangement by muscle and driven in intricate synergy to facilitate the main vegetative functions of the organism, alimentation and respiration. This complex mobile structure and the heavy colonization of the mucosal surfaces by bacteria as well as the deleterious effects of adjuvant radiotherapy (acute inflammation in the early stages and fibrosis and vasculitis in later stages) all make reconstruction extremely difficult.

The basic needs presented by surgical resection are restoration of continuity of the alimentary tube with epithelial lining, provision of reliable external coverage for protection of the great vessels and bony structures, and separation of the central nervous system and upper aerodigestive tract. Restoration of oral continence, facilitation of the coordinated motions of the tongue and larynx, and maintenance of an open passage for swallowing while separating the oral, oropharyngeal, and nasal cavities are refinements on the basic demand that are necessary for a reasonable quality of life. Accurate *analysis of the wound* created by the surgical resection is the first element required for successful reconstruction. Size, exposure of the central nervous system, mobility of the removed parts, presence of bacterial colonization or invasive infection, type of tissue removed (mucosa, bone, cartilage), history of previous surgery or radiotherapy, likelihood of subsequent surgery or radiotherapy, exposure of the carotid or jugular vessels, and effect of external appearance all are important wound characteristics that affect the choice of reconstructive techniques. Whether to attempt to satisfy only the basic reconstructive needs or to restore as many missing elements as possible is a difficult decision involving patient desires and compliance, surgical skill, consideration of disease stage, and many other factors.

The past 15 years have brought enormous advances in reconstructive techniques that have affected mainly the *efficiency* of therapy in restoring the patient to reasonable function and appearance rapidly. Indirectly, however, improved reconstructive techniques have an impact on survival, since more aggressive resections, salvage of radical radiotherapy, and decrease in postoperative complications with attendant infection and malnutrition are accomplished with relative safety. The fundamental improvement has been the ability to transfer large volumes of well-vascularized tissue to the area.

Although flap reconstruction of the external surface of the nose was taught by the early Hindu surgeon Sushruta, and the Renaissance saw a number of reconstructive attempts at nasal and other external defects (by distant flaps attached to the defect and divided after parasitizing their blood supply from local tissues), major reconstructions have been a relatively recent phenomenon. Throughout the development of surgical technique that followed the introduction of general anesthesia in 1846, the principle of random flaps of skin being attached and divided remained the mainstay of the reconstructive effort. Large segments of tissue from the chest and back were moved in multiple stages to the oral cavity, face, and pharynx.

In 1965 Bakamjian described the deltopectoral flap, which possessed an *axial* or direct arterial blood supply from the perforating vessels of the internal mammary artery and vein to the skin of the chest and shoulder. This provided a relatively reliable large segment of tissue that was particularly useful in the reconstruction of the pharynx. The forehead flap, another axial pattern flap, based on the superficial temporal vessels, was described in 1963 and, despite its disfigurement of the donor site, became a useful method of reconstruction of the oral cavity. With the realization in the 1970s that the blood supply to the skin came not only from the randomly oriented subdermal plexus vessels and axial cutaneous vessels but also from perforating vessels from the subjacent muscles, the *musculocutaneous concept* transformed reconstruction, particularly that of head and neck defects. Large flat muscles of the thorax could be rotated on their long vascular pedicles to supply a large volume of well-vascularized tissue in a single operation on the oral cavity, pharynx, or soft tissues of the face. Moreover, if recurrence of disease mandated a subsequent resection, another thoracic musculocutaneous flap was available to repair the defect. The pectoralis major, latissimus dorsi, trapezius, sternocleidomastoid, and platysma muscles all are useful, either alone or with their overlying skin. Now much larger and more complex wounds could be addressed at a single operation, returning the patient to reasonable function and appearance promptly.

Some of the problems with the thoracic musculocutaneous flaps are the effect of gravity on bulky flaps, additive morbidity to the shoulder girdle when neck dissection is performed, and variable blood supply to the skin, particularly in the pectoralis major musculocutaneous flap, depending on where the skin portion of the flap is located. Furthermore, there is no reliable method of transporting vascularized bone with a regional musculocutaneous flap.

Despite these disadvantages, the musculocutaneous concept has made immediate reconstruction of the head and neck resection the accepted procedure in most cases.

An offshoot of the success of reconstructive efforts with musculocutaneous flaps has been the increased interest in vascular anatomy (Fig. 15-23). Subsequent research and improvements in microscope and instrument technology have resulted in the ability to transfer tissue of many different types from various sites of the body by separating arterial supply and venous drainage of the tissue and reattaching it to blood vessels in the head and neck. Bone, muscle, skin, fascia, and combinations of these are available for various sites, as are intraabdominal viscera. Microvascular reconstruction or free tissue transfer has made it possible for the surgeon to close virtually any defect in the head and neck, no matter how large or complex. Even more important, however, is that the large number of methods available allows the reconstructive surgeon to choose the method or methods most suitable to a specific site and analyze the results (Table 15-1). Just as each wound has its own characteristics, so does each flap. Vascular pedicle length, bulk, type of epithelium, presence and durability of bone, and thickness of soft tissue all can be evaluated to select the most appropriate replacement for the individual problem (Fig. 15-24).

Complications

The therapy of squamous cell carcinoma of the head and neck usually requires two potent modalities—surgery and radiotherapy—directed at an area that is heavily contaminated with saprophytic and pathogenic organisms in a patient who is frequently malnourished and immunodeficient, and may be noncompliant. Since many patients present with advanced disease, the failure rate even for combined therapy is high as a result of disseminated disease as well as local or locoregional failure. It is therefore imperative to deliver the therapy in a form that is efficient and results in the patient's rapid return to function, reasonable appearance, and whatever social situation the patient may be able to recover. Recognition of the inevitable sequelae of therapy—complications—and rapid resolution or, preferably, prevention are thus of great importance.

Complications specific to head and neck cancer therapy can be categorized as *anatomic*, injury to nerves or blood vessels within the field of surgery; *physiologic*, the results of interference with blood or lymphatic supply to the area secondary to surgery or radiotherapy; *technical*, surgical rearrangements that result in secondary problems; and *functional* derangements of normal behavior secondary to therapy. All of these can then be grouped into catastrophic or noncatastrophic complications, which will in large part dictate the surgeon's approach to them, whether preventive or therapeutic.

The most appropriate approach to complications is prevention. Restoration of positive nitrogen balance, preoperative pulmonary hygiene, control of diabetes mellitus, and weaning from alcohol and tobacco are important nonspecific measures. Preoperative antibiotics decrease the likelihood of wound infection and its sequelae. Numerous studies have shown that previously administered radiotherapy, particularly if given in definitive therapeutic doses, increases the risk of complication. Dental hygiene or rehabilitation before definitive surgery is important in patients whose mandible has been previously irradiated to prevent subsequent osteoradionecrosis. Patient education is crucial to ensure cooperation in what may be a difficult postoperative rehabilitation.

Other than injury to the thoracic duct, which may result in significant fat and protein loss through a chylous fistula, most *anatomic* complications are nerve injuries, either purposeful or otherwise secondary to primary tumor resection or radical neck dissection. The accessory, marginal mandibular, mylohyoid, and cervical plexus sensory branches are frequently sacrificed in neck dissection. Injuries caused by traction, electrocautery, or other technical misadventure may occur to any structure but are most likely to affect hypoglossal, lingual, mandibular, vagus, phrenic, facial, recurrent laryngeal, motor branches to the cervical plexus and cervical sympathetic chain. Careful technique during surgery, adequate hemostasis to allow good visualization, and knowledge of normal and pathologic anatomy will decrease the likelihood of anatomic complications.

Previous surgery, the planned surgery, and radiotherapy all may interfere with blood supply to the head and neck, resulting in local and systemic problems. Irradiation alone or combined with surgery result in a 22 to 30 percent incidence of clinical hypothyroidism, particularly in laryngeal surgery. Hypoparathyroidism, transient or permanent, may result in up to 10 percent of cases of thyroidectomy and must be considered after laryngopharyngectomy. Obstruction of one or both jugular veins, particularly when combined with lymphadenectomy, results in lymphedema of the face and may result in intracerebral edema, particularly if excessive fluid is administered during surgery. Head elevation, diuretics, and judicious fluid management, however, usually allow collateral flow through the vertebral veins to resolve these problems.

Surgical misadventure, poor planning or execution, or the presence of infection will result in technical complications. Respiratory problems can result from pneumothorax precipitated while operating in the mediastinum or supraclavicular fossa. Hematoma may cause acute upper airway obstruction. Tracheostomy may cause subcutaneous emphysema, tracheoinnominate fistula, or subglottic stenosis. The combination of infection and local ischemia of skin or mucosa may result in wound infection, suture line breakdown, flap necrosis, osteomyelitis, and osteoradionecrosis. Exposure of a previously irradiated carotid artery usually results in a bacterial infection and rupture and must be treated as a surgical emergency. Careful planning, meticulous attention to watertight closure of the pharynx and oral cavity, and provision of adequate independently well-vascularized tissue for reconstruction will minimize the likelihood of *technical* complications.

Restoration of function is one of the main goals of head and neck cancer therapy. Although some dysfunction is inherent in all therapy, proper selection of reconstructive methods, attention to intrinsic function of the structures resected and those remaining, and careful and patient postoperative rehabilitation will decrease the severity of the common functional complications: chronic airway obstruction, aspiration pneumonia, dysphagia, dysphonia, and mental depression.

The potential for catastrophe is great in head and neck cancer surgery. Recognition of a complication and realization of the likelihood of rapid deterioration are important to prevent *catastrophic* complications. Tetany from hypoparathyroidism, acute airway obstruction from hematoma or a dislodged tracheostomy tube, tracheoinnominate fistula, and carotid hemorrhage all can lead to rapid death. Any complication that occurs in a patient who has been previously irradiated must be aggressively resolved. Carotid artery exposure, oropharyngocutaneous fistula, or skin flap necrosis in the irradiated neck could result in subsequent invasive infection of the great vessels and death (Fig. 15-25). Oropharyngocutaneous fistula is relatively common, ranging from 6 to 38 percent of head and neck cancer cases, and can be treated expectantly if salivary flow can be diverted and the carotid arteries protected by well-vascularized tissue. The pectoralis major musculocutaneous flap is a useful method of closing major fistulas and covering the great vessels at the same time. Pharyngocutaneous fistulas of moderate size may be treated by the sternocleidomastoid musculocutaneous flap (Fig. 15-26).

Oral Cavity

Anatomy and Physiology

The anatomic borders of the oral cavity are the mucosal surfaces of the lip externally and the anterior tonsillar pillar posteriorly. The oral cavity usually is considered as a number of distinct entities: the lips, the buccal mucosa, the gums (mandibular and maxillary, including the retromolar trigone), the floor of the mouth, the mobile tongue, and the hard palate. Thus the oral cavity is the aditus of the long seromuscular-mucosal tubular conduit of food and liquid that allows the organism to obtain nourishment. As such it is modified in several ways to facilitate the initiation of alimentation. The lips are a sphincter that allows the oral cavity to be sealed after intake of food and liquid. The buccal surfaces and the buccinator muscles help to collapse and expand the oral cavity to facilitate passage of food back to the pharynx. The hard palate provides a stable platform against which the mobile tongue can push and separates the oral and nasal cavities. The floor of the mouth and the gums are structural components of the reservoir and aid in the preparation functions of the oral cavity in the process of eating; the mobile tongue is the main propulsive agent in the oral cavity. Each site also has a distinct contribution to the modulation of air expelled from the lungs that results in speech.

Therapy

Carcinogenesis in the oral cavity and the natural history of subsequent disease are generally similar independent of anatomic area, although TNM staging has not been a perfect prognosticator for all sites, and histology and site play an important role in outcome. The consequences to the patient of therapy, particularly surgical therapy, however, are very different and depend very much on the function of the area involved and the success with which it can be reconstructed.

Lip Etiology

In the United States and Canada, carcinoma of the lip is common, with a marked male predominance of 20:1. The lower lip is by far the most common site, being involved in approximately 95 percent of cases, and has squamous cell carcinoma as the most common histology. Basal cell carcinoma predominates in the upper lip. The habit of pipe smoking, with chronic thermal injury, was for many years believed to be the carcinogenic stimulus. Recently, however, it has become clear that the protuberant lower lip is exposed to higher doses of ultraviolet radiation, resulting in malignancy that behaves similarly to UV-induced skin cancer. Farmers and other outdoor workers in their sixth to ninth decades, of Celtic and northern European origin, who live in areas of high sunlight exposure are at highest risk. Chronic exposure to sun results in loss of the anatomic vermilion border, the junction between the skin and mucosa of the lip, followed by leukoplakia or carcinoma in situ and by invasive malignancy (Fig. 15-27).

Pathology

Well-differentiated stage I lesions comprise the majority, 60 to 80 percent, of most clinical series. Local recurrence after surgery or irradiation occurs in 10 to 20 percent of cases, but salvage therapy (subsequent surgery with or without radiation or chemotherapy) may be successful. Nodal metastases, usually to the submental or submandibular nodes, are present in 10 to 15 percent of cases and occur in tumors of all histologic differentiation. Treatment by local excision or radiation results in cure rates of approximately 90 percent for stage I disease and 55 to 80 percent in stage II locoregional disease. Aggressive carcinoma of the lip seems to follow a pattern of perineural invasion, down the mental nerve to involve the mandible and pterygoid space, and ultimately via the trigeminal nerve to the base of the skull.

Therapy

Surgical therapy requires resection of the disease with a clear margin of normal tissue around it. If lymph nodes are involved, ipsilateral or bilateral neck dissection is indicated. Elective or prophylactic node dissection for the patient with the N0 neck usually is not recommended in epidermoid carcinoma of the lip. The functional goal in lip reconstruction is restoration of oral continence and reasonable appearance. Because the lower lip is longer and more protuberant than the upper lip, primary closure of defects of approximately 25 percent of the upper lip and 35 percent of the lower lip will result in satisfactory appearance and function. The lip opposite the resection is an important donor site for larger defects. Cross-lip flaps from either the upper or lower lip of the Abbé or Estlander type and advancement of lateral labial and buccal elements are useful, depending on the size and site of the defect. Preservation of sensory and motor function of the remaining orbicularis oris muscle also is possible, to maintain the most efficient sphincter mechanism, using the Karapandzic principle. When the entire lower lip is resected, the damming function can be restored by a radial forearm free flap including palmaris longus tendon, which is inset to the adjacent oral musculature to serve as a dynamic sling. Since the tissue at risk is oral mucosa on the protuberant area of the lip, preneoplastic changes of leukoplakia or dysplasia should be treated by mucosal resection, vermilionectomy (lip shave), and advancement of the labial mucosa to the sun-exposed margin of the skin (mucosal advancement).

Buccal Mucosa Anatomy and Physiology

The buccal mucosa extends from the commissures of the lips to the pterygomandibular raphe and from the maxillary (upper) to the mandibular (lower) alveoli on both sides. The subjacent structures include the buccal fat pad and buccinator muscle, and the surface of the buccal mucosa permits entry to the oral cavity of Stensen's duct from the parotid gland. This area modulates speech and oral capacitance.

Pathology

Buccal mucosa cancer comprises about 5 percent of all oral cancers, and, as with other sites, there is a significant male predominance (3:1). There is a high incidence of advanced disease on presentation, with 18 percent stage I, 36 percent stage II, and 44 percent stage III, with a 56 percent incidence of nodal metastasis. Large cancers of the buccal mucosa are less likely than tumors of other oral sites to have subclinical metastases to the neck. A subset of lesions arising in the buccal mucosa is *verrucous carcinoma*, which presents as an exophytic mass that has the cellular histology characteristic of malignancy but lacks the invasive aspects. Verrucous carcinoma is more common in females than in males and may be related to human papillomavirus. The buccal mucosa is the most common site of this variant of squamous cell carcinoma, which shows warty dense keratinization, sharply circumscribed deep margins, pushing borders, and inflammatory infiltrate. There is a high incidence of multicentricity of malignancy in patients with verrucous carcinoma, with up to 40 percent having other sites of invasive carcinoma, so it probably represents a part of the spectrum of field cancerization (see Fig. 15-10 E). There is some concern that radiation of this lesion may result in dedifferentiation or change to a more malignant histology, but this observation may be a manifestation of tumor cell heterogeneity and clonal resistance to radiotherapy rather than actual malignant degeneration. Carcinoma of the buccal mucosa, both verrucous and infiltrative, occurs commonly in chronic tobacco chewers and snuff dippers in the United States and in people who use *pan* in India and Southeast Asia.

Therapy

Surgical resection with or without adjuvant radiotherapy results in survival rates of 50 to 60 percent, with 60 to 75 percent for localized disease and 25 to 45 percent for locoregional disease. The route of invasion of epidermoid carcinoma of the buccal mucosa is through the buccinator muscle and buccal fat pad dorsally toward the pterygoid musculature or lateral to the skin. In either case significant limitation of oral motion and discomfort on chewing (trismus) occurs.

Surgical resection frequently creates a full-thickness defect of mucosa, muscle, and skin with or without adjacent mandible or maxillary tuberosity. For extensive lesions, restoration of function requires replacement of internal lining as well as external skin coverage. Although the forehead flap based on the superficial temporal vessels and the deltopectoral flap from the shoulder were the standard in the 1960s and 1970s, recent methods have included the combined use of pectoralis major musculocutaneous flap for lining and deltopectoral skin flap for skin coverage or the latissimus dorsi musculocutaneous flap folded on itself to provide both internal and external surfaces (Fig. 15-28). Fasciocutaneous flaps such as the scapula and radial forearm can provide ample tissue for both defects and vascularized bone as well when transferred as a microvascular free flap. For smaller defects, intraoral flaps of mucosa and muscle such as tongue flaps, palate mucoperiosteal flaps, or advancement flaps have been useful. Split-thickness skin grafts, though successful in the short term, ultimately result in fibrosis and difficulty with chewing. For superficial lesions that extend over the mandibular alveolus and require supple coverage, the platysma musculocutaneous flap is an excellent choice (Fig. 15-29).

Hard Palate Pathology

The roof of the mouth, bounded by the soft palate posteriorly and the teeth anteriorly and laterally, is not a common site of intraoral squamous cell carcinoma. More common in this area are tumors, both benign and malignant, of the minor salivary glands (Fig. 15-30). Squamous cell carcinoma in the United States usually is a disease of elderly male smokers and remains superficial for prolonged periods before extending through periosteum and bone and spreading either cephalad into the nasal cavity or maxillary antrum or dorsally through the pterygopalatine fossa. Epidermoid carcinoma of the hard palate is more common in India and Venezuela, where reverse smoking (with the lighted end of the cigarette inside the mouth) is practiced.

Therapy

Treatment is surgical resection with or without adjuvant radiotherapy. Because of the underlying bone, definitive radiotherapy is rarely useful. Cervical metastases are relatively rare in disease of the hard palate, with only 10 to 25 percent of patients presenting with disease at either the prevascular facial nodes or the jugulodigastric nodes. Occult metastases are rare, so elective neck dissection is not part of the therapeutic regimen. Five-year survival rates range from 33 to 75 percent, depending on stage, with an average of 55 to 60 percent for all patients.

Small to moderate-sized defects of the hard palate are best treated with a dental prosthesis in both the dentate and edentulous patient; massive defects may require temporalis muscle flap or local flaps and skin grafting or free tissue transfer, since support for the prosthesis may not be available. The inflammatory process of the minor salivary glands of the hard palate, necrotizing sialometaplasia, which produces an ulcerative lesion with erythematous borders similar to squamous cell carcinoma, may be confused with malignancy. Biopsy examination, however, will show no evidence of malignancy, and the disease is self-limited, usually requiring no therapy.

Floor of Mouth Anatomy and Physiology

The floor of the mouth is the horseshoe-shaped area between the mobile tongue and the lingual surface of the mandible. The papillae that allow Wharton's ducts to empty into the oral cavity lie at the anterior border of this area; posteriorly, the floor of the mouth blends into the glossopalatine fold and the retromolar trigone. In this natural reservoir there may be prolonged contact of the floor of mouth mucosa with carcinogenic agents dissolved in the saliva after oral ingestion or inhalation. This area provides capacity, allowing the tongue to sit low in the mouth, thus increasing the volume of the oral cavity and preventing obstruction of the direct route between the lips and the pharynx.

Pathology

Approximately 13 to 17 percent of oral lesions arise in this area, the third most common site after the lip and mobile tongue. Because of the proximity of the mucosa to the hyoglossus and mylohyoid muscles of the submandibular triangle, and because of the rich lymphatic supply, direct extension of tumor into the neck and bilateral cervical metastases are frequent, especially in anteriorly located lesions. Medial growth at the primary site also invades the ventral surface of the tongue, and lateral growth invades the mandible. Advanced-stage disease is common, with 46 to 52 percent of patients presenting with stage III or stage IV disease. Subclinical disease in the neck or micrometastases in the clinically negative neck are common, with overall neck involvement increasing with primary tumor size and ranging from 15 percent for tumors less than 2 cm (T1) to 50 percent for tumors greater than 4 cm (T3).

Therapy

Because the tumor may abut or actively invade the mandible, resection with an adequate margin of normal tissue in this area frequently requires removal of the mandibular periosteum or actual resection of a segment of mandible. Uncertainty about invasion of the mandible or proximity may require removal of the medial cortex (marginal mandibulectomy) or a segment of the mandible. Because of the proximity of the mandible, therapeutic doses of radiation may result in ischemic necrosis of the bone, osteoradionecrosis. Combined therapy, surgical resection of the primary tumor with neck dissection en bloc or pull-through resection followed by adjuvant radiotherapy, is appropriate for advanced disease. Survival rates are strongly dependent on stage, ranging from 68 to 91 percent for stage I to 35 to 46 percent for stage III disease. Recurrence at the primary site frequently involves the mandible or the suprahyoid complex of muscles and may require laryngectomy because of invasion of the preepiglottic space.

Reconstruction of the floor of the mouth presents a number of challenges. The watertight seal of the oral cavity, the continuity of the mandibular arch, and the mobility of the tongue all depend on this area. For superficial lesions with normal well-vascularized muscle beneath them, split-thickness skin grafts have been advocated. Although they may be successful initially in covering the area, the contracture inherent in this method may result in tethering of the mobile tongue to the subjacent muscle or to the mandibular periosteum. If the neck is not involved by tumor, a musculocutaneous island flap of platysma muscle based on the facial artery provides supple skin coverage. Bulky thoracic musculocutaneous flaps, such as pectoralis major, provide skin for lining but may be compressed by the intact mandible, resulting in ischemic necrosis, or may push the tongue back in the oral cavity, limiting movement and obstructing the pharynx and airway. The thin pliable skin of the volar forearm, based on the radial artery and its venae comitantes as the radial forearm free flap, provides an excellent lining for this area that can drape over the mandible and allows free movement of the tongue while providing a watertight seal. Vascularized segments of bone and skin of varying size also are available as free tissue transfers from the fibula, scapula, dorsum of the foot, and other sites with high success rates if the mandible must be resected (Fig. 15-31).

Gums, Gingivae, Alveolar Ridge Pathology

Squamous cell carcinoma arising on the gums constitutes 10 to 17 percent of oral cavity malignancies. Eighty percent of lesions arise on the mandibular alveolus. Although the male predominance persists at this site, there seems to be a less direct relationship with tobacco and alcohol, and the causation may be related in some cases to chronic trauma from poorly fashioned dentures or jagged teeth. The thin layer of mucosa allows invasion of the underlying mandibular or maxillary bone in 35 to 50 percent of cases. Direct invasion through the periosteum is most common in patients with teeth, but spread through the empty sockets along the occlusal ridge and subsequent perineural invasion are common in edentulous patients. Cervical metastases occur in 30 to 45 percent of the cases, depending largely on the size of the primary.

Therapy

Surgical resection requires removal of the subjacent bone by partial or total maxillectomy or total mandibulectomy. Maxillary defects of moderate size can be treated with dental prostheses, and mandibular defects reconstructed with various combinations of skin and bone as previously described.

Oral Tongue Anatomy and Physiology

The tongue is a complex muscular structure covered with mucosa and receiving motor innervation from the hypoglossal nerve. The bulk of the tongue is made up of the superior and inferior longitudinal muscles joined by the vertical and transverse intrinsic muscles. Inferoposteriorly and laterally the tongue is connected to the hyoid bone by the hyoglossus muscle, and superiorly and anteriorly to the mandible by the genioglossus muscles. The styloglossus and palatoglossus muscles attach the tongue superiorly to the base of the skull. These junctions allow the tongue great mobility, promoting synergy with the larynx and the pharyngeal and palatine muscles. Beneath the smooth ventral surface of the tongue, along the floor of the mouth, are the numerous openings of the sublingual ducts. On the dorsal surface are papillae, with specialized sensory organs for taste at the base. Also opening onto the tongue are the ducts of the minor salivary glands. Sensation is provided to the tongue by the lingual nerve carrying fibers of cranial nerve V, and taste by the glossopharyngeal and chorda tympani of VII. Differentiation of sweet, sour, salt, and bitter taste relies a great deal on intact function of the tongue. As a mucosa-covered muscle, the tongue is the major propulsive force in the oral cavity. It initiates and continues movement of the food bolus to the pharynx, generating pressure of up to 120 mmHg. Numerous investigators have demonstrated that dysfunction after surgery for oral cancer depends almost exclusively on the amount of tongue resected.

Pathology

In most series of oral cancers, the oral or mobile tongue is second only to the lip as the most common primary site. Tobacco and alcohol are the most common associated factors, but chronic irritation from jagged teeth or dental appliances also may be involved. Although the sixth and seventh decades are the peak periods, sporadic occurrence of squamous cell carcinoma in the tongue has been described in patients under thirty and in renal transplant and other immunosuppressed patients and may not be linked to the usual carcinogenic stimuli. In India, submucosal fibrosis seems to be a predisposing influence, and in Scandinavia, Plummer-Vinson syndrome, glossitis, iron-deficiency anemia, and achlorhydria may be related.

Malignancy of the mobile tongue occurs most frequently at the midportion of the lateral tongue and is frequently asymptomatic (Fig. 15-32). Radial spread through the tongue may extend submucosally to the base of the tongue and across the midline or laterally to the floor of the mouth. Because of the rich lymphatic supply, ipsilateral metastases are common to the submandibular and submental nodes. Clinical evidence of cervical metastasis is present in 40 to 61 percent of patients, and subclinical disease in the N0 neck is found in 25 to 31 percent. As in other sites, the presence of lymph node metastases seems to be the most important prognosticator, with survival rates of 73 to 92 percent for localized disease (T1, T2, N0) and only 31 to 45 percent with regional metastasis.

Therapy

Definitive therapy for carcinoma of the oral tongue can be attempted with either external beam radiotherapy or interstitial radiotherapy. External radiation in doses to 65Gy may be useful, but with the implantation of afterloading devices (tubes into which iridium-192 or radium needles can be placed) doses in the range of 100Gy to 150Gy can be delivered over a small area with greater effect.

The surgical therapy of carcinoma of the tongue consists of resection of the tumor with a margin of normal tissue and en bloc removal of the regional lymph nodes. Unfortunately, evaluation of the extent of local disease is difficult in tongue cancer. Although several authors have demonstrated respectable 5-year survival rates (48 to 62 percent) with partial glossectomy with or without en bloc or discontinuous neck dissection, a generally accepted uneasiness about the ability to obtain clear margins has led to the common use of adjuvant radiotherapy. Hemiglossectomy, or resection to the median raphe, has been advocated by some for lesions involving any part of the lateral tongue.

Extensive lesions of the tongue may extend posteriorly to involve the larynx. Even in those patients who do not demonstrate invasion of the larynx, widespread involvement of the tongue or resection of the base of the tongue may predispose the patient to aspiration and ultimate respiratory failure. Despite skepticism on the part of some surgeons, total glossectomy with or without laryngectomy has been shown to be a valuable procedure for both cure and palliation. A 3-year survival of 53 percent has been achieved in one series, with 80 percent of patients demonstrating intelligible speech if the larynx is preserved and 93 percent regaining the ability to maintain their nutritional status by oral alimentation.

Although attempts have been made to innervate muscle of various types transplanted to replace the tongue, there is no satisfactory way to reconstruct the tongue. Denervation of the tongue by resection of, or injury to, both hypoglossal nerves usually renders the patient incapable of swallowing or of effective speech. After surgical resection of a portion of the tongue, the reconstructive goal is to allow free mobility of the remaining tongue while providing a watertight seal to the oral cavity. If the floor of the mouth is not involved in the resection, simply skin grafting of the raw surface may suffice. Suturing the edge of the resected tongue to alveolar or buccal mucosa usually tethers the tongue, impeding its mobility. Advancing the posterior mobile tongue or setting back the excess anterior tongue may provide the optimal solution. Although the pectoralis major flap has been advocated for intraoral reconstruction, its bulk tends to push the tongue back or pull it down into the neck, interfering with its motion and the subsequent elevation of the larynx necessary for effective swallowing and speech. Furthermore, its thickness and weight effectively fix the tongue to the adjacent mandible, further interfering with its motion. The lateral arm or radial forearm free flap provides lightweight supple tissue more appropriate for restoring tongue, floor of mouth, and mandibular alveolar epithelial lining.

The defect of total glossectomy consists of the tongue, floor of the mouth, and sometimes pharyngeal and laryngeal mucosa. Restoration of oral continence usually requires significant amounts of soft tissue. The pectoralis major flap serves well to replace the entire floor of the mouth, as does the jejunal free flap, which also can replace the pharynx and cervical esophagus. If the larynx is preserved in total glossectomy, the radial forearm free flap serves as an excellent diaphragm to pull the hyoid bone anteriorly toward the mandible and assist in swallowing.

When a portion of mandible must be resected for carcinoma of the oral tongue, the urgency of reconstruction depends on what part of the mandible has been resected. Although any mandibulectomy results in some dysfunction, partial mandibulectomy lateral to the mental foramen usually is well tolerated, the main morbidity being weakness of chewing and malocclusion of the remaining teeth. Resection of the symphysis or anterior segment of the mandible, however, is a much more devastating problem and requires immediate reconstruction. Vascularized bone from scapula, fibula, iliac crest, radius, or metatarsal is excellent for reconstruction. If appropriate soft tissue is not available, two free tissue transfers can be performed to satisfy the individual needs of the wound.

Pharynx

Anatomy and Physiology

The pharynx is the continuation of the muscular tube that constitutes the alimentary tract. It is anatomically divided into three sections, each with a slightly different function: the nasopharynx, the oropharynx, and the hypopharynx (see Fig. 15-4). An important role of the pharynx is separating the respiratory and the alimentary tracts, and its specialized structures reflect this function. The nasopharynx is unique in the pharynx in that it is a rigid cavity bounded on three sides by bone—superiorly by the base of the skull and posterior sphenoid sinus, anteriorly by the posterior rim of the ethmoid plate and the choanae, passages from the nasal cavity into the nasopharynx, and posteriorly by the pharyngeal tubercle of the occipital bone and the atlas and axis, with their prevertebral fascial and muscular coverings. The inferior surface is the nasal side of the soft palate. The lateral sides of the nasopharynx give entry to the eustachian tubes (to decompress the middle ear), and the roof is the site of a collection of lymphoid tissue, the pharyngeal tonsil.

The oropharynx is the muscular tube that serves as transit area from the propulsive oral cavity and the recipient nasal cavity to the alimentary and respiratory tracts. This mucosa-lined muscular tube contains the base of the tongue (from the circumvallate papillae back), the tonsils, the oral soft palate, the lateral pharyngeal walls, and the posterior pharyngeal wall. The dominant muscular entity that receives the propulsive energy of the tongue is the superior constrictor muscle, attached on both sides to the pterygomandibular raphe and wrapping 270 degrees to constitute the posterior and lateral walls. Contraction of this muscle closes the palatopharyngeal sphincter, or Passavant's ridge, elevating the palate. This action closes the nasopharynx and pushes the bolus of food into the hypopharynx. Up-and-down motion of the palate is regulated by the tensor veli palatini and levator veli palatini muscles (attached to the base of the skull) and the palatopharyngeus muscle (attached to the lateral pharyngeal wall). Lack of synergy in these muscles is seen in patients with cerebrovascular accidents and hypoxia neonatorum and markedly interferes with speech and swallowing.

The anatomic boundaries of the hypopharynx are reflections of the anatomy of the larynx. The posterior pharyngeal wall runs from the tip of the epiglottis to the inferior border of the cricoid cartilage. The anterior border is the postcricoid mucosa, and the lateral surfaces are the mucosal cavities on both sides of the larynx known as the pyriform sinuses. The middle pharyngeal constrictor muscle, with its attachments to the hyoid bone and prevertebral fascia, and the inferior pharyngeal constrictor, with its distal condensation of the

cricopharyngeus muscle attached to the lateral surfaces of the thyroid and cricoid cartilages, serve as the pharyngeal sphincters. When they contract they close off the entrance of the cervical esophagus to air and direct it through the larynx. When they relax they allow food through the pharynx and into the cervical esophagus. The inferior constrictor and cricopharyngeus muscles serve as the upper esophageal sphincter and may become hypertonic, a condition known as cricopharyngeus spasm. Zenker's diverticulum, a lateral outpouching of the pharyngeal wall that may collect undigested food and result in chronic aspiration, is the consequence of chronic hypertension of the upper esophageal sphincter (Fig. 15-33). Resolution of this upper esophageal sphincter hypertension has been obtained temporarily by injection of botulinum toxin, but permanent treatment requires transection of the muscle (cricopharyngeus myotomy) with or without resection and closure of the mucosal diverticulum.

Base of Tongue Pathology

Carcinoma arising behind the circumvallate papillae in the base of the tongue frequently remains asymptomatic and undiagnosed until late-stage disease has developed. Even when patients complain of pain, either local or referred, as with otalgia, difficulty in examination or reluctance of primary care physicians to perform indirect laryngoscopy and palpation of the base of the tongue results in misdiagnosis and prolonged therapy for pharyngitis, tonsillitis, and other less serious problems. The central location gives rise to cervical lymphatic metastases in up to 70 percent of patients, and there are bilateral metastases in 17 to 25 percent of cases.

Histology and gross morphology in this region predict to some degree the behavior of the lesion and the appropriate therapy. In addition to epidermoid carcinoma, minor salivary gland lesions are also seen. Exophytic lesions, with cells resembling lymphocytes and absence of keratin pearls, arise in the tissues of Waldeyer's ring, the tonsils (lingual and palatine), and the base of the tongue. These lymphoepitheliomas behave like nasopharyngeal carcinoma and have been characterized as undifferentiated carcinomas with lymphocytic infiltration. Such lesions are more radiosensitive, both at the primary site and as cervical metastases, than most other infiltrative keratin-producing squamous cell carcinomas, with 2-year local control rates of 75 percent for T1 lesions and 67 percent for T2 lesions.

Carcinoma arising in the base of the tongue spreads anteriorly into the oral tongue, superiorly up to the tonsillar pillar, and inferiorly into the lateral pharyngeal wall and into the vallecula, preepiglottic space, and larynx. Because of the proximity and functional relationship of the base of the tongue to the larynx, interference with laryngeal elevation and closure of the epiglottis, with the attendant aspiration pneumonitis, is a hallmark of carcinoma of the base of the tongue.

Therapy

Advanced disease at the primary site or disease with cervical metastases requires surgical therapy. If the lesion is lateral enough, partial glossectomy may be adequate. Since resection of the base of the tongue usually removes the hypoglossal nerve to the tongue in that area, subtotal or posterior glossectomy is unlikely to leave functional tongue. Radical resection may require total glossectomy with or without laryngectomy (Fig. 15-34). In most patients, if the oncologic requirements of the resection do not dictate removal of the larynx, reconstruction with the larynx in situ is appropriate. Surgical therapy or surgery combined with postoperative adjuvant radiotherapy results in 5-year survival rates of 50 to 60 percent for stage III disease and 20 to 25 percent for stage IV disease. Advanced primary disease or disease in the neck is unlikely to be successfully controlled locally with radiotherapy alone, and surgical salvage after radiotherapy has been dismal, with a high incidence of osteoradionecrosis of the mandible.

Reconstruction of defects arising from resection of the base of the tongue should effectively close the pharynx and oral cavity with tissue that will heal primarily and withstand subsequent irradiation and still not interfere with the function of tissues left intact by the curative resection. Elevation of the larynx, the normal motion that occurs during the early pharyngeal phase of swallowing to close the epiglottis, cannot occur if the tongue is tethered to the side of the pharynx or oral cavity or if bulky tissue such as the pectoralis major flap is interposed into the area of the resection. The provision of sensate tissue into the area surrounding the larynx, to prevent aspiration, is also an important consideration. Occasionally local tissue can be mobilized for closure without tension to avoid fistula formation and to provide sensate mucosa. More commonly, however, mucosa or skin to line the tongue, mandible, and pharyngeal wall is necessary. Buccal and palatal flaps have been described for small and moderate-sized defects, but free tissue transfer of skin from radial forearm or lateral arm or lateral thigh flaps are more appropriate for the more common extensive defects. Neurotized free tissue transfer reconstructions of the pharynx and oral cavity have shown two-point discrimination and other measures of sensitivity that are characteristic of the recipient site (upper aerodigestive tract) rather than the donor site (arm, back), suggesting that cerebral cortical integration of the reconstruction favors the recipient site.

Tonsil Pathology

Squamous cell carcinoma of the tonsil may arise in the tonsil, the tonsillar bed, or the tonsillar pillars (Fig. 15-35). As one of the Waldeyer's ring structures, the tonsil shows a higher incidence of lymphoepithelioma than other sites. Whatever the histology, it is second only to the larynx in frequency as a site of upper aerodigestive tract primary malignancy, with 12,000 new cases per year in the United States. Like most upper aerodigestive tract tumors, tonsillar carcinoma presents with predominately late-stage disease, with 28 to 32 percent of patients presenting with stage I or stage II disease, 35 to 40 percent stage III, and 40 to 45 percent stage IV. Cervical metastases at the time of presentation are seen in up to 67 percent of patients, and subclinical disease in the N0 neck in 10 percent of patients. Determination of the extent of local disease in advanced tumors is of considerable importance in decision-making and execution of therapy. Growth of the tumor upward into the soft palate occurs in 60 percent of patients, downward to the base of the tongue in 56 percent, into the nasopharynx in 9 percent, and down the lateral pharyngeal wall to the epiglottis in 27 percent of cases. The site of local extension is particularly important, because in treating patients with radiotherapy, geographical misses as a result of underestimating the local extent of disease were a common reason for failure.

Therapy

Carcinoma of the tonsil appears to be more radiosensitive than other primary-site squamous cell carcinomas. The usual approach to disease originating at this site is to treat for curative intent with radiotherapy ranging from 55Gy to 70Gy to the primary site and bilateral cervical lymph node drainage areas (Fig. 15-36). If there is bulky neck disease or extension of the primary tumor into adjacent bone or pterygoid muscles, surgical resection, reconstruction, and postoperative adjuvant radiotherapy are safer and more effective. Risk of local recurrence is directly related to size of the primary tumor, and recurrence is even more likely when the predominant spread of tumor was into the base of the tongue.

The challenge of reconstruction in tonsillar disease is a function of the dimensions of local growth of the lesion and the history of previous radiation. The soft-tissue defect in the lateral wall of the pharynx created by a superficial lesion can easily be resurfaced with a skin graft, a deltopectoral flap, or a fasciocutaneous free flap. Radial spread up to the soft palate or down into the pharynx demands that the surface of the flap be contoured in several planes without obstructing the pharynx, usually requiring a free tissue transfer of relatively pliable skin, such as the radial forearm, lateral arm, or lateral thigh. Invasion of the ascending ramus of the mandible can be treated by addressing the soft-tissue defect alone by transposing a pectoralis major musculocutaneous flap into the lateral pharynx, using the skin for internal lining and the muscle for coverage of the carotid vessels in the neck. In the patient with teeth, soft-tissue reconstruction alone will lead to malocclusion of the dental arches and other problems. Skin and bone together are available with a number of methods. The scapula and the deep circumflex iliac artery free flaps are particularly suited to the lateral defect created by radical resection of the tonsil and mandible.

Soft Palate Anatomy and Physiology

The soft palate is the mucosa-lined fusion of the inferiorly based palatopharyngeus and palatoglossus muscles and the superiorly based levator and tensor veli palatini muscles. Extending backward from the posterior margin of the palatine bone, directly opposite the superior constrictor muscle and its bulge, which creates Passavant's ridge, its main function is to open and close the passageway between the nasal cavity and nasopharynx and the oral cavity and oropharynx. This obturating and modulating effect has obvious importance in speech and in swallowing.

Pathology

Isolated carcinoma of the soft palate is rare, the disease usually occurring in combination with other frank malignancies or premalignant entities such as leukoplakia or erythroplakia and not showing the usual male predominance.

The oral side of the soft palate is by far the most common site for malignancy, which usually extends down the tonsillar pillars to the base of the tongue. Superior and posterolateral spread to the nasopharynx and posterior pharyngeal wall is less common. Ipsilateral cervical lymph node metastases to the jugulodigastric nodes occur in 40 to 50 percent of cases, and, because tumors often pass over the midline, bilateral metastases are seen in 15 percent of cases.

Therapy

Treatment of soft palate carcinoma follows the usual principle that small primary lesions are effectively eradicated by radiotherapy in the range of 65Gy and that combined therapy, surgery with adjuvant radiotherapy, is necessary for best results in larger tumors. The importance of radiotherapy as a treatment was particularly emphasized in the past because of the inability to reconstruct the soft palate and the devastating functional result. Nonrandomized studies of surgery and radiotherapy have shown 5-year survival rates of 31 to 44 percent, with the size of the primary lesion, the absence of a synchronous primary upper aerodigestive tract tumor, the absence of cervical metastases, and moderately to well differentiated histology being favorable prognostic features.

Resection or dysfunction of the soft palate results in escape of air and oral contents into the nasal cavity and ultimately out the nares. Advances in prosthetic technology have made the use of a dental prosthesis a possible solution in some cases. For defects that do not include the lateral and posterior pharyngeal wall, a superiorly based flap of pharyngeal mucosa and muscle sutured into the margin of the palatal resection will obturate the opening between the nasopharynx and oropharynx. More extensive defects require the introduction of epithelium-lined soft tissue; the lateral arm, lateral thigh, and radial forearm free flaps are ideal when soft tissue alone is needed, and the scapula free flap when both skin and bone are necessary (Fig. 15-37).

Posterior Pharyngeal Wall Anatomy

The posterior and lateral pharyngeal walls extend from the oropharynx down into the hypopharynx, where the lateral pharyngeal walls end as the lateral walls of the pyriform sinus and the posterior wall extends to the cervical esophagus. The lymphatic drainage of the posterior pharyngeal walls is to the jugulodigastric, midjugular, and juguloomohyoid nodes but also directly to the retropharyngeal group of lymph nodes.

Pathology

Because of its location and the nonspecific symptoms of mild dysphagia andodynophagia, squamous cell carcinoma of the posterior pharynx usually is detected at a late stage, with 39 to 55 percent of patients presenting with palpable cervical metastases. Local spread of disease is cephalad toward the nasopharynx and lateral to the lateral pharyngeal walls and larynx.

Therapy

Using combinations of surgery and radiotherapy, 3- to 5-year survival rates of 25 to 32 percent overall have been reported.

The location of the posterior pharyngeal wall as the farthest border of the aerodigestive tract and its proximity to the larynx have presented some problems both of access for surgical resection and of potential for appropriate reconstruction. Accurate resection of local disease requires visual access. Midline division of the lip, mandible, and tongue, the

median labiomandibular glossectomy, allows visualization of the posterior pharynx. If disease is limited to the posterior wall, the surface can be relined with a split-thickness skin graft or allowed to epithelialize. Circumferential disease requires more complete pharyngeal resection and sometimes pharyngolaryngectomy. Reconstruction of the complete or partial circumferential defect may be accomplished with a free autograft of jejunum or a radial forearm free flap. If the larynx can be preserved, aspiration will be less likely if free mobility of the larynx is maintained and sensate epithelium is restored, either by sensory-innervated free tissue transfer or by skin grafting.

Hypopharynx Pathology

In addition to the posterior pharynx, the hypopharynx contains the pyriform sinuses and the postcricoid area. Tumor growth in this area, the lateral and posterior mucosal border of the larynx, is intimately related to the function of the larynx, a facet recognized in the staging systems used in assessing the extent of hypopharyngeal disease (Fig. 15-38). Thus the T stage of the pyriform sinus lesion increases not with tumor size but with extent into the medial wall or with fixation of the vocal cord caused by direct extension of disease. Another consideration in hypopharyngeal carcinoma, as in disease of the cervical esophagus, is the problem of submucosal extension of tumor. Spread of disease into the cervical esophagus discovered at surgery may simply represent clinical understaging of disease, but it also could be multifocal disease or field cancerization. Local spread of disease is cephalad toward the nasopharynx or distal into the cervical esophagus, as well as medial and lateral toward the larynx. Advanced-stage local disease is common, with only 10 to 15 percent of cases confined to only one site in the hypopharynx.

The lymphatic drainage of the area is copious, with primary nodal stations in the midjugular, juguloomohyoid, and retropharyngeal lymph node chains. Even with small lesions there is a likelihood of lymph node metastasis, with 55 to 64 percent of patients presenting with palpable lymphadenopathy, and 41 percent of patients with clinically negative N0 necks demonstrating metastatic disease after elective neck dissection. Even with small primary lesions (T1) localized to one part of the hypopharynx, the risk of cervical micrometastases in the clinically negative neck is high (40 percent). Distant metastases at presentation and with treatment of disease appear to be more common than at other primary sites, occurring in up to 47 percent of the cases.

Therapy

Since it is unusual for hypopharyngeal lesions to present at an early stage, the treatment usually is combined, consisting of surgery followed by adjuvant radiotherapy. The extent of the operation depends on the proximity to the larynx, and the laryngopharyngectomy with bilateral modified neck dissection is the procedure that is most frequently necessary. With such an approach, survival rates of 20 to 40 percent have been achieved.

When the larynx can be saved, primary closure of the surgical defect is the most effective method. Preservation of the superior laryngeal nerves, the sensory innervation to the area, is an important consideration to allow swallowing to proceed without aspiration. When the larynx is removed with the hypopharyngeal lesion, however, the goals of reconstructive surgery are rather simple restoration of alimentary continuity with the least likelihood of fistula formation or other devastating problems and with the ability to restore esophageal speech. Primary closure of the pharyngeal mucosa after partial laryngopharyngectomy for pyriform sinus lesions results in a high likelihood of fistula formation (43 percent) and stenosis (48 to 73 percent), both of which interfere with swallowing and esophageal speech (Fig. 15-39).

Although use of local tissue, including the anterior wall of the larynx and the base of the tongue, and skin of the neck has been described, the extent of surgery, the history of previous radiotherapy, or the likelihood of subsequent adjuvant radiotherapy usually require the importation of distant tissue. The deltopectoral flap from the chest was the mainstay of pharyngeal reconstruction after laryngectomy but is at least a two-stage procedure with a fairly high risk of failure or persistent fistula. The pectoralis major musculocutaneous flap has been advocated for both circumferential and partial defects of the pharynx. The effect of gravity, the inhomogeneous blood supply, and the bulk of the flap result in a high rate of fistula formation and dysphagia, making a free autograft of bowel or skin a preferable method. When a circumferential defect is present, the problem of bulk and gravity can be circumvented somewhat by skin grafting the prevertebral fascia as the posterior wall of the neopharynx (new pharynx) and using the pectoralis major muscle and its overlying skin as a 270- degree reconstruction to complete the pharyngeal conduit.

When total esophagectomy is part of the treatment for carcinoma of the hypopharynx, transposition of the stomach or colon through the thorax can reconstitute the alimentary canal. Gastric pull-up—in which the stomach, based on the right gastric and gastroepiploic vessels, is brought through the chest, and the fundus or cardia sutured to the base of the tongue or pharyngeal remnant—is a fairly reliable technique but has a mortality rate of 10 to 20 percent in most series. Right or left colon interposition usually is reserved for caustic strictures but occasionally is useful in hypopharyngeal or cervical esophageal lesions.

Reconstruction of the circumferential defect resulting from pharyngolaryngectomy by transfer of a free autograft of bowel and revascularization of microvascular anastomosis was first performed in the early 1960s. Although colon, stomach, and jejunum have all been used, the greatest experience has been with jejunal free autograft. Successful reconstruction using the jejunum, either in a tube reconstruction for circumferential defects or as a patch for partial defects, has been achieved in 92 percent of patients treated with this method, allowing 83 percent of the total group to achieve total oral alimentation. Mortality with this method has been less than 5 percent, with few abdominal or thoracic problems. Complications in the neck, though frequent, usually resolved without further surgery, and the segment of bowel was able to withstand radiotherapy without major problems (Fig. 15-40). Although segments of jejunum may be used in the unusual situation in which the larynx has been left in situ, the secretory nature of the mucosa sometimes makes aspiration a problem, and another method may be preferable. In addition to segments of bowel, fasciocutaneous free flaps from the radial forearm, lateral arm, lateral thigh and posterior thigh have been used as either a tube or a patch for hypopharyngeal reconstruction.

Squamous cell carcinoma of the cervical esophagus presents the same reconstructive demands as that of the hypopharynx; when disease is localized, the resected portion esophagus may be replaced with a patch of skin as either a vascularized transposition flap or a free tissue transfer. The mode of spread of the local disease, however, may involve submucosal skip areas and thus require total esophagectomy. The lymphatic drainage of the cervical esophagus is oriented more toward the mediastinum and parapharyngeal nodes than laterally into the neck, and hence a different approach is required for lymphadenectomy.

Nasopharynx Etiology

Carcinoma of the nasopharynx is seen intermittently in the Western world, comprising about 0.25 percent of new cancers in the United States. It is endemic in southeastern Asia, however, particularly in southern Chinese populations such as those originating from Kwantung province and constitutes 21 percent of cancers in Taiwan, 18 percent in Hong Kong, and 14 percent in Indonesia. The incidence is much lower in Asians who have immigrated to North America but still seven times higher than in the white population, suggesting genetic susceptibility to an environmental carcinogen. The sporadic and genetically linked cases of nasopharyngeal carcinoma behave in the same manner. There is a high association of the Epstein-Barr virus with this malignancy.

Pathology

The nasopharynx is a small, mucosa-lined, boxlike cavity at the base of the skull containing the pharyngeal tonsil and the openings of the eustachian tubes and the sphenoid sinus. Tumors arising in this area present local symptoms that vary with their pattern of growth and spread. Lesions that are exophytic and grow out into the cavity may obstruct the eustachian orifices or the choanae, leading to hearing loss (15 percent), nasal stuffiness or obstruction (30 percent), and epistaxis (22 percent). Infiltration and bony erosion of the base of the skull into the cavernous sinus results in cranial nerve palsies in 16 to 25 percent of cases, the most commonly involved being the abducens nerve, followed by the trigeminal nerve and the oculomotor nerve, resulting in paresthesias and diplopia. The most common presenting sign of nasopharyngeal carcinomas is a mass in the neck secondary to cervical metastasis (60 percent). The site of cervical metastasis may be the jugulodigastric nodes or the posterior triangle. Mirror examination of the nasopharynx is an important part of any evaluation of suspicious cervical adenopathy.

Staging of nasopharyngeal carcinoma in the past has been relatively inaccurate because of difficulty with examination. CT has helped to delineate invasion of both the paranasopharyngeal fascial planes and the bony skull in the absence of cranial nerve palsy. Recent staging systems have included histology, multiple symptoms, time from onset of symptoms, location of cervical adenopathy (supraclavicular), and local extent of disease. Variance of histology also has been related to survival and thus is important in prognosis. Keratinizing squamous cell carcinoma has the worst 5-year survival rate at 21 percent; the rate for spindle cell is 41 percent, round cell 51 percent, and mixed nonkeratinizing 54 percent. These histologic predictors of therapeutic response are consistent with the subset of tumors arising as variants from Waldeyer's ring, the lymphoepitheliomas.

Therapy

Despite the frequent presence of cervical lymph node metastases, nasopharyngeal carcinoma is a curable disease. Radiotherapy in doses varying from 50Gy to 84Gy to the primary site with 50Gy to 70Gy to both sides of the neck results in 5-year survival rates varying from 100 percent for stage I disease to 34 percent for stage IV, with overall survival rates ranging from 29 to 49 percent. The total dose of radiotherapy has an effect on survival, with patients receiving lower total doses having poorer survival. Even the presence of skull-base invasion and cranial nerve dysfunction is not a sign of incurable disease. Sixty-two percent of cranial nerve defects can be reversed by radiotherapy, with an overall 31 percent survival rate in this subset of patients. Residual disease at the primary site occasionally may be resected by craniofacial technique, and residual neck disease may be eradicated by radical neck dissection. Distant metastatic disease in nasopharyngeal carcinoma is common, particularly in patients who have bulky cervical metastases. At present, however, adjuvant chemotherapy has not been particularly successful in improving survival.

Nasal Cavity and Paranasal Sinuses

Etiology

The nasal cavity and paranasal sinuses (maxillary, ethmoid, frontal, and sphenoid) are the aditus to the respiratory tract and function to filter impurities from the inspired air, regulate its temperature, and humidify it. As such they are exposed to the many carcinogens in the air, and yet malignancies in these sites are rare. In the Western world they constitute 0.3 percent of all malignancies, with a slightly higher incidence in men than in women. In the Orient this is a more common primary site, comprising 1 percent of new cancers and 23 percent of head and neck cancers in Japan. Endemic areas are found in South Africa, where inspired snuff has a high concentration of nickel. There also may be an increased risk of adenocarcinoma of the paranasal sinuses in woodworkers secondary to inspired wood dust. The disease presents most frequently in the fifth to seventh decades.

Pathology

Squamous cell carcinoma is the most common histology (60 to 80 percent), although minor salivary gland lesions, adenocarcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma make up about 20 percent of the tumors. Other malignancies, such as teratocarcinoma, lymphoma, osteogenic sarcoma, schwannoma, fibrous dysplasia, carcinosarcoma, and melanoma, occasionally are encountered. Lymph node metastases are uncommon, with only 15 percent of cases presenting in the neck, since the retropharyngeal lymph nodes are the first station of drainage. There is a questionable relationship between nasal and sinonasal malignancy and the inverting papilloma of the nasal cavity.

Late-stage disease is common, since symptoms usually are rather diffuse, including nasal obstruction (35 percent), local pain (16 percent), epistaxis (12 percent), and cheek swelling (29 percent). Loosening of maxillary teeth or paresthesias also may occur. Diagnosis is made by intranasal biopsy through a speculum or by antrostomy through the lateral nasal wall or labial buccal sulcus (Caldwell-Luc procedure). The maxillary sinus is by far the most common site of origin of the disease (62 percent), followed by the nasal cavity (26 percent), ethmoid sinus (10 percent), and sphenoid sinus (2 percent).

Therapy

Treatment of paranasal sinus tumors is by a combination of radiotherapy and surgery. Radiotherapy alone provides poor palliation and unacceptably low survival rates. Preoperative radiotherapy to 60Gy combined with radical surgery has been the usual approach, resulting in 3-year survival rates ranging from 13 to 32 percent for all sites, 35 to 40 percent for nasal cavity, and 38 to 53 percent for maxillary sinus. Failure of therapy is most commonly manifested by local recurrence (70 percent) and only rarely disease in the neck (5 percent).

Surgical resection involves en bloc removal of the affected sinus and the surrounding involved structures. Total maxillectomy with or without orbital exenteration may be required for adequate clearance. The introduction in 1963 of the intracranial-extracranial approach to tumors, the craniofacial technique, has improved the ability to safely remove tumors of the ethmoid and other paranasal sinuses and has increased 5-year survival rates from the range of 30 percent to 58 percent.

Reconstruction of the postoperative defect that has been previously irradiated is a difficult problem. Unnatural passageways among the paranasal sinuses, oral cavity, nasal cavity, and external environment interfere with the normal flow of air, drying the mucosa and causing discomfort and bleeding as well as interfering with alimentation and speech. Small defects can be obturated with nasal or dental prostheses. Larger defects, however, require three-dimensional reconstruction with free tissue transfer with the intention of restoring pathways of air and ingested substances to as normal a state as possible to improve function and appearance (Fig. 15-41).

Larynx

Anatomy and Physiology

The larynx is a complex, mucosa-lined, bony and cartilaginous box whose function depends on motion coordinated with the adjacent tongue and pharynx. The larynx is divided into three anatomic areas: the supraglottic larynx, from the epiglottis to the ventricle, including the preepiglottic space, hyoid bone, arytenoid processes, and false vocal cords; the glottic larynx, including the true vocal cords and the anterior commissures; and the subglottic area, surrounded by the cricoid cartilage. The different clinical behavior of supraglottic lesions comes in part from their separate embryologic origin. The supraglottis is a derivative of the pharyngobuccal anlage, and malignancy arising in this area behaves similarly to pharyngeal carcinoma, with early metastatic disease to the neck. The glottis arises from the tracheobronchial anlage, and malignancy is more likely to be indolent, with lower incidence of cervical metastases.

The predominant function of the larynx is the modulation of air inspired through the nose and nasopharynx and expired from the lungs. Coordination of respiration with swallowing is a complex function that prevents food from entering the respiratory tree and air from entering the digestive tract. As air enters the pharynx it is shunted to the larynx, which sits in its neutral position with the epiglottis open. Air is then drawn through the larynx by negative pressure from the thorax and prevented from entering the esophagus by the sphincter action of the middle and inferior constrictor muscles. Saliva and other oral contents are prevented from entering the larynx by sensitive reflexes mediated by the sensory component of the superior and recurrent laryngeal nerves and the intrinsic and extrinsic muscles of the larynx. In the act of swallowing, the food bolus is prevented from entering the larynx by the simultaneous relaxation of the middle constrictor muscle and the elevation of the larynx toward the relatively fixed epiglottis, which seals the aditus. This elevation is initiated as the food passes through the faucial arch by the intrinsic and extrinsic muscles of the tongue pulling through the hyoid bone. Speech is produced by air expired from the lungs through the larynx, mouth, and nose. The thickness and degree of abduction or adduction of the cords produce tone and volume, and the actions of the tongue, palate, lips, and buccal mucosa modify the expelled air into an articulated pattern, speech. Although the respiratory tract can be short-circuited and separated from the digestive tract by tracheostomy, either with or without laryngectomy, the maintenance of normal speech and swallowing depends on adequate synergy in the pharyngolarynx and oral cavity of tongue, larynx, and pharyngeal musculature and normal central nervous system afferent and efferent signals. Perhaps more than at any other body site, therapeutic decision-making in laryngeal carcinoma by both patient and physician has been influenced by the desire to preserve the voice.

Etiology

Carcinoma of the larynx is the most common malignancy of the upper aerodigestive tract in the United States, with about 10,000 new cases presenting each year. As with most other head and neck cancers the risk for development for laryngeal cancer is directly proportional to the amount of exposure to tobacco, with a lesser relationship to alcohol intake. Changing mores have decreased the male-to-female ratio for incidence of laryngeal carcinoma from 11:1 in 1960 to 4.5:1 in 1990. Furthermore, women with carcinoma of the larynx are more likely to have supraglottic than glottic laryngeal cancers. Increasing age also is a risk factor, although disease in young patients has been reported and likewise is related to tobacco use. Black patients in the United States have an increased risk of developing laryngeal carcinoma at a younger age and a slightly lower male- to-female ratio (3.5:1) than the general population. Other risk factors suggested have been metal dust (particularly nickel), asbestos, hair dyes, and wood dust, but these are likely cofactors to the insult created by tobacco smoke. The relationship of papillomas of juvenile or adult onset in the causation of the larynx is unclear.

Diagnosis

Because of the obvious symptoms of hoarseness, other voice changes, tickling in the throat, and coughing, carcinoma of the glottic larynx is more likely than many upper aerodigestive tract malignancies to present with early-stage disease. Evaluation of the patient includes indirect (mirror) laryngoscopy as well as physical examination of the neck (Fig. 15-42). The geographic site and extent of the lesion, whether confined to the larynx or spreading beyond, are of importance, but the mobility of the vocal cords also is crucial, since it predicts invasion of the tumor into the deep structures of the larynx. CT and MRI are useful in determining whether there is invasion of the thyroid cartilage in the staging process (Fig. 15-43). Definitive staging and diagnosis to clearly define extent usually require direct laryngoscopy and biopsy, which can be performed with a rigid laryngoscope with the patient anesthetized or with a flexible fiberoptic scope with the patient awake and able to inspire and vocalize.

Pathology

The biologic behavior of malignancy in the various areas of the larynx is somewhat different and plays a major role in the choice of therapy. Supraglottic laryngeal carcinoma or extrinsic laryngeal carcinoma is more likely than glottic cancer to present with advanced-stage disease. There is an abundant lymphatic supply that extends anteriorly through the preepiglottic space as well as laterally to the midjugular and paratracheal lymph nodes. Involvement of the preepiglottic space occurs in 29 percent of clinically unremarkable supraglottic tumors. Micrometastases in the clinically negative neck also are common, with 26 to 33 percent of necks showing metastases and 25 percent bilateral metastases. In patients with inadequate primary therapy for supraglottic carcinoma recurrence in the neck and distant metastases is more likely than local recurrence alone.

The vocal cords (glottis) or intrinsic larynx is a small area that is in constant use and thus regularly exposed to carcinogenic stimuli. When tumors are confined to the small cartilaginous box with its paucity of lymphatics, they usually behave indolently. When tumors extend outside the glottis—transglottic lesions—a more aggressive pattern is noted. Unlike supraglottic cancer, early changes are noticeable and appear to have a long natural history, making them amenable to less radical therapy. Keratosis or thickening of the keratin layer of the squamous mucosa results in transformation to carcinoma in situ in 14 percent of cases and microinvasive cancer in 28 percent of cases over a period of 2 to 24 months. Keratosis with atypia progresses to carcinoma in situ in 18 percent and invasive carcinoma in 25 percent in 1 to 24 months, and carcinoma in situ progresses to invasive carcinoma in 38 percent of cases in 8 to 48 months. Recognition and treatment of these early changes in laryngeal mucosa is crucial to prevention of disease and prolonged survival.

Therapy

This rather indolent behavior and the low likelihood of clinically evident or micrometastatic cervical disease (1 to 7 percent in T1 and T2 lesions, 13 percent with T3 lesions) make glottic cancer more suitable for less radical therapies, with a high probability of salvage after failure of primary therapy. Because of the propensity for submucosal extension, however, advanced- stage disease with cartilage invasion requires initial radical therapy.

Subglottic carcinomas are rare, comprising only 1 to 2 percent of all laryngeal carcinomas, and tend to spread by submucosal extension down the trachea and through the cricoid cartilage and cricothyroid membrane into the soft tissues of the neck. Because of their rarity, they frequently present with advanced-stage local disease, although cervical metastasis is not as common as in supraglottic disease. Radical combined therapy, surgery and radiotherapy, is necessary.

Despite the peculiarities of growth of squamous cell carcinoma of the glottic larynx, prognosis for carcinoma at all sites is related to similar variables predicting other sites. Unifactorial and multifactorial analyses have identified the presence of lymph node metastases, advanced local disease, vocal cord fixation, histologic grade, ulceration, site within the larynx, male gender, and 3H-thymidine labeling index as significant factors in survival after therapy with both surgery and radiotherapy.

Because of the importance of preserving the voice and because of the low incidence of subclinical cervical metastases in glottic cancer, radiotherapy has become the accepted treatment for most early squamous cell carcinomas of the larynx. Conventional radiotherapeutic techniques that deliver doses of 60Gy over 30 fractions over 6 weeks result in cure rates of 80 to 90 percent for T1,N0 carcinoma of the glottis and 70 to 90 percent for T2,N0. Furthermore, salvage of radiotherapy failures with voice preservation by subtotal laryngectomy is possible in 75 percent and overall surgical salvage in 92 percent of T1 patients and 82 percent of T2 patients. More advanced T3 lesions also have been approached with standard radiotherapy and hyperfractionation (more than one course per day) in doses of 65Gy to 76.8Gy through ports that include the cervical lymphatics, resulting in local control rates of 36 to 67 percent over 2 to 4 years and surgical salvage of 67 to 83 percent. Such high-dose radiotherapy does, however, result in significant complication rates, such as persistent laryngeal edema and chondronecrosis.

Radiotherapy as treatment for supraglottic carcinoma is somewhat more controversial because of the late-stage presentation and the tendency for bilateral cervical metastases to occur. Although control rates of 74 percent for T1 and T2 supraglottic lesions have been obtained, and 40 percent for T3 and T4 lesions with radiation and surgery held as a salvage method, the possibility of preserving the voice with supraglottic laryngectomy and treatment with preoperative or postoperative adjuvant radiotherapy has made this combined approach more popular for late-stage disease or disease with ominous histologic features.

The surgical approach to the larynx is varied, with the unifying principle that local and locoregional disease may be eradicated with preservation or restoration of whatever function is possible. Early lesions of the glottis, such as keratosis with atypia, carcinoma in situ, or minimally invasive carcinoma, that involve the mobile cord and do not extend to the anterior or posterior commissures may be treated with reasonable success by removal of the mucosa over the cord by vocal cord stripping. Performed transorally, by either laser diathermy or sharp dissection, this technique has minimal morbidity, leaving good voice quality. T1 lesions of more bulk but confined to one cord may be removed by cordectomy, occasionally performed transorally but usually by opening the larynx through laryngofissure. Although this interferes with voice quality, most patients are cured, and surgical salvage by total laryngectomy is a successful backup procedure.

The conventional therapy for cancers that cross the anatomic boundaries of the supraglottis and glottis or the glottis and subglottis, and the so- called transglottic lesions, is total laryngectomy. Glottic lesions that cross the anterior or posterior commissure and are not felt to be amenable to radiotherapy similarly require total laryngectomy. Depending on the presence of palpable lymph nodes or suspicion of metastatic disease because of the site of primary disease, radical or modified radical neck dissection may be indicated. Removal of all disease is the aim of total laryngectomy, although whole-organ pathologic examinations have shown presence of microscopic disease at the margins in up to 30 percent of cases, with anterolateral (19 percent), posterolateral (11 percent), postcricoid (7 percent), and superior margins being most commonly involved. Free margin status is the most

reliable predictor of local control, with 48 percent of patients with positive margins developing local recurrence. When total laryngectomy is used as definitive therapy for advanced-stage disease, 3- to 5-year survival rates of 65 to 69 percent for T3,N0 and T3,N1 lesions and 45 to 54 percent for T4,N0 lesions have been reported.

The goal of voice preservation when surgical extirpation is a necessary part of therapy is met in two ways: by conservation surgery, removing only part of the larynx, or by reconstruction of a voice-producing mechanism after total laryngectomy.

In conservation surgery lesions confined to one part of the larynx are removed with the goal of preserving enough larynx to allow speech that is superior to esophageal or mechanical speech. Standard supraglottic laryngectomy or horizontal hemilaryngectomy is appropriate in patients where lesions are smaller than 3 cm, the vocal cords are mobile, a margin of 5 mm is possible at the anterior commissure, there is no cartilage or preepiglottic space invasion, the pyriform sinus apex and postcricoid and interarytenoid areas are clear, and tongue mobility is normal. The approach to the larynx is through the thyroid cartilage, removing the epiglottis, false cords, and ventricular mucosa en bloc with the hyoid bone. If posterior extension involves the arytenoid cartilage on one side, this may be included with the specimen. Although postoperative aspiration for a limited period of time is frequently seen, good voice quality is usually obtained and the temporary tracheostomy can almost always be removed. Total laryngectomy as a salvage procedure for intractable aspiration, fistula, or recurrent disease is successful in 33 to 50 percent of cases. Five-year survival rates in the range of 70 to 85 percent for supraglottic carcinoma make it superior to radiotherapy, although no prospective randomized studies have tested this thesis.

Vertical hemilaryngectomy is the standard conservation procedure carried out for invasive carcinoma of one vocal cord or a vocal cord and the anterior commissure that does not invade the thyroid cartilage. Total resection of the cord and its subjacent muscle and adjacent cartilage is necessary. Access to the larynx is obtained posterior to the cord by cutting through the thyroid cartilage, leaving the external perichondrium sutured to the sternothyroid muscle. The cord with or without the ipsilateral arytenoid cartilage is resected, and if the commissure is involved, the keel of the thyroid cartilage is resected as well. The strap muscles and perichondrium or a cartilage graft provides a buttress against which the normal cord can be apposed. Five-year survival rates of 75 to 87 percent for stages I to III disease treated in this fashion have been reported, again superior to radiotherapy alone. As with supraglottic laryngectomy, removal of the temporary tracheostomy and resumption of oral nutrition without aspiration usually is possible, with voice preservation. Extended hemilaryngectomy has been described for T3 lesions, where a small segment of vocalis muscle with its overlying cartilage, with sensory and motor innervation left intact, is used with the adjacent hypopharyngeal mucosa to create a phonatory shunt through which air from the lungs can be forced to provide speech. Although permanent tracheostomy is necessary, voice quality has been described as superior to esophageal speech and obtainable in a high percentage of cases.

Voice restoration after total laryngectomy is a difficult problem. Despite widespread availability of speech therapy and extensive preoperative teaching and aggressive postoperative rehabilitation, only 24 to 45 percent of alaryngeal patients acquire esophageal speech. Inability to expel air from the stomach, cricopharyngeus spasm, and other physiologic reasons have been cited, but depression and social and emotional withdrawal play an important part as well. Mechanical devices inserted into the airway have been remarkably unsuccessful, although external vibrators do allow intelligible speech of low volume. Various attempts have been described to create a neolarynx or neoglottis, a mucosal or epithelial diaphragm which fits over the transected end of the cricoid or trachea and serves as a pathway for air inspired through the tracheostomy to exit through the oral cavity as speech. With these various methods, good speech quality may be obtained in 50 to 75 percent of cases, but there is a significant risk of aspiration, requiring takedown of the reconstruction. A simple tracheoesophageal puncture described by Singer, maintained patent by a small tube, allows pulmonary air to enter the esophagus and thus the pharynx, to be modulated by the tongue, lips, and buccal mucosa. This method has allowed fluent speech restoration in 71 to 88 percent of patients with little risk of aspiration or other serious complication. This procedure may be performed either at a second stage after healing of the wound or at the time of laryngectomy, whether closed by primary approximation or reconstructed with a pectoralis major flap, gastric pull-up, or free tissue transfer. Transplantation of the larynx has as yet been unsuccessful, but research is continuing with this method.

Extensive surgery on the larynx is associated with complications. Pharyngocutaneous fistula occurs in up to 38 percent of laryngectomies and has been associated with previous radiotherapy, malnutrition, and cell-mediated immunodeficiency. Prophylactic metronidazole has been suggested as a method to prevent fistula, but prompt recognition and closure with well-vascularized tissue will prevent prolonged drainage and rupture of the adjacent irradiated carotid vessels. Problems specific to the method of reconstruction also occur, such as regurgitation of acid and food after pharyngogastrostomy after gastric pull-up or hypersecretion of mucus after jejunal autograft. The problem of stenosis after laryngectomy, particularly in the patient who receives adjuvant radiotherapy, is similar to that after pharyngolaryngectomy. Combined with the alterations in cricopharyngeus function (upper esophageal sphincter mechanism), stenosis greatly impedes the acquisition of esophageal speech. Interposition of well-vascularized soft tissue, such as the radial forearm or lateral arm free flap, can decrease the likelihood of postlaryngectomy speech and swallowing problems (Fig. 15-44).

Nonepidermoid malignancies of the larynx are uncommon. Adenosquamous carcinoma is a poorly differentiated aggressive lesion that behaves in a manner similar to advanced squamous cell carcinoma. Rhabdomyosarcoma, chondrosarcoma, schwannoma, and other mesenchymal malignancies have been reported in both children and adults. Carcinoid or moderately differentiated neuroendocrine carcinoma behaves in a fashion similar to malignancy in other sites and may be treated by partial or total laryngectomy, depending on its stage. Adjuvant radiotherapy and chemotherapy do not seem to contribute to the cure of the patient. Anaplastic small cell carcinoma (oat cell) also occurs in the larynx rarely and, like its counterpart in the lung, is associated with smoking and increased age. Prognosis is also similar to lung disease, with average survival of 10 months after diagnosis. Multimodal therapy with chemotherapy as the basis is the most appropriate approach.

One of the most difficult problems associated with laryngectomy is recurrence of disease at the stoma. Occurring in approximately 5 percent of patients, it may be the result of submucosal subglottic extension or unresected pretracheal or paratracheal lymph node metastasis. Resection of disease is possible in some patients by mediastinal dissection, repositioning the stoma lower and removing the soft tissues of the superior mediastinum to the innominate vessels. Esophageal reconstruction may be performed by gastric pull-up or jejunal free autograft, and interposition of vascularized pectoralis major muscle usually is necessary to separate the great vessels from the stoma. With this aggressive surgical approach, 17 to 28 percent of the patients can be treated successfully.

Benign lesions of the larynx may present a diagnostic problem but usually are seen in different age groups and rarely affect mobility of the vocal cords. Tuberculosis of the larynx, though rare, may mimic malignancy. Papillomatosis may present in children, possibly secondary to contamination of the fetus at delivery by the human papillomavirus, a DNA virus. This persistent problem may require tracheostomy, since repeated excisions by laser or other means may result in laryngeal or subglottic stenosis. Adult-onset papillomatosis of the larynx may come with immunosuppression of various types as recurrent disease or as an opportunistic infection. Immunotherapy with the bacille Calmette-Guérin (BCG) has been suggested as an adjuvant of surgery. Vocal nodules or singer's nodules and polyps and sebaceous cysts also may occur in the mobile cords and may be treated by simple excision.

CONNECTIVE TISSUE NEOPLASMS

Soft-Tissue Sarcomas

General Considerations

Soft-tissue sarcomas arise within tissues that develop embryologically from the mesoderm, such as skeletal and smooth muscle, adipose and fibrous tissue, and endothelial cells. They are uncommon tumors overall, with fewer than 5,000 new cases diagnosed each year in the United States. Less than 10 percent of all sarcomas arise in the head and neck; they represent less than 1 percent of all head and neck malignancies. This low incidence, with the attendant difficulty in developing a comprehensive management plan, may partially account for the poor survival rates in adults with soft-tissue sarcomas. Unlike epidermoid carcinoma, the most important determinant of the biologic behavior of sarcomas is histologic grade. Low-grade tumors tend to recur locally, while high-grade lesions often metastasize early to distant sites, including lung, liver, and bone. Other prognostic indicators include the histologic type, the location, the size and the degree of local invasion of primary lesions, and the presence of locoregional or distant metastatic disease.

Typically soft-tissue sarcoma of the head and neck presents as a painless mass. The more advanced or more deeply invasive lesions may cause pain, obstructive symptoms, or cranial nerve deficits. Evaluation of local extent of disease in soft-tissue sarcomas is similar to that of squamous cell carcinoma and includes indirect laryngoscopy, palpation endoscopy, and CT or MRI. Depending on histology and stage of disease, a metastatic work-up should be performed. Pleomorphic sarcomas of the head and neck, like those arising in other areas, frequently demonstrate cellular changes consistent with indolent disease in one part of the tumor and characteristic of very aggressive disease in another part. A generous incisional biopsy often is necessary to confirm the diagnosis. The mainstay of treatment for the majority of these lesions in adults remains extensive local resection with clearly negative margins (tumor no less than 1 mm from the surgical margin). Regional node dissections usually are performed only if nodal disease is clinically evident. In adults, adjuvant radiation therapy and chemotherapy may be of some worth, whereas in children their therapeutic value has been clearly established.

Fibrosarcoma

This is the most common type of soft-tissue sarcoma in adults. There is a bimodal age distribution, with the first peak in infants under 2 years of age and the second in adults 40 to 60 years of age. Fibrosarcoma often presents as a painless mass of the face or neck. Histologically, many fibrosarcomas are low grade. The rate of metastasis to regional nodes is 5 percent, but 50 percent metastasize to lungs, liver, or bone. With aggressive local resection, 5-year survival rates around 45 percent have been reported.

Malignant Fibrous Histiocytoma

The reported incidence of these tumors in the head and neck has grown in recent years because of the reclassification of other high-grade sarcomas as malignant fibrous histiocytomas. Two histologic variants exist, myxoid and inflammatory, with the latter carrying a poorer prognosis. Whereas local recurrence remains the most common manifestation of treatment failure, the incidence of nodal metastasis may approach 50 percent. Therefore, in addition to aggressive local resection, prophylactic neck dissection is advocated in some centers, depending on stage of disease. The 5-year survival rate is approximately 50 percent.

Angiosarcoma

These rare cutaneous malignancies most often present as an ulcerated painless mass of the scalp or face in middle-aged men. They are highly aggressive tumors, with perivascular extension most often cited as the cause of local failure as well as of distant metastasis. Radiation therapy and chemotherapy have both been used as adjuvants to local resection, but 5- year disease-free survival is rare.

Rhabdomyosarcoma

This is the most common type of soft-tissue sarcoma in children, and after lymphoma is the second most common malignancy of the head and neck in children. Two important histologic subtypes have been identified. The embryonal variant occurs in young children (average age four) and carries the better prognosis. Seventy-nine percent of orbital rhabdomyosarcomas are of the embryonal type. Most of these neoplasms are now treated successfully with a combination of radiation therapy and chemotherapy (vincristine, doxorubicin, and cyclophosphamide), yielding survival rates of 77 to 90 percent. Alveolar rhabdomyosarcoma occurs in older children (average age ten) and in the cervical soft tissues. While the initial response rate to radiation therapy and chemotherapy is comparable to that of embryonal rhabdomyosarcoma, the rate of local recurrences and of distant metastasis is significantly higher, decreasing survival rates to approximately 50 percent at 5 years. The Intergroup Rhabdomyosarcoma Study has established specific multimodal treatment protocols for each type and stage of disease. To date the improvements in management of rhabdomyosarcoma in children have not yet been realized in adults.

Neural Tumors

Esthesioneuroblastoma (Olfactory Neuroblastoma)

This rare tumor arises from the supporting cells of the olfactory neuroepithelium at the apex of the nasal cavity. In its earlier stages it may present as a fleshy upper nasal mass causing epistaxis, unilateral nasal obstruction, or rhinorrhea. In its more advanced stages the tumor may extend throughout the cribriform plate into the anterior cranial fossa, invading the frontal lobe and leading to anosmia, rhinorrhea, headaches, or even personality changes. While this tumor may arise in all age groups, it has higher incidence in the third and fourth decades of life and a slight male predominance. When esthesioneuroblastoma is suspected on the basis of the history or CT scans showing bony erosion, a biopsy procedure of the nasal mass should be performed in the operating room because its highly vascular nature. Metastasis occurs in 20 percent of cases, most commonly to the cervical lymph nodes (often bilateral), lungs, and bone, but the majority of patients succumb to aggressive intracranial extension. Therefore, surgical treatment is directed at complete local control. Early lesions may be resected through a lateral rhinotomy and complete ethmoidectomy. More extensive tumors require a combined neurosurgical-craniofacial effort, with exposure and complete resection of the cribriform plate and ethmoid sinuses from both a superior and inferior approach. Adjuvant radiation therapy may improve local control and survival, and inoperable tumors often are treated with radiation therapy alone.

Paraganglioma

Paragangliomas or chemodectomas are neoplasms that arise from neural crest cells and histologically resemble their adrenal gland counterpart, the pheochromocytoma. They are classified by their location: carotid body, jugular (arising from the glomus jugulare), vagal body, orbital, and laryngeal. Although these extraadrenal paraganglionic cells do contain small amounts of catecholamines, it is rare for them to produce a clinically significant excess of catecholamines. The most common of the paragangliomas, the carotid body tumor, usually presents as an asymptomatic neck mass. Chemodectomas at other sites often produce compressive symptoms resulting in hearing loss, tinnitus, or facial nerve paralysis. Only 6 percent of these tumors are malignant, and only 4 percent metastasize. Malignancy is determined by clinical behavior rather than histology. They are highly vascular and have a characteristic appearance on angiography, with carotid body tumors separating the internal and external carotid vessels by a mass effect. When technically feasible, treatment should include complete resection, which in the carotid body tumor requires subadventitial dissection. The poor-risk patient with an asymptomatic mass may be managed more conservatively.

Osteogenic Sarcoma

Ten percent of osteogenic sarcomas occur in the head and neck. Most arise in the mandible or maxilla in the third or fourth decade of life. Risk factors include prior radiation therapy, fibrous dysplasia, and retinoblastoma. These malignancies present most frequently as a hard mass with radiographic changes of cortical destruction as well as new bone formation. These tumors are highly infiltrative not only of bone but also of secondary mucosa and muscle and must be resected with a wide zone of adjacent soft tissue. Nodal metastasis is uncommon; however, distant metastasis to lung occurs in some patients if local control is not achieved. There has nonetheless been some enthusiasm for chemotherapy administered after surgical resection. Radiation therapy is generally reserved for curative situations. As with rhabdomyosarcoma, the use of neoadjuvant or adjuvant chemotherapy has been effective in children with osteogenic sarcoma but not in adults.

AIDS-RELATED DISORDERS

HIV infection and its consequence, AIDS, produce a large number of abnormalities in the head and neck region, both neoplastic and nonneoplastic.

Symbiotic Infections

The generalized immunosuppression allows normally symbiotic or latent organisms to cause serious disease and morbidity. Oral candidiasis is sometimes one of the earliest manifestations of AIDS. The combination of xerostomia, which may be related to the chronic fibrosis of the salivary glands or benign lymphoepithelial lesions seen in HIV-positive patients, and the disturbance of normal flora of the oral cavity results in the proliferation of yeast and other fungi to pathogenic levels. Herpes simplex virus infections, resulting in painful ulcerations of the lips, oral mucosa, and oropharynx, as well as varicella-zoster, with its painful distribution along the fifth cranial nerve, also are common in patients afflicted by AIDS, again probably a result of generalized immunosuppression. Other infectious disorders less commonly seen are human papillomavirus, cytomegalovirus, cat-scratch disease, tuberculosis, and opportunistic bacterial infection localized to the oral cavity and oropharynx.

Leukoplakia

Oral hairy leukoplakia is similar to the leukoplakia seen in chronic smokers except that it has a shaggy or more nodular appearance and is more likely to present on the lateral border of the tongue, frequently as a bilateral lesion. Cellular hyperplasia with parakeratosis is seen, and there is a high correlation, both serologically and by electron microscopy, with the Epstein-Barr virus. This lesion is sometimes an early sign of ultimate HIV positivity, again as an expression of decreased immunosurveillance.

Lymphoproliferative Disorders

Lymphoproliferative disorders are characteristic of AIDS and frequently occur in the head and neck. Obstruction of the nasopharynx secondary to overgrowth in the Waldeyer's ring area has been reported. Cervical lymphadenopathy is commonly a part of the AIDS-related complex (ARC), and involvement of the intraparotid and submandibular lymph nodes, with cystic degeneration and symptomatic accumulation of fluid within them, causes enlargement of the nodes and is an early indicator of the full-blown disease. Malignant lymphomas, most commonly of the B-cell type, also have been reported and are second only to Kaposi's sarcoma in frequency, occurring in up to 10 percent of AIDS patients. These lymphomas usually are extranodular, with an unusual frequency of primary central nervous system disease. Lymphoma also has been reported in the neck, oral cavity, and paranasal sinuses. Although the tendency to disseminate is lower than in other lymphomas, the disease course is rapid and lethal. Lymphoma occurs more commonly in intravenous drug users than in patients who have developed AIDS from other sources. Again there is a high correlation of lymphoma with elevated antigen titers for Epstein-Barr virus and electron microscopic evidence of its presence. T-cell lymphomas also occur but are less common. For disease localized to one area, radiotherapy may be an effective treatment. Multidrug systemic chemotherapy also is effective but places the already immunosuppressed patient at higher risk for disseminated infection.

Kaposi's Sarcoma

Kaposi's sarcoma is the most common malignancy in AIDS, arising in 15 percent of patients. There is probably a sexual mode of transmission, since it is much more common in homosexual AIDS patients than in those acquiring the disease from intravenous drug use or contaminated blood products. Unlike the classical form of Kaposi's sarcoma, which occurs in elderly males usually on the lower extremities, this form of the disease occurs in oral or perioral mucosa in 55 percent of the cases. The palate is the most common site, although the tongue, pharynx, and larynx have been described as sites as well. Usually multifocal within the region, it may arise in or metastasize to the cervical lymph nodes or the salivary glands. The tumor initially presents as a flat blue to purple patch and may appear to be a submucosal hematoma secondary to trauma. Later in the course of growth it becomes nodular. Biopsy examination reveals endothelial cell and fibroblast proliferation, with increased capillary growth, prominent spindle cells, few mitoses, and extravasation of erythrocytes. The causation of Kaposi's sarcoma is unclear, although there is some evidence linking it to cytomegalovirus infection or viral induction of local angiogenic factors.

As with all malignancies in AIDS patients, the use of conventional multidrug systemic therapy is somewhat hazardous because of chronic infection. Single-drug treatment with vinblastine or etoposide, systemically or by intralesional injection, results in partial regression of tumor and significant palliation in up to 30 percent of patients. Interferon- α , systemically or as an intralesional injection, also has been moderately effective. Local radiotherapy with an energy source, such as electrons, that has low penetration, in total doses of 800 to 1,500 cGy, delivered in ten fractions, also is effective in shrinking lesions and allowing significant palliation. With all therapies, median survival of patients is 2 years, with a 5-year survival rate of only 10 percent.

Carcinoma

Squamous cell carcinoma of the upper aerodigestive tract has been reported in the mouth, tongue, larynx, and other sites in AIDS patients. Although the true risk is uncertain, squamous cell carcinoma has appeared in patients of earlier age and without the usual risk factors of smoking and ethanol intake. This pattern is suggestive of a defect in immunosurveillance similar to that seen in patients having undergone organ transplantation. In AIDS patients, the median age of presentation of squamous cell carcinoma is 32 years, in contrast to 60 years in the noninfected patient, and the clinical course seems to be somewhat more aggressive.

SALIVARY GLANDS

Physiology

The production and excretion of the mixture of mucus, water, and electrolytes known as saliva into the entrance to the upper aerodigestive tract are the function of the salivary glands. The major salivary glands are the symmetrically paired parotid, submandibular, and sublingual glands, which discharge saliva into the oral cavity via Stensen's ducts, Wharton's ducts, and the numerous small orifices in the floor of the mouth, respectively. Clustered primarily in the soft and hard palates but also found in the sinuses and other sites of the upper aerodigestive tract are the minor salivary glands, which produce mucus for lubrication. Saliva consists of varying concentrations of numerous substances. To some degree its composition reflects the osmolality and electrolyte concentration of the extracellular fluid, but its specific functions require other components as well.

The normal volume of salivary secretion in the adult male ranges from 1,000 to 1,500 mL per day, mainly as serous fluid from the parotid and submandibular glands (95 percent) but also composed of mucus (5 percent) from the sublingual and minor salivary glands. Active water resorption, sodium and potassium ion exchange, and bicarbonate production couple with passive diffusion of urea and uric acid to determine the inorganic content of saliva. Immunoglobulins A, G, and M, albumin, lysozyme, and other enzymes also are secreted. In addition to its lubricating properties, which allow food to be moved through the mouth, saliva has antibacterial and antiviral properties, which protect the soft tissues of the oral cavity as well as the teeth.

The neurogenic control of salivary secretion depends on reflex arcs that carry afferent stimuli from the specialized sense organs via cranial nerves I, V, VII, and IX to the brainstem and hypothalamus, and efferent signals, both sympathetic and parasympathetic, along the branches of the external carotid artery, the superficial petrosal nerve, and the chorda tympani.

Anatomy

Parotid Gland

The parotid gland is shaped like a flattened pyramid, with its apex in the parapharyngeal space behind the mandible adjacent to the pterygoid muscles and its base extending into the preauricular area from below the angle of the mandible in the neck, sometimes as low as the mid–sternocleidomastoid muscle, to just below the zygomatic arch. The medial extent of the gland usually reaches over the masseter muscle and the vertical ramus of the mandible. The parotid gland is surrounded by the continuation of the investing layer of the cervical fascia, the superficial layer of which is continuous with the platysma. The parotid gland parenchyma is arbitrarily divided into the deep and superficial lobes by the facial nerve, which exits the skull via the stylomastoid foramen and passes through the substance of the gland. Approximately 70 percent of the gland lies superficial to the plane of the nerve and 30 percent deep to it.

The lymphatic drainage of the midface, forehead, and anterior portion of the scalp empties into lymph nodes that lie superficial to the fascia of the parotid and within the gland itself before sending efferent channels to the jugulodigastric area. Sensory supply to the gland derives from branches of the trigeminal nerve and from the great auricular nerve, carrying cervical plexus axons. Stensen's duct, the parotid duct, condenses from the larger intralobular ducts and passes adjacent to the buccal branch of the facial nerve on a line between the tragus of the ear and the midline of the upper lip. It enters the oral cavity adjacent to the second maxillary molar tooth.

The facial nerve, which supplies motor innervation to the muscles of facial expression and several other muscles, exits the base of the skull from the stylomastoid foramen, passing deep to superficial and caudad to cephalad before branching at the pes anserinus into an upper and lower division. Although there is some variability in branching patterns, particularly of the buccal branch, the upper division usually includes the temporal, zygomatic, and buccal branches, and the lower division, the mandibular and cervical branches.

Submandibular Gland

The submandibular salivary gland is surrounded by a condensation of the cervical fascia that lies beneath the platysma muscle, connecting to the parotid fascia and known as the *pars interglandularis*, separating the parotid and jugulodigastric areas from the submandibular triangle. The anatomic boundaries of the submandibular triangle are the anterior belly of the digastric muscle medially, the posterior belly laterally, and the mandible superiorly. The gland lies on the hyoglossus muscle and wraps both superficial and deep to the mylohyoid muscle medially. The submandibular ganglion of the lingual nerve carries efferent nerve supply via the chorda tympani. Wharton's duct conveys the secretions of the submandibular salivary gland into the oral cavity.

Sublingual Glands

The sublingual salivary glands lie immediately beneath the mucosa of the floor of the mouth, intimately related to the lingual artery, and release their mucous secretions into the oral cavity through numerous orifices along the alveololingual sulcus.

Inflammatory and Infectious Disorders

Inflammation usually presents as diffuse enlargement or firmness of the gland, unilateral or bilateral, associated with tenderness and erythema. Bacterial infection usually is the result of duct obstruction and retrograde infection with oral bacteria. Acute bacterial parotitis may be seen in the elderly postoperative patient who becomes dehydrated and is usually caused by *Staphylococcus aureus*. Although rehydration and antibiotic therapy may be successful, drainage of localized abscesses and even total parotidectomy may be required for resolution. Because of the septate nature of the parotid, simple drainage of the gland is frequently unsuccessful. Acute sialadenitis of the submandibular gland also may necessitate gland resection.

Mumps, coxsackievirus, and echoviruses also may cause acute parotitis, usually panglandular but occurring as unilateral gland enlargement. Tuberculosis, actinomycosis, and cat-scratch disease also may present with enlargement of the salivary glands or of their adjacent lymph nodes. Systemic disorders such as sarcoidosis, Sjögren's syndrome, and cirrhosis with liver failure also result in salivary gland enlargement. Mikulicz's syndrome, enlargement of the gland with histologic changes reflecting loss of acinar epithelium and replacement with chronic inflammatory cells, is a nonspecific accompaniment of several diseases, such as leukemia, lymphoma, and tuberculosis.

Tumors

Pathology

The clinical problem most frequently presented to the surgeon is that of a discrete mass in the salivary gland, particularly the parotid gland. Of salivary gland tumors, 70 to 80 percent present in the parotid gland. Of parotid gland tumors, 70 to 80 percent are benign and, of the benign tumors, 80 percent are pleomorphic adenomas. Although lymph nodes, lipomas, cysts, or other benign entities may present as solitary masses, the benign pleomorphic adenoma is by far the most common mass. Occurring most frequently in the fifth decade, with a slight female predominance, the benign mixed tumor or pleomorphic adenoma is the proliferation of epithelial and myoepithelial cells of the ducts as well as an increase in the stromal component, which histologically may appear similar to cartilage. A true epithelial benign neoplasm, it may grow to a large size without causing facial nerve symptoms (Fig. 15-45). Pleomorphic adenomas usually present as a solitary painless mass in the superficial lobe of the gland. Deep lobe growth may present as an intraoral pharyngeal mass as growth extends into the pharynx via the parapharyngeal space. Malignant degeneration of pleomorphic adenomas occurs in 2 to 10 percent of adenomas followed for long periods, with carcinoma ex pleomorphic adenoma occurring most frequently as adenocarcinoma.

The second most frequent benign neoplasm of the salivary glands is the papillary cystadenoma lymphomatosum or Warthin's tumor. With a marked male predominance, it usually occurs in the tail of the parotid gland and presents with a lymphocytic infiltrate as well as cystic epithelial proliferation. There is a 10 percent incidence of bilaterality and multicentricity. A subset of the group of monomorphic adenomas, Warthin's tumors comprise 4 to 8 percent of all parotid tumors. Other benign monomorphic adenomas include oxyphilic adenoma, oncocytoma, basal cell adenoma, sebaceous adenoma, sialadenoma papilliferum, and canalicular adenoma, all of which are rare. Pleomorphic adenoma is the most common benign tumor of the parotid, submandibular, and minor salivary glands.

Malignant tumors of the salivary glands occasionally (4 percent) present as a diffuse enlargement of a gland, almost always as a discrete mass. Pain is associated with malignancy in 12 to 24 percent of cases. Other symptoms include formication (a paresthesia that is described as the feeling of ants crawling on the skin), facial nerve dysfunction (8 to 26 percent), or complete paresis of the nerve (7 to 9 percent). All of these symptoms and signs carry a poorer prognosis than asymptomatic disease (Fig. 15-46). Facial nerve palsy is almost never seen with benign disease, so the presence of nerve palsy, even without a discrete mass, must be considered a possible sign of malignancy.

Fixation to the masseter muscle or pterygoid muscles occurs in approximately 17 percent of cases, and skin ulceration in 9 percent. The risk of clinical or subclinical metastases to the cervical lymph nodes from salivary gland cancers depends on the histology and grade of the primary tumor. High-grade mucoepidermoid adenocarcinoma and squamous cell carcinoma have a high risk of metastatic disease (Fig. 15-47), whereas adenoid cystic acinic cell and lower grades of mucoepidermoid and squamous cell have a low risk of metastasis. Approximately 20 percent of parotid gland neoplasms are malignant. The risk of malignancy is inversely proportion to gland size, with the submandibular glands having 40 percent malignant tumors and the minor salivary glands 60 percent.

Diagnosis

The discrete mass in the salivary gland must be considered a possible malignancy. History and physical examination may provide some indication that the lesion is malignant. Complete resolution after 10 days of antibiotics and clinical features consistent with inflammation may constitute an adequate therapeutic trial. Definitive histologic diagnosis, however, is ultimately necessary. Fine-needle aspiration may be helpful in planning surgery, but any uncertainty should be treated with adequate surgical excision. CT scan of the parotid is helpful in determining extension of the tumor into the deep lobe. MRI can be formatted in both axial and coronal planes, giving even better anatomic information. When carefully performed and analyzed MRI can provide information about the facial nerve and its anatomic relationship to the tumor. Contrast-enhanced studies may allow discrimination between the gland and metastatic lymph nodes, particularly in the submandibular area, differentiating metastases from the head and neck site to an intraglandular or epiglandular lymph node from intrinsic malignancy of the salivary gland. Sialography, or injection of contrast material into Stensen's or Wharton's ducts, is useful in demonstrating the chronic stenotic changes of a benign lymphoepithelial lesion or chronic parotitis and in showing complete occlusion from stones. Eighty percent of parotid duct stones are radiolucent. Eighty percent of submandibular gland stones are radiopaque.

Treatment

The surgical approach to a salivary gland mass is predicated on the assumption that it is malignant. The major confounding factor is the presence of the facial nerve in the parotid gland. Since the facial nerve passes through the gland, the usual surgical oncologic approach to head and neck malignancy—en bloc resection—would require excision of the nerve in all cases. This approach, however, is not appropriate in most situations. If there is no evidence of nerve involvement, the tumor should be excised by superficial lobectomy, removal of the parenchyma above the nerve with a margin of normal tissue, preserving the nerve.

If the tumor is malignant, total parotidectomy with preservation of the nerve is indicated, though it is a piecemeal procedure (Fig. 15-48). Involvement of a branch of the nerve requires removal of that branch. In young patients, nerve graft should be used to replace the resected nerve segment in the hope of avoiding the long-term sequelae of facial nerve palsy. In the event of invasion of the nerve by tumor, any proximal extension of the malignancy to the base of the skull should be evaluated, and in some cases resection of the nerve to clear margin in the stylomastoid foramen or the facial canal may improve survival. If the facial nerve is not involved by malignancy but preservation of the nerve would result in gross disruption of the tumor, the nerve should be removed and replaced with a nerve graft.

When clinical examination, with or without fine-needle aspiration cytology, does not clearly define the problem, a biopsy specimen should be obtained by superficial lobectomy, with identification and preservation of the main trunk of the facial nerve and its branches. Benign tumors of the superficial lobe should be removed with a clear margin by superficial lobectomy. If the deep lobe is involved, total parotidectomy may be required even for benign disease, although partial parotidectomy is sometimes possible.

Treatment of the neck in patients with malignant disease of the parotid depends on the histologic type and the grade of the tumor and its risk of metastatic disease or the presence of the metastatic disease itself. Node- positive necks are treated by the appropriate neck dissection—radical neck dissection if there is involvement in the sternocleidomastoid muscle or the jugular vein, or modified or selective neck dissection depending on the site of metastasis. Although elective or prophylactic neck dissections are not as frequently necessary as in mucosal malignancy, they are indicated in high- grade mucoepidermoid carcinoma, squamous cell carcinoma, and high- grade adenocarcinoma.

Neoadjuvant (preoperative) or adjuvant chemotherapy has not been effective in treating malignancy of the salivary glands—parotid, submandibular, or minor glands. Adjuvant postoperative radiotherapy, however, is effective. Radiation portals should include the entire site of surgery, the foramen ovale, the base of the skull, including the mastoid process and the stylomastoid foramen, and the ipsilateral neck depending on the risk of metastasis.

The risk of recurrent disease and the pattern of recurrence also depend on histology and grade. Mucoepidermoid carcinoma, squamous cell carcinoma, and high-grade adenocarcinoma have a high frequency of cervical and distant metastasis as well as local recurrence. Adenoid cystic carcinoma is characterized by an indolent course but relentless local progression and perineural invasion, with disease eventually extending to the base of the skull and the brain. Both adenoid cystic and mucoepidermoid carcinoma may demonstrate extensive pulmonary metastasis that remains asymptomatic for relatively prolonged periods, and the patient's death may be caused by locoregional disease rather than by disseminated disease. Just as adjuvant chemotherapy has been unsuccessful, so is treatment of disseminated disease, although both doxorubicin and cisplatin have demonstrated finite response rates without prolongation of survival. Local recurrence may be successfully treated by radical resection with or without adjuvant radiotherapy.

The treatment of submandibular gland abnormalities follows the same basic rule as for the parotid gland. If definitive diagnosis cannot be made before surgery, total excision of the gland, with preservation of the uninvolved marginal mandibular, hypoglossal, and lingual nerves, is indicated and is adequate therapy for benign tumors and inflammatory or autoimmune disorders. Radical resection of the nerves, platysma, skin, and underlying muscle is reserved for extensive local invasion. Adenoid cystic carcinoma is the most common malignant histology of the submandibular gland, and pleomorphic adenoma the most common benign tumor. Adjuvant postoperative radiotherapy appears to be helpful in the malignant tumor.

Minor salivary gland disorders reflect the spectrum seen in the major salivary glands. Mucocele is a cystic enlargement of the intraoral glands usually seen in the lip or the floor of the mouth. Sjögren's syndrome of keratoconjunctivitis sicca is diagnosed by lip biopsy and histologic confirmation of the chronic inflammatory changes seen in the minor salivary glands. Necrotizing sialometaplasia, an ulcerative but self-limited disorder affecting the junction of the hard and soft palates, clinically mimics malignancy but eventually heals; biopsy examination reveals no evidence of malignant change.

Tumors of the minor salivary glands, either benign or malignant, may occur in any of the mucosa-lined areas of the upper aerodigestive tract but are most common in the hard and soft palates. Their presentation may be as a submucosal or an ulcerative mass. Pleomorphic adenoma is the most common benign tumor, and mucoepidermoid and adenoid cystic carcinoma (Fig. 15-49) occur with roughly the same frequency as malignancies. Therapy is wide local resection, including subjacent bone if the hard palate is involved, with adjuvant radiotherapy for malignancy. Since subclinical metastases to the neck are rare, cervical lymphadenectomy is reserved for patients with histologically proved lymph node metastases. Palatal defects usually can be rehabilitated with dental prostheses, though local or distant tissue transfer may be necessary for extensive disease.

CHAPTER 16 - Chest Wall, Pleura, Lung, and Mediastinum

Valerie W. Rusch
Robert J. Ginsberg

INTRODUCTION AND HISTORY

Thoracic surgery focuses primarily on the organs that support the delicate sequence of events that move air to blood and blood to tissues. The cardiorespiratory system functions to ensure that those events occur dependably, the margin of error being extremely small. The analysis and management of surgical problems involving the chest and its contents, whether relating to congenital anomalies, tumors, trauma, or infection, all center on maintaining the mechanical transport of oxygen to the vital organs and the necessary exchange of gases. Air with adequate oxygen content must pass through the upper airway, the trachea, and the bronchi to reach the alveoli, properly warmed and humidified, for movement across alveolar membranes. Those membranes must allow efficient diffusion of oxygen and carbon dioxide. Blood with sufficient oxygen-carrying capacity must circulate through the alveolar capillaries in adequate volumes and at the proper speed to take up oxygen and discharge carbon dioxide; it also must be at the proper pH and temperature and must have the proper biochemical characteristics for optimal exchange. The vascular system must have the appropriate integrity, pressure gradients, volume, and flow dynamics to traverse the pumps and conduits from alveolar capillaries to vital organ capillaries and back. At the end-organ interface, the characteristics necessary for release from the blood to the tissues of oxygen, and recapture of carbon dioxide must be present. Irreparable damage to vital organs may occur in minutes if any part of the system fails.

The early history of thoracic surgery was limited to the management of trauma and was closely linked to the history of weaponry. Management of chest wounds received in battle was recorded in ancient writings, including the Iliad (ca. 950 b.c.). Galen described a patient who recovered after partial excision of the sternum and pericardium for recurrent abscess due to an injury. Writing about chest wounds in the thirteenth century, Theodoric noted that “the stitches should be placed. . . so that the natural heat cannot escape in any way nor the air outside be able to enter.”

The introduction of firearms in the fourteenth century complicated the management of chest wounds. The proper care of the open pneumothorax (sucking chest wound) remained unsettled for centuries. Consistent with many of his other revolutionary insights, Napoleon's surgeon, Baron Larrey, confirmed the sporadic observations of other surgeons about the lifesaving value of closing an open wound of the thorax. His description of the cardiopulmonary effects of an open chest wound can hardly be improved on:

A soldier was brought to the hospital of the Fortress of Ibrahyn Bey, immediately after a wound penetrated the thorax, between the fifth and sixth true ribs. It was about 8 cm in extent. A large quantity of frothy and vermilion blood escaped from it with a hissing noise at each inspiration. His extremities were cold, pulse scarcely perceptible, countenance discolored, and respiration short and laborious; in short, he was every moment threatened with a fatal suffocation. After having examined the wound, the divided edges of the part, I immediately approximated the two lips of the wound, and retained them by means of adhesive plaster and a suitable bandage around the body. In adopting this plan, I intended only to hide from the sight of the patient and his comrades, the distressing spectacle of a hemorrhage, which would soon prove fatal; and I, therefore, thought that the effusion of blood into the cavity of the thorax, could not increase the danger. But the wound was scarcely closed, when he breathed more freely, and felt easier. The heat of the body soon returned, and the pulse rose. In a few hours he became quite calm, and to my great surprise grew better. He was cured in a very few days, and without difficulty.

The development of elective thoracic surgery has followed closely the history of airway management, particularly techniques for tracheal intubation and mechanical ventilation. During the first third of the twentieth century, surgeons devised imaginative techniques to control the open pneumothorax associated with chest operations. These included hand bellows and tracheostomy devices as developed and modified by Fell (1883), O'Dwyer (1896), and Matas (1900), as well as various packing techniques, preoperative pneumothorax for “conditioning,” and suturing the lung to the parietal pleura. Improvements in laryngotracheal intubation techniques, in design and materials of endotracheal tubes, and in anesthesia gradually displaced these improvisations.

In 1904 Sauerbruch developed a negative-pressure chamber in which the operating team and the patient could be housed. Under these conditions, the lung would not collapse when the chest was open. Although animal experiments produced some success, operations on patients were not rewarding. Orotracheal intubation with metal tubes for the treatment of croup and for the prevention of aspiration during oral surgical procedures provided the early experience that led to positive-pressure endotracheal anesthesia for thoracic surgery.

World War I saw the development of techniques for managing empyema. Almost two-thirds of all deaths in that war were related to pneumonia and subsequent empyema. The Empyema Commission of the United States Army, led by Evarts Graham, developed the principles of management of empyema in an era long before antibiotics. The mortality rate of this complication dropped remarkably after the commission established the standard of tube thoracostomy instead of open drainage for acute empyema.

During the same era, thoracic surgeons began developing techniques for managing “the white plague”—tuberculosis. This included the concepts of cavitory collapse and thoracoplasty. Pulmonary resection for tuberculosis, although attempted in the late 1800s, was not successful until the techniques of pulmonary resection were developed in the twentieth century. It wasn't until 1932 that the first successful pneumonectomy for cancer was performed by Evarts Graham in St. Louis. Thereafter, surgeons rapidly elaborated sophisticated techniques of hilar dissection and individual ligation of vessels, thereby allowing safe resection of lungs, lobes, and segments.

During World War II the Army Medical Corps, faced with many severe chest injuries, developed standards for the surgical management of hemothorax, and subacute and chronic empyema that remain accepted to this day.

The advent of antibiotics greatly reduced the hazards of pulmonary infections and the need for surgical intervention. After World War II the incidence of cigarette smoking rose dramatically, leading thoracic surgeons to focus on the surgical management of lung cancer. As lung cancer became epidemic and improvements in radiotherapy and chemotherapy occurred, combined-modality therapy for locally advanced tumors became integral to the treatment of lung cancer.

With increasing knowledge of pulmonary physiology and the emergence of intensive care units in the past half century, thoracic surgery has become safer, with rapidly decreasing postoperative complications and mortality.

The introduction of flexible fiberoptic equipment allowed flexible bronchoscopy to replace, for most indications, the use of rigid equipment and largely eliminated the need for general anesthesia in diagnosing pulmonary problems. These small-caliber instruments allow examination not only of the major airways but also of the segmental and subsegmental airways for diagnostic and therapeutic purposes.

The past decade has seen another revolution in thoracic surgery. Improved optical and video equipment has led to the development of minimally invasive video-assisted techniques (video-assisted thoracic surgery, or VATS). Surgeons now are able to perform intrathoracic diagnostic and therapeutic procedures without the debilitating effect of a thoracotomy. In many instances, this has decreased postoperative pain and shortened hospital stays.

Improved surgical techniques also have allowed diseases that previously were managed non-surgically to be treated curatively by surgical resection. The work of Grillo and Pearson in developing mobilization techniques for the trachea now routinely permits tracheal resections for benign and malignant conditions.

Surgery for non-infectious benign conditions of the lung previously was limited to the resection of compressive bullae. The successful development of lung transplantation by the Toronto group during the 1980s now offers patients with end-stage pulmonary disease a new lease on life. Spurred by the pioneering work of Brantigan and Cooper, surgeons are focusing attention on lung volume-reduction surgery as a bridge or an alternative to lung transplantation for patients with diffuse severe emphysema.

Throughout its history, the demise of pulmonary surgery has been predicted, first with the successful management of empyema, next with the introduction of antibiotics to treat pulmonary infection, and finally with the decreasing incidence of smoking in developed countries. Instead, the specialty has evolved rapidly as improved medical therapies obviated the need for surgical intervention in some diseases, but new diseases or technologies made thoracic operations necessary and appropriate. The spectrum of problems managed by thoracic surgeons today is broader and more complex than a decade or two ago.

ANATOMY OF THE THORAX AND PLEURA

Thoracic diseases often can be localized by physical examination to underlying anatomy because the bony parts of the thorax are palpable and cardiac and breath sounds are transmitted through the chest wall. Several anatomic factors can be misleading. The “squaring off” effect of the shoulder girdle gives the chest the physical appearance of a rectangle, obscuring the fact that the chest wall is conical in shape, tapering quite sharply in the upper chest. The lung apices rise well above the level of the clavicles anteriorly and the scapula posteriorly. The diaphragm rises as high as the level of the nipple, and the upper part of the abdomen, including the liver, spleen, stomach, distal pancreas, and kidneys, is overlapped by six of the ten anterior ribs and the lower four posterior ribs. These easily overlooked anatomic facts can lead to serious errors in patient management, especially in patients with penetrating trauma (Fig. 16-1).

The framework of the thoracic cage consists of the sternum, twelve thoracic vertebrae, ten pairs of ribs that end anteriorly in segments of cartilage, and two pairs of floating ribs. The thoracic inlet has a rigid structural ring formed by the sternal manubrium, the short, semicircular first ribs, and the vertebral column. As a result of its articulation with the manubrium and the attachment of the costoclavicular ligament, the clavicle helps protect the subclavian vessels and brachial plexus, which traverse the thoracic inlet. The same rigidity that provides protection from trauma leaves little room for pathologic swelling, enlarging masses, or age-related postural adjustments.

The cartilages of the first six ribs have separate articulations with the sternum; the cartilages of the seventh through the tenth ribs fuse to form the costal margin before attaching to the lower margin of the sternum. Since there is significant flexibility of the chest wall in children, serious trauma can be transmitted to the intrathoracic structures with little injury to the bony framework. Although this flexibility decreases progressively with age, surprising damage can occur occasionally in the chest of adults without evidence of skeletal injury.

The pectoralis major and minor muscles are the principal muscles covering the anterior thorax, and the lower margin of the pectoralis major forms the anterior axillary fold. Auscultation of the chest in the axilla often allows the best determination of breath sounds because the thoracic cage is covered only by the origins of the serratus anterior muscle in that location. The long thoracic nerve and vascular pedicle pass vertically on the anterior surface of that muscle—a point to remember when doing a thoracentesis or tube thoracostomy. The latissimus dorsi and teres major muscles converge to form the posterior axillary fold on each side. The auscultory triangle can be palpated near the inferior medial border of the scapula. Posterior and inferior to this, the latissimus dorsi, trapezius, rhomboid, and other shoulder girdle muscles form a strong muscular coat for the posterior thorax.

The sternal angle is easily palpable and allows quick identification of the second rib because of its articulation with the sternum at this location. A plane that is parallel to the floor and passes through the sternal angle of an upright patient also passes through the fourth or fifth thoracic vertebra. The tracheal bifurcation lies in this same plane, whereas the apex of the aortic arch is located slightly higher. There is a gradual increase in the length of ribs from the first to the seventh and a progressive lateral displacement of the rib–costal cartilage junctions. Because of the radiolucency of the cartilages, standard anteroposterior chest x-rays may not show an injury to the thoracic cage even though a severe blunt trauma to the chest has disarticulated and fractured multiple costal cartilages.

The pleura is a serous membrane of flat mesothelial cells overlying a thin layer of connective tissue in which a vascular and lymphatic network is distributed. The part covering the lungs is referred to as the *visceral pleura*, and it is continuous over the pulmonary hilus and the mediastinum with the parietal pleura, which covers the inside of the chest wall and the diaphragm. As shown in Fig. 16-2, the line of pleural reflection extends slightly beyond the lung border in each direction. While it is convenient to consider the pleura as a closed sac around the pleural cavity, this concept misrepresents a highly dynamic structure. The pleural surfaces behave more like a flowing syncytium across which fluids actively move (from visceral pleura to parietal pleura), phagocytosing cells and debris and sealing air and capillary leaks. It is this physiologically active membrane that contributes to the general resistance of the pleural space to infection and the lung's remarkable ability to tolerate the trauma of surgery or injury with such a low frequency of persisting air-leak problems. With normal lung expansion, the pleural cavity is completely filled, and only a potential space exists. When lung volume is decreased, such as with lobar atelectasis, the normally negative pressure in the pleural space becomes positive, allowing fluid to be drawn into the pleural cavity. Other disease processes such as infection or malignancy, which either increase production or inhibit clearance of pleural fluid, also lead to the accumulation of fluid in the pleural space.

There is no communication between the pleural cavities, but the anteromedial borders of the two pleural sacs come nearly into apposition behind the sternum. The interior border of each pleural cavity is located at the ninth rib in the midaxillary line, and the borders continue posteriorly in the eleventh intercostal space. Occasionally, the pleural sac extends as low as the twelfth rib. Posteriorly, the margins of the two pleural sacs lie on the anterolateral surfaces of the vertebrae separated by the esophagus. A retroesophageal recess is formed when the pleural margins are in near apposition, and pulmonary lesions arising in the recess can be mistaken for mediastinal tumors or cysts. At the inferior margin of the lung hilus on each side, a double layer of mediastinal pleura is formed (the inferior pulmonary ligament).

The structures occupying the intercostal spaces are important in relation to thoracic function, disease, and diagnostic procedures. The parietal pleura, for example, is well supplied with nerve endings for pain, whereas the visceral pleura is insensitive. Only when pulmonary disease extends to involve the parietal pleura or chest wall is pain produced. Fig. 16-3 shows the structures in an intercostal space and emphasizes the layering effect of the muscles and fascia. Three layers of intercostal muscles are present in a major part of the thoracic wall, but some anatomists consider the intercostals to be a single muscle entity. With quiet respiration, the ribs are elevated by synchronous contraction of the intercostal muscles. Because the ribs of each side move as a unit in respiration, a localized painful lesion may disrupt effective function of the entire side. During quiet respiration, however, movements of the diaphragm provide approximately 75 percent of pulmonary ventilation, and temporary loss of unilateral intercostal muscle function is not a threat to breathing. With labored breathing or in individuals who have impaired diaphragmatic muscle function, the muscles of the upper extremity and the cervical muscles attached to the chest wall assist in elevation and expansion of the thorax.

The endothoracic fascia is a layer of light areolar tissue subjacent to the parietal pleura. At the apex of each hemithorax, it is thickened into a more substantial layer referred to as *Sibson's fascia*.

The vein, artery, and nerve of each interspace are located deep to the external and internal intercostal muscles and lie just behind the lower margin of the rib. For most interspaces, a smaller collateral artery runs along the top border of the rib below. There is significant overlap of neural supply by adjacent nerves, and complete anesthesia in an interspace generally will not occur unless the intercostal nerve of the adjacent space above and below and the space in question are anesthetized. To minimize the risk of lacerating the intercostal artery, a thoracentesis needle or a clamp used to perforate the pleura for insertion of a catheter should be passed across the top of the lower rib of the selected interspace.

The lymphatic drainage of the chest wall extends in both anterior and posterior directions. Lymph draining from the anterior region of the first four or five intercostal spaces passes to lymph nodes along the internal thoracic arteries. These nodes may be connected by cross-anastomoses before draining into a single or double trunk that joins the thoracic duct, a right lymphatic duct, or a bronchomediastinal trunk. Lymphatics that drain the posterior and lateral regions of the intercostal spaces are tributary to lymph nodes that lie near the vertebral ends of each interspace. In the lower part of the thorax, these nodes join the drainage from the posterior mediastinum to contribute to the cisterna chyli. The posterior lymph nodes of the upper thorax drain into the thoracic duct or a right lymphatic duct.

A musculofibrous floor is provided for the thorax by the diaphragm. The peripheral muscular portions of the diaphragm arise from the lower six ribs and costal cartilages, from the lumbar vertebrae (right and left crus), and from the lumbocostal arches. Additional fibers arise from the xiphoid cartilage, and all the muscular elements converge into the central tendon. The central part of the tendon underlies the pericardium, whereas the right and left divisions extend posteriorly. Some of the lower intercostal nerves are thought to contribute to the sensory innervation of the diaphragm, but motor innervation is supplied by the phrenic nerve on each side.

Of the three major openings in the diaphragm, the aortic hiatus is most posterior. The aorta, azygos vein, and thoracic duct pass through this opening. The esophageal hiatus transmits the esophagus and the vagus nerves, and only the inferior vena cava goes through the foramen of that name.

Contemporary imaging techniques (including computer-assisted tomographic and nuclear magnetic resonance scanning) have increased the clinician's ability to identify anatomic relationships and their clinical significance. They have dramatically altered the preoperative assessment of pulmonary and mediastinal lesions.

Fig. 16-4 shows the cross-sectional anatomy at four different levels in the thorax associated with identifiable topographical landmarks. These studies provide considerable anatomic clarification of intrathoracic problems.

THORACIC INCISIONS

In recent years, an increasing variety of incisions has been used to diagnose, stage, and treat thoracic disease. This reflects an evolution in the types of procedures performed and technological advances, such as videothoracoscopy, that permit some procedures to be performed through a minimally invasive approach. Some incisions are used primarily for diagnostic operations, whereas others are used for therapeutic procedures.

Cervical mediastinoscopy and parasternal mediastinotomy incisions are used mainly for diagnostic purposes, particularly for staging lung cancers or determining the cause of mediastinal adenopathy. Mediastinoscopy is performed via a 3-cm incision in the suprasternal notch, which is carried down to the trachea in the midline between the strap muscles. The pretracheal fascia is incised, and blunt digital dissection along the anterior tracheal wall to the level of the carina then permits insertion of the mediastinoscope for biopsy of the mediastinal lymph nodes. These nodes are accessed by blunt dissection (using a suction cautery), back through the pretracheal fascia into the mediastinal soft tissues. A standard staging procedure for lung cancer includes biopsies of the right and left paratracheal and the subcarinal lymph nodes.

A parasternal mediastinotomy, which usually is performed on the left side, is also known as the *Chamberlain procedure* (after Maxwell Chamberlain, the surgeon who popularized this approach for staging left upper lobe cancers). A 6-cm incision is made over the left second costal cartilage, which is excised. The internal mammary vessels are ligated or preserved, and dissection is carried medial to the pleura posteriorly into the mediastinum along the aortic arch. This permits direct biopsy of the aortopulmonary window lymph nodes and an assessment of the resectability of the primary tumor with respect to the pulmonary artery. This approach also is used frequently to biopsy anterior mediastinal lymphomas, which are usually located just beneath the second and third costal cartilages.

For therapeutic procedures, the most frequently used incision is the posterolateral thoracotomy, but the anterolateral thoracotomy incision also is used for many general thoracic operations. Both these incisions require division of one or more major shoulder-girdle muscles and this results in voluntary restriction of shoulder motion in the early postoperative period. Patients must be encouraged to begin active shoulder and arm motion after operation, but elderly patients are especially likely to develop a restricted range of shoulder motion if not supervised carefully. The distal parts of the transected muscles lose their nerve supply and can atrophy to a significant degree postoperatively. Patients usually note a zone of reduced sensation in the skin on the caudal side of the incision for several months after operation.

The posterolateral thoracotomy incision traditionally has been used for most pulmonary resections (except lung biopsy), for esophageal operations, and for the approach to the posterior mediastinum and vertebral column (Fig. 16-5). The skin incision is begun at the anterior axillary line just below the nipple level in the male and at the corresponding position in the female. The incision extends posteriorly below the tip of the scapula and ascends midway between the vertebral border of the scapula and the spinous processes of the vertebrae. To expose the thoracic cage, it is necessary to divide the latissimus dorsi and divide or retract the serratus anterior, trapezius, and rhomboid major muscles. The pleural cavity is entered by dividing the intercostal muscles in the chosen interspace, most often the fifth intercostal space, which provides good general intrathoracic exposure. Division of the rib posteriorly before the mechanical rib spreader is put in place helps avoid accidental fracture of one or more ribs or a costochondral separation by the instrument. Injury to the rib or cartilage may increase postoperative incisional pain and prolong restricted motion of the chest cage.

The anterolateral thoracotomy has some advantages in trauma victims who are hemodynamically unstable. The incision allows rapid entry into the chest with the patient supine or semisupine on the operating table. This is tolerated better than the lateral decubitus position and gives the anesthesiologist maximum control over the patient's cardiorespiratory system. The incision may be used for mediastinal operations, for some cardiac procedures, and for wedge resections of the upper and middle lobes of the lung. The preferred approach is a submammary skin incision starting at the sternal border overlying the fourth intercostal space and extending to the midaxillary line. The pectoralis major muscle and part of the pectoralis minor are divided at the level of the fourth or fifth intercostal space, and the incision is extended into the serratus anterior. By extending the intercostal muscle incision posteriorly along the top of the subjacent rib, it is possible to obtain a wider opening in the chest than the length of the skin incision would suggest. In an emergency situation, more exposure to the lung and mediastinum can be obtained by transecting the sternum.

The routine use of double-lumen endotracheal tubes makes it possible to use a less extensive midlateral thoracotomy incision. This incision has evolved from the transaxillary approach through the bed of the third rib that was used extensively in some clinics for upper-lobe biopsies for resection of small apical pulmonary blebs and pleural abrasion in patients with recurrent pneumothorax, for upper thoracic sympathectomy, and for biopsy of upper mediastinal lymph nodes or masses. By moving down the lateral chest wall several ribs, and with the advantage afforded by single- lung anesthesia, good exposure can be obtained for most pulmonary resections and hilar dissections. The incision has the advantage that it requires cutting no major muscles, can be made and closed rapidly, and results in less postoperative discomfort. An important requirement for adequate exposure in the incision is proper positioning of the patient. The patient is placed in a straight lateral position with the arm at right angles (to facilitate mobility of the scapula). The skin incision parallels the course of the fifth rib, extending from a few centimeters anterior to the middle of the lateral border of the scapula forward toward the submammary fold. The latissimus dorsi is elevated along its entire anterior border, as is the pectoralis major along its axillary border. The serratus anterior is separated from its insertion into the fifth rib, which is removed after the periosteum is stripped. Two rib retractors are placed at right angles to one another, one retracting the two muscle groups anteriorly and posteriorly and one

retracting the ribs caudad and cephalad (Fig. [16-6](#)).

A hazard that is common to all the lateral thoracotomy incisions is the potential for injury to the brachial plexus and the axillary neurovascular structures from excessive displacement of the shoulder in positioning the patient on the operating table after anesthesia has been induced. By preventing posterior displacement of the shoulder, this complication can be minimized.

The thoracoabdominal incision combines an upper abdominal incision with an incision in a lower intercostal space (sixth, seventh, or eighth) that may be carried as far posteriorly as the posterior axillary line. The costal margin and diaphragm are divided to provide an extensive exposure of the upper part of the abdomen and the retroperitoneal and posterior thoracic structures. Prolonged pain associated with incomplete healing of the costal margin, as well as complicated wound management involving two body cavities if infection occurs, has reduced the enthusiasm for this incision. Although elective use of this incision is becoming less common, it is still appropriate for some operations involving retroperitoneal structures (kidney, thoracoabdominal aorta) and for hepatic or thoracoabdominal trauma under emergency conditions.

A bilateral anterior thoracotomy incision with transection of the sternum ("clamshell" thoracotomy) was the standard operative approach to the heart and mediastinum before experience was gained with the median sternotomy. It is the preferred incision for double-lung transplantation and for resection of bilateral pulmonary metastases. It also is useful in circumstances in which the instruments necessary to perform median sternotomy are not available and there is urgent need to have access to both hemithoraces. It provides some cosmetic advantage in young women because bilateral submammary incisions leave less disfiguring scars than the median sternotomy. A median sternotomy also can be carried out through a submammary incision with large skin flaps, although hypesthetic nipple is a frequent complication of this approach.

The median sternotomy incision provides optimal exposure for anterior mediastinal lesions, and it is the principal incision used for cardiac operations. Either pleural cavity may be entered or incision into the pleural cavity may be avoided if it is unnecessary. Disadvantages of the incision include an increased risk of infection if it is necessary to do a tracheostomy within a few days after operation and the protracted course that occurs with infection because of involvement of the sternal fragments. An occasional patient who develops an acute wound infection also develops a severe mediastinitis associated with dehiscence of the sternal wound. The morbidity of this complication is high but has decreased with the evolution of effective treatment, particularly including rotation of pectoralis or rectus abdominis muscle flaps.

The skin incision extends from just below the suprasternal notch to a point several centimeters below the xiphoid process (Fig. [16-7](#)). A saw or, if not available, a Lebsche knife and mallet are used to split the sternum. A mechanical retractor is used to spread the incision, but care is taken not to fracture the sternal halves or injure the C₈-T₁ component of the brachial plexus by excessive spreading of the retractor blades. Postoperatively, a sternotomy is associated with less pain and interference with pulmonary function than a lateral thoracotomy.

The rigid thoracoscope was used for many years, particularly in Europe, for diagnostic visualization of the pleural space. The recent development of videoendoscopic technology revolutionized thoracoscopy, making it possible to perform therapeutic as well as diagnostic procedures. *Video-assisted thoracic surgery (VATS)* has become an accepted approach to diagnosis and treatment of pleural effusions, recurrent pneumothoraces, lung biopsies, resection of bronchogenic and mediastinal cysts and esophageal myotomy. However, after an initial wave of enthusiasm, thoracic surgeons have largely abandoned VATS for major cancer resections in favor of more traditional open incisions.

VATS is performed via two to four "port" incisions measuring 1 to 1.5 cm in length to allow insertion of the videothoracoscope and various instruments. The location of these incisions varies depending on the type of procedure being performed. Occasionally, a 8-cm non-rib-spreading intercostal "access" incision is added to improve exposure or allow insertion of additional instruments.

At the conclusion of any thoracic operation, the pleural cavity is drained with one or two chest tubes connected to an underwater seal system. Each tube is brought out through a separate stab incision in the chest wall at least two interspaces away from the incision. If the pleural cavity is not entered in operations through a median sternotomy, it is advisable to drain the mediastinum for at least 24 h with an intercostal tube that is brought out through a stab incision in the epigastrium.

PATIENT EVALUATION

Because all operations on the chest result in some short-term respiratory dysfunction and many require partial removal or permanent alterations in function of intrathoracic organs, the surgeon must make a careful assessment of the patient's ability to withstand the contemplated procedure. This assessment includes most components of the patient's overall state of health.

The initial patient encounter is by far the most important step in preoperative assessment. Major predictors of postoperative complications include the extent of resection, pre-existing cardiopulmonary disease, age, and other co-morbid conditions (e.g., diabetes, other systemic illness, immune-depressive diseases and drugs, obesity, and recent weight loss). Most of the first encounter with the patient should be devoted to accurate history taking. This initial step not only suggests the diagnosis but also determines the indications and need for a surgical intervention. It also determines the suitability of the patient to undergo such a procedure, the extent of co-morbid disease, and the need for additional testing.

If the patient is young and in good health, little further evaluation may be necessary. However, because most candidates for thoracic operations are middle-aged or older, are former or active smokers, and have some symptoms or signs of *chronic obstructive pulmonary disease (COPD)* or heart disease, careful inquiry and examination for evidence of preexisting impairment in pulmonary or cardiac reserve is essential. The patient who can climb two flights of stairs at a steady pace without dyspnea or wheezing probably has the strength, endurance, and reserve for an uncomplicated postoperative course. Any history of exercise intolerance, dyspnea on exertion, wheezing, smoking, or productive cough or physical findings of obesity, clubbing, or cardiopulmonary disease require additional evaluation and preoperative preparation.

All patients undergoing thoracotomy experience some compromise in their cardiopulmonary function postoperatively, particularly if lung tissue is resected. For those with preexisting impairment, this additional loss of pulmonary reserve may result in serious postoperative problems unless the patient is carefully evaluated preoperatively in order to give the surgeon reliable guidelines about how much pulmonary tissue the patient can safely lose.

Pulmonary Function

The major consideration in evaluating the potential thoracotomy patient is whether or not the patient's pulmonary function is adequate to tolerate the operation, the stress of the postoperative period, and the long-term functional demands. When the planned operation will result in a loss of functioning pulmonary tissue (lobectomy, pneumonectomy), there is a risk of postoperative respiratory insufficiency if the patient's preoperative pulmonary function is already compromised.

Complete pulmonary function tests including lung volumes, spirometry, diffusion capacity, and arterial blood gas determinations provide the critical information used by thoracic surgeons to determine the feasibility of pulmonary resection. Fig. [16-8](#) illustrates the subdivisions of lung volume in relation to a spirographic tracing and Table [16-1](#) indicates typical values in pulmonary function tests.

Pulmonary Mechanics

Vital capacity (VC), the amount of air that can be forcefully expelled from a maximally inflated lung position, is a useful determination if its limitations are understood. The predicted value decreases with age, and its measurement requires full cooperation from the patient. The VC is an indicator of the volume of air that a patient is able to move, but the ability to move postoperative secretions is more closely related to the velocity of forced air movement. The forced expiratory volume in 1 s (FEV₁) is a dynamic measurement of a patient's ability to move volumes of air during units of time. The FEV₁ usually is reported as a percentage of the VC (FEV₁/VC) as well as an actual volume. It is important to note its value both ways. If the VC is significantly reduced by restrictive lung disease (e.g., pulmonary fibrosis), the FEV₁/VC ratio may be satisfactory, whereas the actual volume exhaled may be markedly abnormal. While the VC is near normal in patients with moderately severe obstructive airway disease, it is reduced in individuals with restrictive pulmonary disease and those weakened by neuromuscular disease. The FEV₁ is reduced in obstructive airway disease, but the degree of reduction may vary from day to day or week to week in the same individual and may be improved by medications and pulmonary rehabilitation programs. The FEV₁ is a useful test to monitor patients with marginal pulmonary function who are being prepared for operation by aggressive respiratory therapy programs (See Fig. [16-8](#)).

Blood-Gas Determination

Measurement of the arterial blood gases and pH is routine in the preoperative evaluation of a candidate for thoracic surgery. An occasional patient is discovered to have hypoxemia or CO₂ retention that was not suspected on the basis of clinical examination or spirometry. A measurement of the arterial carbon dioxide pressure (PaCO₂) provides an immediate indication of the patient's alveolar ventilation; any value above 46 torr means that there is hypoventilation. There are multiple causes for this, and the specific reason should be sought in each patient. The ability of the lungs to excrete CO₂ is remarkable, and any persistent elevation in a patient otherwise considered a candidate for a thoracotomy suggests severe chronic lung disease and serious abnormalities in distribution of ventilation and perfusion. Most operations temporarily increase the ventilation-perfusion abnormality. A mild elevation of the PaCO₂ in a patient with chronic lung disease may be treated aggressively with measures to improve pulmonary function and allow the patient to be considered for operation. If pulmonary resection is contemplated in such an individual, the risk of postoperative respiratory failure is high, and the decision to operate may depend on whether functioning pulmonary tissue (versus nonfunctioning) is to be removed.

The measurement of arterial oxygen pressure (PaO₂) is valuable in the preoperative assessment of pulmonary function but must be viewed with a consideration of the possibilities for error in its measurement. At sea level, the normal PaO₂ is greater than 85 torr. The majority of patients with *COPD* have a PaO₂ of 80 torr or below, and values in the range of 70 to 80 torr are not associated with significant postoperative problems. *If the PaO₂ is less than 70 torr, an attempt should be made to determine the cause and to improve the patient's gas exchange preoperatively. The most frequent cause is uneven distribution of ventilation and perfusion (/ mismatch), but other possibilities include right-to-left shunting as a result of the thoracic disease for which the patient is being considered (e.g., shunting through a lung cancer or a non-functional lobe). More sophisticated pulmonary function tests may be required, including determination of alveolar-arterial oxygen difference, calculation of right-to-left shunt fraction, and split pulmonary function (/ scanning).*

In assessing the pulmonary reserve in patients in whom lung resection is contemplated, determination of the amount of lung tissue that can be removed safely is important. The surgeon must begin the operation knowing the maximum amount of lung tissue that can be removed without leaving the patient a pulmonary cripple. The *split-function test* of lung function is quantitative radionuclide ventilation-perfusion scanning for regional lung function (/ scans) and has been especially helpful in making this decision. The perfusion data are obtained by comparing the counts over each lung during ^{99m}Tc perfusion scanning. Perfusion scans can then be correlated concurrently with ventilation scanning to measure regional function.

The practical value of such split-function studies is that postoperative VC and FEV₁ can be predicted for the patient who may require resection of a portion of lung neoplasm (predicted postoperative FEV₁ = preoperative FEV₁ minus the percentage perfusion in the involved lung). A patient may require only a lobectomy, but the acute effects of a major

thoracotomy reduce lung function to a greater extent than this because of some congestion in the remaining lung, restriction of chest wall motion, and incisional pain. In the early postoperative period, pulmonary function can be reduced by as much as 50 percent. This is particularly true if there is significant preoperative reduction in pulmonary function. An important prospective study by Boysen and associates demonstrated the validity of the split-function concept in a group of patients with impaired ventilatory function (preoperative FEV₁ <2.0 L). If the predicted postoperative FEV₁ exceeded 800 mL, the patients were considered acceptable candidates for pulmonary resection up to and including a pneumonectomy. The perioperative mortality in this series was 15 percent, a figure no longer considered acceptable for major pulmonary resections even in extremely high-risk patients. Other investigators have corroborated their data and demonstrated that the measured values for FEV₁ after a pneumonectomy correlated closely with the predicted values. Fig. 16-9 illustrates the use of a split-function study to decide that a patient with severely decreased pulmonary function is a reasonable risk for pneumonectomy.

Testing patients' ventilation and gas exchange during maximal effort and exercise also is important. Previously, maximum voluntary ventilation (MVV) was used. This test is performed by having a patient inhale as deeply and rapidly as possible for up to 15 s. The MVV measures the status of respiratory muscles, the compliance of the lung-thorax system, and airway resistance. In the past, surgeons depended heavily on the results of the MVV because patients with an MVV less than 50 percent of predicted experienced a prohibitively high operative mortality after pneumonectomy.

The carbon monoxide diffusion capacity (DLCO) is increasingly recognized as an important parameter of pulmonary reserve. The DLCO is decreased by severe chronic obstructive and restrictive pulmonary disease. It also can be decreased by some chemotherapy drugs (e.g., bleomycin, mitomycin, and perhaps paclitaxel) and occasionally by radiation. Measurement of the DLCO is particularly important in cancer patients who have received chemotherapy or radiation preoperatively. A DLCO of less than 50 percent of predicted is associated with high risk of postoperative pulmonary complications, and a DLCO of less than 30 percent of predicted generally precludes consideration of a thoracotomy and any pulmonary resection.

In recent years there has been interest in exercise testing for patients who are candidates for pulmonary resection but have impaired pulmonary function. By combining respiratory gas analysis with ergometric testing, oxygen consumption can be correlated with work capacity. These tests measure maximal oxygen uptake (MVO₂). This is particularly useful in evaluating patients who have reasonable exercise capability despite severe obstructive airway disease. Patients with MVO₂ measurements of less than 10mL/kg/min have prohibitive risk of postoperative complications. By using these tests, patients can be selected who are "good" risks to tolerate thoracotomy and resection even with significant impairment on spirometry.

Unilateral balloon occlusion of the pulmonary artery with right-sided heart catheterization is rarely indicated in the preoperative evaluation of patients who require a major pulmonary resection. Normally, after pneumonectomy, the remaining lung accepts the entire pulmonary blood flow without development of pulmonary hypertension. In an occasional patient, occlusion of one pulmonary artery (simulating a pneumonectomy) results in pulmonary hypertension to levels above 30 torr, and this has been correlated with excessive mortality after pneumonectomy. This test is rarely done and only in circumstances where there is conflicting information from other pulmonary function tests.

Numerous studies have shown that there is no data-analysis technique that absolutely separates the operable patient from the inoperable. Instead, the goal of preoperative evaluation is to separate patients into low- and high-risk groups. Of the standard function tests, surgeons have come to place the greatest reliance on the FEV₁, FEV₁/FVC ratio, DLCO, and MVO₂ as the best determinants of operability for the patient with reduced function from respiratory disease, advanced age, or chronic illness.

Although studies have failed to support a precise correlation between a given level of reduced pulmonary function and surgical outcome, guidelines suggested in a recent review by Miller and colleagues predict which patients being evaluated for resective surgery are at high risk (Table 16-2).

The continuing improvements in facilities and technology for postoperative care have allowed surgeons to become more liberal in recommending thoracotomy to selected patients with compromised pulmonary function. Several recent reports provide encouraging indications that suitably selected and well-managed patients with FEV₁ of less than 70 percent of predicted expect satisfactory results after lung resection if pulmonary function is preserved by aggressive perioperative management and pain control and, when necessary, limiting resections to the wide local removal of tumors (wedge resection or segmentectomy) rather than lobectomy or pneumonectomy.

Another important facet of preoperative management is to provide the patient with whatever physical and mental preparation is needed. Many patients are smokers. They must be persuaded to stop smoking before operation, preferably for 2 weeks or more. The use of nicotine substitutes is helpful. Surgeons agree that the character and amount of bronchial secretions have a major impact on postoperative morbidity. Aggressive attention to reducing the amount and tenacity of the secretions must be made before the operation. Any pre-existing pulmonary infection should be identified and treated intensively using appropriate antibiotics, bronchodilators when indicated, and chest physiotherapy.

It has been shown that the patient's attitude toward their disease, the desire to have a favorable outcome, and confidence in their doctors are all predictive of success. The initial patient encounter is extremely important in developing these favorable conditions.

Cardiac Evaluation

In reviewing the epidemiology of postoperative cardiac events, Mangano and colleagues have pointed out that 1 in 8 of the 25 million patients in the United States who undergo noncardiac surgery have coronary artery disease and that 50,000 of these will have perioperative myocardial infarctions. Half the 40,000 annual postoperative deaths in this country are the result of cardiac disease. Careful preoperative evaluation allows the surgeon to identify those at highest risk and, in collaboration with the anesthesiologist, to protect them by appropriate medications and intraoperative monitoring.

The need for preoperative cardiac evaluation is based on the expected postoperative demand for increased cardiac output, the frequency of coincidental cardiac disease in the elderly smoking population, and the likelihood of cardiopulmonary complications after thoracic operations. Because cardiac symptoms are sometimes masked by the symptoms of the primary thoracic disease for which the patient is being considered, the screening evaluation must be precise. A preoperative electrocardiogram (ECG) should be obtained. If the history, examination, or ECG reveals any abnormality, consultation with a cardiologist may be appropriate. Exercise or pharmacologic stress tests and gated radionuclide angiocardiograms provide excellent noninvasive evaluation of suspected myocardial ischemia and of ventricular functions such as cardiac output, stroke volume, and ejection fraction. Rest and stress echocardiography also is useful in detecting valvular disease, in estimating ventricular function, and in assessing a patient's ability to respond appropriately to the stress of a pulmonary resection. For patients with evidence of significant coronary artery disease, it may be necessary to proceed to coronary arteriography and even angioplasty or coronary stenting before planned thoracotomy (Fig. 16-10).

Other Organ Systems

Any preoperative evaluation should include screening tests for renal and hepatic function even in the absence of historical data that suggest disease of those organs. Under ordinary circumstances, a hospital admission biochemical profile that includes measurements of blood urea nitrogen, creatinine, serum proteins, transaminases, lactate dehydrogenase, alkaline phosphatase, and bilirubin is an adequate initial screening test. The discovery of any abnormality mandates a more detailed evaluation.

Malnutrition increases the morbidity and mortality rate of any major surgical procedure, and an assessment of the preoperative nutritional state is important. In clinical practice it may be difficult to separate the effects of total calorie deficit from a deficiency of protein alone. There is a reduced blood volume and reduced tolerance for intraoperative bleeding in hypoproteinemic patients. Impaired antibody production, reduced host resistance to infection, decreased lymphocyte proliferative response, and depression of the delayed skin reactivity to antigens are associated with weight loss and hypoalbuminemia.

Particularly important in thoracic surgical patients are the adverse effects of protein depletion on pulmonary functions and ventilatory capacity. As skeletal muscle is catabolized during starvation, the muscle groups in the thorax, abdomen, shoulder, and diaphragm involved in respiration and coughing share in the unselective loss of strength that is seen in all muscles, and this results in an increased risk of a major thoracic operation.

Cardiopulmonary Rehabilitation

Patients who are malnourished, chronically ill, or have chronic cardiopulmonary diseases can benefit from cardiopulmonary rehabilitation before surgery. There is no evidence that delaying surgery to improve function adversely affects cancer therapy. One, two, or three weeks of intensive preoperative rehabilitation using modern cardiopulmonary exercise techniques supervised by competent therapists can markedly improve cardiopulmonary function. Surgeons frequently fail to take advantage of these simple maneuvers that can significantly decrease the operative risk.

POST-OPERATIVE CONSIDERATIONS

The complications that develop most often after thoracic operations are pulmonary. These also are the most common causes of postoperative death. Although postoperative cardiac events, particularly supraventricular arrhythmias, are common, they rarely lead to significant mortality after thoracic surgical procedures.

Pulmonary Function Changes

Significant physiologic changes in pulmonary function occur after major thoracic and upper abdominal operations. Each produces similar changes in pulmonary function and has similar initial complications; with lung resections, some of these changes may be permanent. The magnitude of the changes is affected by preexisting pulmonary disease, the length of the operation, the use of postoperative analgesics, and immobilization in bed. Patients without pulmonary disease develop similar changes and are subject to similar complications, although the risks are much lower. The pulmonary changes occur in (1) lung volumes, (2) ventilatory patterns, (3) respiratory gas exchange, and (4) defense mechanisms.

Lung Volume

Total lung capacity and each of its subdivisions are significantly reduced after abdominal or thoracic operations. *VC is reduced by 25 to 50 percent or more, with the maximum reduction occurring during the first 4 days after operation. Similarly, functional residual capacity and expiratory reserve volume are decreased, with a gradual return toward normal beginning in the second week after operation. The reduction in lung volume is often accompanied by an increase in the closing volume (early airway closure) and potentiates the development of atelectasis. If a pulmonary resection has been performed, the magnitude of change is even greater and is proportional to the amount of functioning lung that was removed.*

Ventilatory Pattern

The sedative effect of the anesthetic agent and the postoperative analgesics, combined with the severe pain of the thoracotomy incision, produces sharp reductions in tidal volume after operation. The expected response is an increase in respiratory rate sufficient to maintain minute ventilation. Parenteral narcotics ordinarily used to manage postoperative pain all depress the respiratory center, inhibiting the compensatory rate increase and leading to carbon dioxide retention and hypoxemia. Nonsteroidal anti-inflammatory agents (e.g.,

indomethacin or ketorolac) often can provide pain relief nearly equivalent to narcotics without respiratory depression but also may have significant gastrointestinal and renal toxicities.

Another important effect in changes in ventilatory pattern is the sharp reduction in or elimination of the normal periodic hyperinflations (sighs). Normal adults sigh at the rate of nine or ten times per hour under quiet conditions. With loss of periodic hyperinflations, there is closure of lung units resulting in atelectasis and a reduction in compliance.

Gas Exchange

Decreases in PaO₂ and mild elevations of PaCO₂ are frequent as patients recover from anesthesia. PaCO₂ generally returns to normal or below normal in the early postoperative period, whereas PaO₂ can remain depressed during the first week. The factors responsible for the reduction in the PaO₂ include abnormal ventilation-perfusion relationships and intrapulmonary shunting associated with atelectasis.

Pulmonary Defense Mechanisms

The lung is normally protected against inhaled particulate matter and microbes by several mechanisms. The cough reflex defends the upper airways against inhaled or aspirated material in the tracheobronchial tree. Clearance of inhaled particles and microbes from the lower airways depends on the mucociliary system, and the alveoli are defended by mucociliary transport, lymphatic drainage, and alveolar macrophages. Because coughing is inhibited by several mechanisms in the postoperative period, there is significant impairment of that defense mechanism. Ciliary function is decreased, and multiple factors, including arterial hypoxemia, depress the activity of alveolar macrophages. Finally, the composition and physical properties of mucus are altered in a way that reduces the effectiveness of the mucociliary transport system.

Preventive Measures

Many of these changes in postoperative ventilation can be minimized or prevented by preoperative optimization of the patient with regard to cardiopulmonary function using appropriate drug treatment (antibiotics, mucolytics, bronchodilators, etc.) and rehabilitation. In the postoperative period, pain relief is important. In the past two decades, many pain-relieving measures have been introduced in an attempt to provide the patient with a painless postoperative course, and the routine use of these is critical to preventing postoperative complications.

Pain Control

In the first few postoperative days, effective management of incisional pain is of central importance in the maintenance of adequate ventilation. The pain that accompanies a thoracotomy incision is severe and disabling. Unless well managed, it will cause hypoventilation, retention of secretions, atelectasis, hypoxia, hypoxemia, shallow and ineffective respiratory effort, and pneumonia. It is a constant challenge to find the delicate balance between giving patients enough pain medication so that they are able to cough without giving them so much that they lose their initiative to do so.

Pain is frequently managed by parenteral narcotics administered intramuscularly or intravenously on a fixed schedule (by-the-clock) or on-demand (p.r.n.). Particularly when given on demand, use of these narcotics can be associated with swings in patient alertness ranging from obtundation with respiratory depression and suppression of cough to severe pain and anxiety. When parenteral narcotics are used as the primary means of postthoracotomy pain control, they are best administered by a continuous intravenous infusion carefully regulated by observation or by a patient-controlled analgesia (PCA) device. These devices allow adequate continuous pain relief without undue somnolence. Success with this approach requires careful patient education and close nursing care. Nausea, vomiting, and respiratory depression remain potential side effects.

The search continues for the optimal way to control incisional and pleural pain without the deleterious consequences of systemic narcotics. Either short-acting (lidocaine) or long-acting (bupivacaine) local anesthetic agents can be given as one-shot intercostal blocks before closing the chest or by intermittent or continuous injections through catheters left in place in the pleural space at completion of the thoracotomy. When these methods are used, great care must be taken to avoid inadvertent intravascular or subdural injection. Severe vasomotor hypotension is occasionally reported with this technique, and the patient should be monitored closely whenever it is used. Some advocate use of intercostal nerve cryoanalgesia and have reported excellent pain relief by this approach (each nerve receives one 30-s exposure to the probe). Long-term intercostal neuralgia can be a complication of this technique.

There are opiate receptors in the spinal cord with specific endorphins and enkephalin mediators. The use of continuous epidural infusion of preservative-free morphine, hydromorphone, or fentanyl administered via a thoracic or lumbar epidural catheter provides excellent pain control. Although well-controlled studies have not shown that epidural analgesia improves pulmonary function, it is considered in many centers to be the optimal approach to pain control.

Advances in anesthesia techniques, particularly improvements in the design of double-lumen endotracheal tubes, offer the surgeon other ways to reduce postthoracotomy pain. Wide exposure for delicate hilar dissection was necessary when the dissection was carried out around a retracted but filled, moving lung. The ability to work in the chest with a fully deflated lung encourages surgeons to avoid unnecessary rib spreading and to seek other, less traumatic means for entry into the chest. Urschel has reported a large series of lobar resections in both chest cavities through a median sternotomy. The extensive experience with this incision in the open-heart surgery population has demonstrated that it is much less painful and much better tolerated physiologically. Others have developed muscle-sparing incisions to allow major resections without the need for dividing the muscles to the shoulder girdle. This incision is rapidly opened, rapidly closed, and leaves a chest wall with more functional integrity. Postoperative pain is less. The combination of these less traumatic incisions and intrapleural bupivacaine infusions or epidural analgesia as an approach to pain control is gaining favor worldwide.

Complications

Pulmonary complications of thoracic operations have their origins in these postoperative changes in physiology and usually begin in the operating room or soon thereafter. The principal pulmonary complications include atelectasis and respiratory infections.

Atelectasis

Atelectasis begins as closure of lung units, causing microatelectasis, a diffuse sublobular form not visible on chest x-rays, and macroatelectasis, the collapse of a segment, lobe, or entire lung. The three mechanisms that are considered responsible for atelectasis are accentuations of the postoperative pathophysiologic changes described earlier: (1) retained bronchopulmonary secretions, (2) decreased sighing, and (3) decreased expiratory reserve volume.

Retention of secretions is a major cause of atelectasis in patients with chronic bronchitis. It is more subtle in patients with normal lungs, although they also develop either microatelectasis or macroatelectasis. Decreased sighing and reduced tidal volume contribute to the reduced compliance in the postoperative period. Unless reversed by voluntary efforts at deep breathing, induced coughing, or attentive respiratory care, these changes will contribute to the development of atelectasis. Similarly, the postoperative reductions in lung volumes are related to airway closure that is associated with the changes in ventilatory pattern.

Pneumonia

Postoperative bronchopulmonary infectious complications consist of tracheobronchitis and pneumonitis. While these complications also occur in “normal” patients, their incidence is higher in patients with preexisting chronic airway disease. Decreased cough, atelectasis, reduced mucociliary clearance of inhaled particles and bacteria, pain, and analgesic drugs all contribute to these infectious complications. Interference with the mucociliary clearance mechanism leads to rapid bacterial proliferation distal to obstruction in an area of atelectasis. Of equal importance has been the demonstration that the respiratory tract becomes colonized with gram-negative bacilli, particularly in the presence of tracheal intubation, coma, hypotension, hypoxia, acidosis, and azotemia. Many of these conditions exist in the postoperative period in patients subjected to major thoracic procedures.

Cardiovascular Complications

Postoperative myocardial infarction, cerebrovascular accident, or peripheral arterial embolus or thrombosis occur infrequently after pulmonary resection. These complications can be avoided if patients are carefully evaluated preoperatively for cardiovascular disease and placed on appropriate medications.

The most common cardiac complication is supraventricular arrhythmia, usually atrial fibrillation. This occurs in approximately 17 percent of lobectomy patients, 25 percent of pneumonectomy patients, and 33 percent of extrapleural pneumonectomy patients. The risk of postoperative atrial arrhythmias increases with age, being more common over the age of 60 years. Digoxin, previously used routinely to prevent or treat post-thoracotomy atrial arrhythmias, has proved in prospective studies to be ineffective in this regard. Calcium channel blocking drugs, especially diltiazem, provide effective treatment and may reduce the frequency of this complication.

Deep venous thrombosis (DVT) is another potential complication after thoracotomy. As for the other major operations, the frequency of DVT is related to the type and duration of the operation, prior history of DVT, the patient's ability to resume ambulation postoperatively, and the patient's other medical problems (e.g., obesity). Routine DVT prophylaxis with intermittent venous compression boots or with subcutaneous heparin is an integral part of perioperative care for patients undergoing major thoracic procedures.

Other Complications

Other complications occur less frequently after thoracotomy. Renal insufficiency, usually transient, can develop in patients with underlying renal disease who receive nephrotoxic drugs (aminoglycoside antibiotics, non-steroidal anti-inflammatory agents). Wound infections and empyemas occur in less than 5 percent of patients. Routine perioperative antibiotic prophylaxis with cephalosporins reduces the risk of such postoperative infections.

THORACIC INJURIES

General Considerations

The leading cause of death, hospitalization, and short- and long-term disability for all ages from the end of the first year through the forty-fifth year of life is trauma. Twenty-five percent of all trauma deaths are a result of chest injuries alone; respiratory problems contribute significantly in 75 percent of traumatic deaths. The respiratory system works on a small margin of safety, and physical disruption of the integrity of the system, which is expected in trauma, must be corrected rapidly, or irreversible damage resulting from hypoxia in vital structures will occur. With complete loss of oxygen and with normal tissue oxygen demands (e.g., normal ambient temperature), such damage occurs after only 4 min. Lesser disruptions of delivery extend the tolerance time, but it should be apparent that accurate diagnosis of the failing or disrupted elements of the system and their prompt correction are delayed at progressive peril to the patient. Eighty-five percent of patients with life-threatening thoracic injuries can be managed by simple interventions.

General considerations about the management of the injured patient are discussed in Chap. 6. The preinjury cardiopulmonary functional status must be considered carefully. The rib fracture or modest pneumothorax that is well tolerated without hospitalization in a healthy young patient may lead to pneumonia, empyema, or death in an older patient with chronic airway disease. The patient with preexisting cardiac disease is particularly vulnerable to the development of pulmonary edema and hypoxia that can occur with the rapid administration of intravenous fluids during resuscitation.

A rapid, overall evaluation of the patient must be carried out to determine the severity of the injury. Chest trauma often is associated with other injuries, and the overlap of the upper part of the abdomen by the thoracic cage provides a border zone that is difficult to assess and often is the site of combination injuries. Patients who cannot describe symptoms because of associated head injuries or profound shock are particularly challenging to evaluate.

Types of Injuries

Injuries to the chest are usually classified according to the type of insult that caused the damage. The injury often is influenced by the setting (military or civilian, urban or rural) in which it occurred. Most military injuries are high-velocity penetrating wounds. Low-velocity gunshot wounds are replacing knife wounds as the most common in urban civilian populations. Blunt injuries from motor vehicular or occupational (e.g., logging) accidents make up the majority of nonurban injuries. Penetrating wounds are becoming more frequent in suburban and rural areas as violent crimes increase, and blunt trauma also occurs commonly in urban areas.

The mortality rate of major blunt injuries has decreased steadily during the past quarter century, but complications and death associated with pulmonary contusion, posttraumatic pulmonary insufficiency, and trauma to the heart and great vessels are significant. It is characteristic of blunt injuries that the maximal extent of cardiopulmonary functional loss and often the complete diagnosis require several days to become fully evident.

Penetrating wounds of the lower thoracic region are treacherous. The diaphragm normally rises to the level of the nipples during expiration, and penetrating trauma to this area can injure the subdiaphragmatic viscera. Some surgeons believe that a stab wound of the left lower part of the chest mandates early abdominal exploration, because the knife may have injured the spleen, stomach, or colon. The abdominal findings in these patients may be overshadowed by more obvious chest injuries and can be missed by initial peritoneal lavage. The consequence of error is costly. Because the liver usually is the abdominal structure injured by right-sided stab wounds that penetrate the diaphragm, it may be reasonable to delay exploration until the patient is more stable. Early abdominal exploration is indicated if there is evidence of continuing blood loss. The late consequence of diaphragmatic lacerations justifies operative repair as soon as it is safe to do so.

Whatever the cause, the principles of management should remain focused on the mechanical systems involved: the pump, the hydraulics, and the bellows (the suction-blow system that draws atmospheric air into the alveoli and expels it). The pump must be working, and the vessels must have the integrity and suitable contents to transport the gases to and from the tissues.

Conditions Requiring Urgent Correction

Airway Obstruction

Most patients with major disruption of the airway leading to obstruction will not survive the initial accident; the leading cause of death at the accident site is airway obstruction. At any stage of the early resuscitation and transportation of the patient, correctable airway obstruction may occur. The oropharynx should be cleared of mechanical debris and the chin and neck positioned to facilitate opening the posterior pharynx. Until the stability of the cervical vertebrae has been ascertained, the neck should be positioned only by an anterior chin-thrust motion while applying continuous cephalad traction (Fig. 16-11). If the upper airway remains at risk after clearing and positioning, tracheal intubation is indicated. If it can be done safely, orotracheal intubation with a size n 8-mm or larger endotracheal tube is indicated. If cervical spine injury is suspected and midface soft- tissue damage is not extensive, nasotracheal intubation is preferred, even though the small caliber of the nasotracheal tube may prevent subsequent flexible bronchoscopic examination. Fiberoptic orotracheal intubation performed over the flexible bronchoscope is another safe method of obtaining control of the airway in patients with fractures of the cervical spine or the cribriform plate.

If the equipment or expertise is not available, or if the upper airway injury precludes safe access to the vocal cords from above, cricothyroidotomy should be performed. If high-pressure oxygen is available, catheter jet ventilation may be used (percutaneous passage of cricothyroid membrane catheter, 12-gauge or larger) while the patient is being stabilized and arrangements for tracheal intubation are being completed.

Tension Pneumothorax

When an injury to the lung parenchyma has occurred that allows air to enter the pleural space with each respiratory effort, and when the flap- valve effect of the injury prevents that air from reentering the bronchial tree for egress through the trachea during expiration, tension develops within the pleural space until equilibration with the negative pressures the patient is able to generate is reached; at that time, effective ventilation ceases and venous blood can no longer enter the chest. The mechanics of a developing tension pneumothorax may not be obvious when the patient is first seen. Pain may be the primary complaint, with no evidence of respiratory distress. However, if the lung wound is behaving as a check valve, some air escapes into the pleural cavity with each inspiration or with each cough. Gradually, intrapleural pressure builds up, the lung collapses, and tension pneumothorax can develop. A shift of the mediastinum and compression of the large veins result in a decreased cardiac output that may lead to sudden death.

The diagnosis should be made instantly by observation of a patient with dilated neck veins making respiratory effort but not respiratory motions and unable to move air. It is immediately confirmed by the hyperresonant percussion note over the injured hemithorax and absent or distant breath sounds. The immediate release of the tension by placement of a large-bore needle followed immediately by insertion of a thoracostomy tube is lifesaving.

Open Pneumothorax

The sucking chest wound is one in which a full thickness segment of the chest wall has been destroyed and the negative intrapleural pressure sucks air directly through the chest wall defect rather than through the trachea into the alveoli. It occurs most commonly after shotgun blasts, explosions with flying debris, or impalement injuries. It may or may not be associated with underlying parenchymal damage.

The diagnosis can be made by noting a patient with normal or collapsed neck veins who is making respiratory motions but not moving air. Confirmation is immediate on inspection of the patient's chest and observation of the wound. The patient is stabilized by any mechanical covering over the open wound. As soon as convenient, a watertight dressing should be placed and an intercostal catheter inserted into the pleural cavity. Early debridement and formal closure of the wound should then be performed.

Massive Flail Chest

When severe blunt injury results in two-point fractures of four or more ribs, a segment of the chest wall becomes flail. On inspiratory effort, the negative pressure in the chest pulls the unstable segment of the wall inward in a paradoxical motion. The patient may be unable to develop sufficient intratracheal negative pressure to maintain adequate ventilation, and atelectasis, hypoxia, and hypercapnia occur. A patient who is conscious may splint the segment sufficiently to make it inapparent to cursory examination, but the continuing extra effort in the attempt to move air soon leads to tiring and may result in sudden respiratory decompensation. The progressing failure is aggravated by the developing pulmonary contusion that accompanies blunt trauma sufficient to break multiple ribs. In the unconscious patient, the lesion may be less dangerous because it is more readily recognized and more apt to be treated early.

In the massive flail chest, the diagnosis may be difficult unless the chest wall is visualized during the respiratory effort. If unconscious, the patient ordinarily is making vigorous respiratory motions but moving little air; the paradoxical segment should be obvious. The patient who is awake may exhibit a very rapid shallow breathing pattern at or above 40 breaths/min. Other aspects of the management of lesser flail injuries are discussed below, but when massive flail is diagnosed, endotracheal intubation and positive- pressure controlled ventilation are mandatory.

Massive Hemothorax

When 1500 mL or more of blood is acutely removed from the pleural space as a thoracostomy tube is placed, a high proportion of patients will have a surgically correctable injury requiring urgent thoracotomy. If a patient with penetrating injury or multiple rib fractures is found to have a complete hemothorax dull to percussion in association with hypotension, a chest tube should be inserted. If massive hemothorax is found, the patient should be taken directly to the operating room as blood volume resuscitation is taking place.

Conditions Requiring Urgent Thoracotomy

Continued Intrapleural Bleeding

If bleeding continues from a thoracostomy tube after initial placement at a rate exceeding 100 mL/h for 6 h or more, most surgeons would now agree that a surgically correctable lesion is present. Ordinarily it will be a bleeding intercostal vessel, because bleeding from the lower-pressure pulmonary system almost always stops when the lung is reexpanded after the pleural space is evacuated. In making a decision to proceed with surgical exploration, the rate and pattern of bleeding are more important than the amount.

Massive Air Leak

This uncommon injury usually results from steering wheel compression of the trachea against the vertebral bodies following high-speed head-on collisions. Complete disruption of the trachea or a major bronchus may occur. The injury is often fatal but may be tolerated for a brief period if the surrounding mediastinal soft tissues maintain continuity of the airway. All levels of the trachea and all major bronchi can be involved; however, more than 80 percent of these injuries occur within 2.5 cm of the carina. Patients with intrathoracic tracheal or central bronchial disruption exhibit a variety of signs and symptoms depending on whether there is free communication between the site of injury and the pleural cavity. Important pathognomonic findings are complete unilateral atelectasis in the face of a large air leak or symmetrical downward displacement of both hila. Distal injuries often result in pneumothorax, which is manageable by tube thoracostomy alone because the air leak is small. Lazar reported a case in which a complete tracheal disruption just above the carina with 6 cm of discontinuity was tolerated in a young athlete for 24 h before accurate diagnosis and repair.

Extreme care must be taken in the evaluation of patients with massive air leaks, because overly aggressive diagnostic bronchoscopy or endotracheal intubation and positive-pressure ventilation before the defect is located accurately and preparation for repair are made can result in rapid death. Occasionally, as in other tracheobronchial injuries, an injury may seal itself off and fail to be recognized until severe stenosis develops.

Other Indications

Several other important causes are listed here, but discussed elsewhere.

Acute or rapidly recurring pericardial tamponade

Acute heart failure secondary to valvular or septal injury

Widened or widening mediastinum

Perforation of the intrathoracic esophagus

Dangerous But Less Compelling Injuries

Diaphragm Rupture

Urgent repair of massive diaphragmatic rupture is necessary if high-volume herniation of abdominal contents into the chest prevents adequate ventilation. Ordinarily, however, the acute problems associated with diaphragm rupture are related to the associated injuries to abdominal viscera resulting from the force necessary to rupture the diaphragm. Penetrating trauma to the lower chest or upper abdomen and crush injuries, most often secondary to automobile accidents, are the usual causes of traumatic rupture of the diaphragm. The left hemidiaphragm is ruptured more frequently by blunt trauma than the right, at a ratio of about 9:1. The right hemidiaphragm is protected by two mechanisms: The liver on the right and the heart in the center have a buffering effect that diffuses the sudden increase in intraabdominal pressure; and cadaver studies have shown an inherent weakness in the posterolateral aspect of the left diaphragm. When rupture of the right side does occur, the liver usually is the only abdominal structure that herniates into the chest early, although gradual aspiration of the stomach into the right chest through the diaphragmatic defect can occur over time. With rupture of the left hemidiaphragm, the stomach, spleen, left transverse colon, and omentum in any combination may enter the left pleural cavity immediately. If the diagnosis is delayed for several days or longer, there is progressive displacement of the abdominal viscera into the chest or progressive gaseous distention of the herniated stomach. The latter may occur despite an indwelling nasogastric tube and can precipitate respiratory distress (Fig. [16-12](#)).

Patients with diaphragmatic rupture from blunt trauma usually have associated injuries that demand attention first and prevent a detailed initial evaluation. The first chest x-ray after rupture of either hemidiaphragm may show nothing more than a blurring of the diaphragm with or without evidence of a small hemothorax. In some patients the diagnosis is made very early because the nasogastric tube is seen to lie within the confines of the left pleural space.

Penetrating diaphragmatic injuries rarely produce early symptoms except those related to other structures that may be injured. After several months or years, gastrointestinal obstruction may develop and lead to strangulation of herniated viscera. The hole in the diaphragm is small, and herniation occurs slowly. When the diagnosis is made early, hours to days after the injury, diaphragmatic repair should be performed via laparotomy in order to manage associated intraabdominal injuries. The wound in the hemidiaphragm may vary from a simple radial tear to an extensive and complex laceration. Repair usually can be accomplished by direct suture, but a prosthetic patch of nonabsorbable material occasionally is required. If the diagnosis is delayed, a transthoracic approach is preferred because it provides better exposure to reduce the hernia, free adhesions between the abdominal viscera and intrathoracic structures, and repair the defect in the diaphragm.

Pneumothorax

Pneumothorax usually is the result of injury to the lung or the tracheobronchial tree. Esophageal perforation may be followed by a pneumomediastinum that ruptures into the pleural cavity. Whether the pneumothorax is associated with blunt injury and fractured ribs or is the result of a penetrating wound, there is a variable amount of bleeding into the pleural cavity. When sufficient blood is present to require its removal or transfusion, it is termed *hemopneumothorax*.

Pneumothorax can vary from one that is so slight that it may be missed on the initial x-ray examination to a massive, continuing air leak that displaces the mediastinum, depresses the diaphragm, and compresses the opposite lung, such as the tension pneumothorax discussed previously (Fig. [16-13](#)). A pneumothorax due to a parenchymal lung injury is self-limited because the developing lung collapse combines with blood clotting in the wound for a sealing effect. For some patients, extensive adhesions already present between the visceral and parietal pleura may localize the pleural air and prevent a collapse of the lung (Fig. [16-14](#)).

With any chest injury it is wisest to presume that a pneumothorax is present until proved otherwise. Because of pain and limited chest motion on the injured side, physical examination may be inadequate for diagnosis of a minimal pneumothorax. Since attention may be diverted to the management of other injuries, and because of the risks of tension developing should a general anesthetic with positive-pressure ventilation be given, prophylactic thoracostomy catheters usually should be placed whenever there is significant chest injury. The catheter is best placed in the midaxillary line, just above the fifth rib, after finger exploration has ensured that the pleural space is free at the site of insertion.

Treatment of the more usual pneumothorax depends on symptoms of respiratory insufficiency, the extent of the pneumothorax, and the presence of significant hemothorax. There is a tendency to think of pneumothorax in terms of the two dimensions conveyed by the anteroposterior chest x-ray. Instead, the hemithorax should be considered a modified cone, and when the lung surface is separated from the chest wall by 3 cm or more, the patient may have a 50 percent lung collapse (by volume) rather than the 25 or 30 percent collapse that the chest x-ray suggests. Rarely, when a pneumothorax is less than this amount because of a nonpenetrating injury and is not accompanied by significant blood or fluid in the pleural cavity, treatment may not be required. A decision not to remove the pleural air implies that the patient has had a minor injury and that conditions for observation are ideal. Approximately 1.25 percent of the air will be absorbed each day, with full expansion expected in 3 to 6 weeks.

Aspiration of the air with a needle and insertion of an intercostal catheter only if lung collapse recurs constitute a reasonable method of treatment advocated by some even when the pneumothorax amounts to as much as 50 percent. In all patients with collapse greater than 50 percent, in those with hemopneumothorax, and in those whose pneumothorax is the result of penetrating trauma, an intercostal catheter should be inserted and attached to a water seal with 10 to 25 cmH₂O of negative pressure. In the majority of patients, lung reexpansion and cessation of the air leak occur within a few hours or a few days. If not, a major bronchial injury may be present, and a thoracotomy may be required after appropriate diagnostic procedures.

The use of prophylactic systemic antibiotics in patients with chest trauma is controversial, and their use in cases of nonpenetrating trauma seems unjustified. The simple insertion of an intercostal catheter does not require prescribing antibiotics.

Interstitial Emphysema

Disruption of the respiratory tract at any level results in the passage of air into the surrounding tissues. Mediastinal emphysema occurs when air enters the areolar tissue planes from a tracheobronchial wound or from a perforation of the esophagus. Occasionally, blunt injuries to the chest may disrupt the integrity of a group of bronchioles or alveolar units without disrupting the visceral pleura. As air escapes into the pulmonary interstitium, it dissects centrally along the bronchi and pulmonary vessels to reach the mediastinum. When the mediastinal pleura remains intact, progressive loss of air into the tissue carries the dissection into the neck, where the air escapes the deep tissue planes and spreads in the subcutaneous tissue. The development of subcutaneous emphysema may cause marked distortion of the patient's appearance, but there is no reason to "treat" the condition, except to take whatever steps are appropriate to stop the air leak. The source of the leak must be found, because some potential causes (esophageal perforation or major bronchial injury) require early intervention.

Rib Fractures and Lesser Flail Injuries

The most common injury of the chest is a fracture of one or more ribs, including fracture at the costochondral junction ("separation"). Children seem less liable to rib fractures, but chest x-rays are made less frequently in young age groups with minor trauma. Fractures occur most commonly in the middle and lower ribs with blunt trauma, but the distribution with penetrating wounds varies with the distribution of the penetrating objects.

First Rib Fractures

First rib fractures historically have been associated with high probability of associated upper rib fractures and major vessel injuries. Recent reports by many physicians have demonstrated isolated first rib fractures without other significant injuries in the thoracic outlet in a wide variety of patients. Because of the relative high frequency in association with cranial and maxillofacial injuries and in the "surfer's" rib (an injury occurring in surfers performing the lay-back maneuver), it is probable that isolated first rib injuries are secondary to avulsion of the first rib by its muscular attachments rather than direct trauma to the relatively protected first rib. There is inconclusive evidence that a direct relationship exists between first and second rib fractures and trauma to major vessels at the apex of the hemithorax (Fig. [16-15](#)). Arteriography should be considered in stable patients with first rib fracture who have (1) absent or decreased upper extremity pulses, (2) hemorrhage, especially large extrapleural hematoma or hemothorax, or (3) brachial plexus injury. Additional criteria for angiography include displacement of fragments and multiple thoracic injuries.

Multiple Fractures

The problem of massive flail chest was discussed briefly earlier. Lesser degrees of flail occur whenever there are multiple fractures of the chest wall skeletal structure. Flail chest is present when there is paradoxical respiratory movement in a segment of the chest wall. This requires at least two segmental fractures in each of three adjacent ribs or costal cartilages or other multiple combinations of rib or sternal fractures with costochondral or chondrosternal separations. Posterior flail segments, in the absence of disrupted intrathoracic structures, are easier to manage because of the strong muscular and scapular support and because of patients' natural tendency to lie with their back against the mattress.

Chest wall stabilization, reduction of respiratory dead space, and management of the underlying pulmonary contusion are the major goals of treatment. In the past, endotracheal intubation or early tracheostomy were recommended for the management of flail chest, to allow easy access for tracheobronchial suctioning and to facilitate internal stabilization of the chest wall through mechanical ventilation. Improvements in respiratory therapy, bedside monitoring, and pain management now permit individualization in the treatment of patients with flail chest injuries. The severity of the associated pulmonary contusion and the extent to which vigorous pain management allows adequate pulmonary toilet often dictate whether or not intubation and ventilatory support are necessary. In this regard, epidural analgesia or intercostal nerve blocks should be used liberally to provide pain relief. For some patients with a small flail area and minimal pulmonary injury, close observation may allow satisfactory recovery without the use of assisted ventilation. Intubation is delayed until clear evidence of a need for ventilatory support develops: a respiratory rate of 40 breaths/min, a falling PaCO₂ (evidence of excessive work of breathing to maintain adequate oxygenation), or a PaO₂ below 60 torr on inspired oxygen fractions of over 0.5. Rarely, a patient presents with localized chest wall fractures amenable to direct operative stabilization. When feasible, this approach can shorten convalescence. Other techniques for stabilizing the flail segment, such as the use of external compression dressings or the application of traction by encircling the fractured ribs with towel clips or wire, are historical oddities.

Several long-term follow-up studies have been published analyzing the late consequences of flail chest injuries. Significant disability was reported in 50 to 64 percent of the patients, with pain as the common residual complaint. In one study, 40 percent of patients examined had found it necessary to change their life-style as a result of the chest injury. Attention to the early and continuing rehabilitation of these injured patients is undoubtedly indicated by these findings.

Other Rib Fractures

An inward displacement of the fracture fragments at the time of injury may lacerate the lung parenchyma and produce a pneumothorax with bleeding into the pleural cavity. With a single rib fracture, the incidence of pneumothorax is not high, but there is an increasing likelihood of this complication as the number of fractured ribs increases. The occurrence of pneumothorax may be delayed for some hours or even days after the injury has occurred. Hemothorax of a significant degree occurring with rib fractures usually is a result of laceration of an intercostal artery rather than of bleeding from the lung. Bleeding may be delayed in onset or may recur after an interval of several days, and it may be life-threatening. In the patient who has multiple rib fractures with segmental fractures of one or more ribs, a delayed pneumothorax or hemothorax may coincide with some shift of

the rib fragments demonstrated in serial chest x-rays.

In elderly or chronically ill patients, rib fractures may occur with severe coughing or hard straining. The occurrence of a spontaneous fracture should alert the physician to the possibility of a bone abnormality such as metastatic neoplasm or hyperparathyroidism. Pneumothorax and hemothorax are infrequent with rib fractures that do not result from external trauma.

The diagnosis of a rib fracture should be suspected from the pleuritic type of pain and marked tenderness over the fracture area. A localized contusion of the chest wall structures may mimic the findings, including shallow respirations with chest wall splinting. Green stick fractures are those not associated with separation of the fragments, and they may not be demonstrated by the initial chest x-ray examination. Several weeks may elapse before a suspected fracture is confirmed. When the patient has two or more adjacent fractured ribs, especially if the ribs are broken in more than one place (segmental fractures), the diagnosis is made with greater certainty by examination alone. Cartilage fractures and separation from either the rib or sternum are not demonstrated by chest x-rays. In a review of emergency room practice, Thompson and coworkers emphasized how infrequently management is influenced by rib radiographs and urged higher reliance on physical findings and avoidance of efforts to obtain confirmatory radiographs unless the findings might alter treatment.

The principal goal of treatment for patients without serious injury is relief of pain. If this is accomplished, patients may resume their normal activities except those which require a vigorous work effort. Adhesive strapping of the chest or chest binders to splint the fracture area should be avoided in all but the very young. In the majority of other patients, an adequate oral analgesic or an intercostal nerve block plus oral analgesics provides reasonable pain relief with minimal risk of side effects (Fig. 16-16). Binders and strapping are particular hazards in the elderly and in patients with chronic lung disease. The nerve block may need to be repeated once daily for several days, but a single injection may suffice for individuals whose injury does not require hospitalization. A patient whose rib fractures are accompanied by minimal pneumothorax (<1.5 cm separation between the lung and the inner chest wall by x-ray) may be treated as an outpatient.

Sternal Fractures

Any major blunt trauma to the anterior chest wall may cause a fracture of the sternum. Such fractures may occur alone or in combination with multiple rib fractures. The fractures usually are transverse and are located in the body of the sternum at or near the junction with the manubrium (Fig. 16-17). The injury is painful and can be pinpointed by the conscious patient. The diagnosis should be made on physical examination and confirmed by lateral x-rays of the sternum or tomography. It is essential to rule out significant injury to underlying structures, especially the heart. In the absence of other major injury, the treatment of the fracture is aimed toward relief of pain and observation for signs of respiratory embarrassment. In patients with compromised pulmonary function or obvious instability of the fragments, more vigorous treatment is required, e.g., positive-pressure ventilation or operative reduction and stabilization of the fragments. When the pain of a sternal fracture persists for a long period of time, a nonunion should be suspected. This is the result of persistent displacement of the proximal fragment. In this instance, open reduction is appropriate.

Hemothorax

Intrathoracic bleeding occurs with any form of chest injury that disrupts tissues. Hemothorax usually develops at the time of injury, but occasionally the bleeding is delayed for several days. Rarely, an extrapleural hematoma breaks into the pleural cavity and gives the impression of a delayed hemorrhage.

Bleeding from the lung as a result of rib fractures, stab wounds, or small- missile wounds generally stops before a sufficient volume has been lost to mandate an emergency thoracotomy. Accumulated military and civilian experience indicates that slightly more than 10 percent of patients with traumatic hemothorax require thoracotomy for the control of bleeding or determination of the extent of injury.

Movement of the diaphragm and thoracic structures causes partial defibrination of blood that is shed into the pleural cavity, and clotting usually is incomplete. Sufficient coagulation does occur to interfere with efficient drainage of the pleural blood through intercostal catheters, and the latter often become plugged with blood clot. Pleural enzymes begin to produce clot lysis within a few hours after bleeding stops, and the process of hemolysis with protein breakdown increases the osmotic pressure. Unless the pleural space is drained adequately, the transudation of fluid into the space can produce a significant compression of the lung and a shift of the mediastinum toward the opposite hemithorax.

The main diagnostic concerns in the management of the patient with traumatic hemothorax are how much bleeding has occurred, is it continuing, and if stopped and clotted, when should clot be removed. Consideration of the type and extent of injury, general signs of blood loss, physical signs of fluid in the pleural cavity, and chest x-ray findings are guides to the assessment of the extent of hemothorax. Between 400 and 500 mL of blood may be hidden by the diaphragm on the upright chest x-ray, and 1 L or more may be overlooked on a supine film. A large hemothorax may be missed on the upright chest x-ray unless the observer is aware of the phenomenon of subpulmonary trapping of the blood (Fig. 16-18). A lateral decubitus x-ray can confirm the diagnosis of hemothorax and guide placement of an appropriate drainage catheter.

A small hemothorax that produces little more than blunting of the costophrenic angle on the chest x-ray does not require initial treatment; follow-up x-rays at appropriate intervals will assist with the decision to drain the pleural cavity if there is a progressive accumulation. When the hemothorax exceeds an amount that fills the costophrenic sulcus, or when there is associated pneumothorax, one or more large catheters should be placed in the pleural cavity through the seventh or eighth intercostal space in the posterior axillary line. Low suction applied to the catheters is helpful when combined with active efforts at stripping the tubes of blood clot. If the initial drainage of blood is followed by continued bleeding in the absence of a clotting defect, a decision to operate must be made, with a broad consideration of the possible sources of the bleeding.

With a major hemothorax, the success of tube drainage often is frustrated by extensive clot that obstructs the tubes. A nonfunctioning chest tube represents a liability to the patient because of discomfort and the risk of carrying infection from the skin wound into the pleural clot. Especially with penetrating trauma, a hemothorax that fails to drain adequately through intercostal catheters may develop into empyema. An additional hazard is the organization of residual clot to form a fibrothorax. Coselli and colleagues in Houston reviewed their experience with clotted hemothorax and found that early thoracotomy substantially reduces hospitalization time and empyema rates. Videothoracoscopy has become an effective and less invasive way to evacuate a clotted hemothorax. Thoracotomy is performed only if more extensive exposure is needed to manage an active source of bleeding or if extensive decortication of the lung is necessary.

Tracheobronchial Injury

The management of massive tracheobronchial injuries is discussed above. For small penetrating injuries of the intrathoracic trachea and major bronchi, tracheostomy and effective pleural decompression may provide satisfactory definitive treatment. Those injuries which are associated with an actual defect in the tracheobronchial wall, including partial disruption, require operative exploration and repair. Tracheostomy may be necessary to prevent high intratracheal pressures and to allow tracheal care postoperatively, but positive-pressure assisted ventilation should be avoided.

Penetrating injuries of lobar or segmental bronchi may produce a similar clinical picture to proximal tracheobronchial injuries. Bilateral pneumothorax is rare, and the immediate problem is to begin management of the major air leak and confirm the presence of a major bronchial injury. The bronchial air leak often stops soon after an intercostal catheter is put in place. The definitive diagnosis may be delayed if the bronchus becomes obstructed by blood clot or mucus, and the air leak ceases. Under these conditions, the pulmonary lobe or segment becomes atelectatic and resists conservative methods to produce reexpansion. If infection does not occur, the injured bronchus may heal with significant distortion and obstruction, or the atelectasis may persist and lead subsequently to a correct diagnosis. Operative repair of the disrupted bronchus can be achieved even years after injury. If infection occurs at the site of the bronchial injury, the patient may develop pneumonia, distal bronchiectasis, and empyema. Resection of the bronchus and the involved pulmonary lobe is then required.

Pulmonary Injury

The lungs have a remarkable ability to tolerate penetrating injuries and blunt trauma without long-term residual effects. Civilian gunshot wounds of the chest penetrate a lung more frequently than any other structure, but the majority of patients with no other significant injury can be treated without a thoracotomy. Any penetrating object produces an air leak with a variable degree of pneumothorax. The disruption of tissue along the missile track causes bleeding, which usually ceases as the damaged parenchyma becomes swollen and filled with blood clot. With small-caliber and low- velocity bullet wounds that pass through the lung periphery, the amount of tissue damage produced may be sufficiently small that late follow-up chest x-rays fail to demonstrate the area of injury. With high-velocity bullets, the tissue destruction extends more widely; a peripheral bullet pathway may result in irreversible damage to a lobar or lung hilus.

The immediate management of the patient with a penetrating injury is the insertion of at least one intercostal catheter for evacuation of the associated hemopneumothorax. Serial arterial blood gas determinations and frequent evaluation of the patient's ventilatory ability allow an overall estimate of the effect of the injury on respiratory exchange. Low-velocity penetrating wounds rarely require ventilatory assistance or surgical intervention. However, high-velocity gunshot wounds frequently require thoracotomy to control bleeding or to resect an irreversibly injured lung.

Pulmonary Contusion

Pulmonary contusion is the consequence of blunt trauma to the lung. The frequent causes of contusion include rapid deceleration of the chest against a fixed object (e.g., an automobile steering wheel), falls from a height, and blast injuries. Particularly in young persons, severe pulmonary contusion can occur by transmission of force through the chest wall with minimal fractures of the ribs or sternum. In middle-aged or elderly persons, significant pulmonary contusion usually is accompanied by multiple fractures of the thoracic cage.

The contused lung is characterized by capillary disruption that results in intraalveolar and interstitial hemorrhage, edema, protein and fluid obstruction of small airways, and leukocyte infiltration. Serial chest x-rays begun right after injury show a fluffy infiltrate that progresses in extent and density over a period of 24 to 48 h. Although the maximum lung injury is directly related to that region of the chest wall that receives the trauma, a "contrecoup" effect may be responsible for a wider distribution of the pulmonary damage. Unless the contusion involves only a small region of one lung, it may result in serious loss of respiratory function. The associated injury to the chest wall is aggravated by the loss of pulmonary compliance, increasing the work of breathing. Small areas of atelectasis become confluent, and progressive hypoxia further diminishes the patient's ability to compensate for the loss of function.

Pulmonary contusion often is part of a major chest injury that includes one or more fractures of the thoracic cage, pneumothorax, and hemothorax. If not present initially, a pneumothorax may develop subsequently from actual disruption of the contused pulmonary parenchyma. Although it is infrequent in patients who survive to reach the hospital, a major pulmonary laceration may represent the maximum extent of pulmonary contusion. In some instances the tissue disruption is the result of extensive penetration by rib fragments, but in others the causative factor is probably a severe shearing force. The clinical and x-ray findings suggest a serious chest injury but do not differentiate the patient with a major lung laceration from the patient with pulmonary contusion and associated hemopneumothorax. Continued or uncontrolled hemorrhage and massive air leak generally mandate an early thoracotomy. A major pulmonary resection may be necessary, and the mortality rate is high.

Treatment of pulmonary contusion must include an accurate clinical assessment of the patient's respiratory exchange and careful monitoring by serial measurements of the arterial blood gases. Steroids have no role in the management of pulmonary contusion.

A high percentage of patients require temporary assisted ventilation, and it may be evident at the time of admission that endotracheal or nasotracheal intubation should be performed. Without question, aggressive respiratory therapy, including ventilatory support, should be initiated before cardiopulmonary decompensation requires treatment measures that add additional risks. Criteria for instituting assisted ventilation are shown in Table [16-3](#). For most patients, the need for assisted ventilation does not extend beyond a few days unless there is major injury to the chest wall or to other body regions.

Posttraumatic Pulmonary Insufficiency

The development of acute respiratory failure can be expected in a high percentage of patients who suffer major thoracic trauma. Preexisting pulmonary status influences the severity of respiratory insufficiency, and the extent of actual pulmonary damage determines whether the patient survives. An initial evaluation of respiratory exchange and ventilatory ability, confirmed by measurement of pulmonary mechanics and arterial blood gases, should be followed by serial reevaluations.

Especially in patients who have suffered multiple trauma, a respiratory distress syndrome may develop that is out of proportion to the extent of thoracic injury. Previous terms used to designate post-traumatic respiratory insufficiency included *wet lung*, *shock lung*, *congestive atelectasis*, and *adult respiratory distress syndrome*. There is certainly some overlap in the causation of the several forms of respiratory failure that follow major trauma, and it is important to determine the specific causes in individual patients. Blaisdell and Lewis have presented a thorough discussion of posttraumatic pulmonary insufficiency, choosing the term *respiratory distress syndrome of shock and trauma* for those cases not due to a specific cause. They suggest that eight different explanations for respiratory failure, other than the respiratory distress syndrome, occur with reasonable frequency in patients who suffer major injury. These include aspiration, simple atelectasis, lung contusion, fat embolism, pneumonia, pneumothorax, pulmonary edema, and pulmonary embolism.

On the basis of their experience with a large number of patients, Blaisdell and Lewis concluded that the respiratory distress syndrome (RDS) is one and the same as the fat embolism syndrome. Originally thought to result from fat embolism from fracture of long bones, the syndrome consists of pulmonary, neurologic, and systemic manifestations. The pulmonary manifestations appear first, generally within 24 to 36 h after injury, and consist of dyspnea, tachycardia, fever, and cyanosis. Documentation that much of the fat that appears in the blood after injury represents a mobilization of free fatty acids from body neutral fat as a result of shock and increased levels of catecholamines has helped in understanding the mechanism of this condition. Because some degree of intravascular coagulation can be demonstrated in all patients, this is almost certainly a factor in development of the syndrome.

For patients who suffer major chest injury, it may be impossible to define what part of their respiratory failure is a result of direct trauma and how much is a consequence of the RDS. Treatment must be based on correction of the direct results of injury and on the anticipation or early recognition of respiratory insufficiency. The radiologic changes of RDS, consisting of diffuse lung infiltrates that progress to become confluent, may be superimposed on the effects of pulmonary contusion and atelectasis. Changes observed on serial chest x-rays lag behind the changes in pulmonary function, and a patient may be in critical respiratory failure before the films suggest a progressive pulmonary lesion.

Management of RDS requires maintenance of good cardiovascular function and prompt institution of ventilatory support. An adequate volume replacement for external fluid and blood losses is complicated by the internal fluid losses because of increased capillary permeability in the lung, in all areas of direct tissue trauma, and to a varying degree throughout the body. Placement of a Swan–Ganz catheter to measure left atrial and pulmonary artery pressures is superior to monitoring central venous pressures for guidance of fluid and diuretic therapy. The need for inotropic myocardial support can be detected earlier by this access to left-sided heart pressures.

Current ventilatory support techniques allow a wide selection of methods of assisted respiration. These should be chosen to optimize oxygenation while minimizing airway pressures and adverse effects on cardiovascular function. There is no clear role for the use of steroids, which have not been shown to be effective in preventing or reversing RDS. Patient survival depends on meticulous supportive respiratory care and aggressive treatment of conditions (e.g., intra-abdominal sepsis, ongoing blood loss requiring transfusions) that may aggravate RDS.

CHEST WALL

Congenital Deformities

Pectus Excavatum

The most common congenital deformity of the chest wall is pectus excavatum, in which the body of the sternum is displaced posteriorly to produce a funnel-shaped depression (Fig. [16-19](#)). The etiology is not certain, but most authors believe that overgrowth of the lower costal cartilages and ribs is responsible. The severity of the defect varies widely. The depression is centered most often at the xiphisternal junction but may extend to the manubrium in rare patients. In lateral extent, the presentation varies from a narrow central cleft to a broad, dish-shaped defect extending from nipple to nipple. The depth of the depression is equally variable, with the sternum reaching or even overlapping the spine in extreme forms. Asymmetry is common and always involves greater depression of the right costal cartilages with rotation of the sternum to the right.

Pectus excavatum is present at birth and progresses at a variable and unpredictable rate through childhood. Infants and young children often have a protuberant abdomen that accentuates the deformity. Later in childhood a characteristic posture has been described, with rounded and forward-sloping shoulders, forward angulation of the head and neck, and dorsal kyphosis of the spine. Breast development in young women is frequently asymmetrical, with a smaller breast on the right.

Although most cases appear in isolation, a familial tendency has been noted, and the defect is seen frequently in more than one sibling. The anomaly is about three times more frequent in males. Pectus excavatum is frequently seen in Marfan syndrome and is one of a variety of chest wall deformities seen with increased frequency in patients with congenital heart disease.

A variety of classifications based on radiographic findings has been proposed. Haller and associates have used a “pectus index” based on the ratio of transverse to anteroposterior diameter measured on a single standard computed tomographic (CT) scan image. In their series, all patients undergoing operative correction had a pectus index greater than 3.25.

That pectus excavatum produces a cosmetic deformity is not a matter of debate. Between 30 and 70 percent of patients are reported to be symptomatic, with a broad range of presentations including exercise intolerance, atypical chest pain, dyspnea, bronchospasm, poor feeding, and arrhythmias. In all reported series, symptoms are almost always relieved by operative correction. Systolic ejection murmurs are reported frequently and are thought to reflect compression of the right ventricular outflow tract. ECG abnormalities are frequent and usually resolve after repair but are believed to reflect changes in axis due to rotation and displacement rather than any fundamental electrophysiologic disturbance.

Whether or not a physiologic defect is responsible for the characteristic symptomatology is controversial. Wynn and associates and Ghory and associates have reviewed previous reports spanning 70 years and have added their own observations. Ghory and associates studied 14 children with pectus excavatum and 14 normal controls and found a higher diastolic blood pressure and a decreased preejection period with exercise in older children (older than age 11) with pectus. No differences were seen in maximal work load, oxygen consumption, cardiac output, and stroke volume. Wynn and associates studied 12 patients with pectus excavatum. Eight were studied before and after operative correction, and four were tested twice but not corrected. No significant differences were observed in most parameters, such as maximal oxygen uptake, cardiac output, and stroke volume. The only difference that resulted in statistical significance was an 8 percent decrease in total lung capacity after operation; total lung capacity was unchanged in the nonoperated group ($p < 0.01$).

Pectus excavatum is primarily a cosmetic defect with a very broad anatomic and symptomatic spectrum. There is no conclusive evidence supporting the existence of a consistent functional defect. Operation is indicated to correct the cosmetic defect and can be expected to eliminate symptoms in the majority of patients, even though a physiologic basis for the symptomatology cannot be defined.

Operative Treatment

Most authors recommend operative correction during the preschool years (before 5 years of age) but not before 18 months. Operation at that age is thought to prevent the secondary postural, physiologic, and psychological consequences of the defect.

The technique most widely used is that described by Ravitch. All the deformed costal cartilages are excised, the xiphisternal joint is disarticulated, intercostal muscle bundles are separated from the sternum, and transverse posterior osteotomy of the sternum is performed above the point of depression. The osteotomy can be combined with a forward fracture of the sternum and insertion of a bone wedge in the osteotomy site to provide an overcorrection of the deformity.

In certain cases, the repair is reinforced with a metal strut that can be removed several months later. In recent large series, excellent short- and long-term results have been reported. Haller and associates achieved excellent long-term results in 95 percent of 664 patients followed for 1 to 40 years. Shamberger and Welch achieved satisfactory long-term results in 98 percent of 704 patients followed for 1 to 27 years.

Excellent results also have been reported with a very different operative approach. Sternal eversion involves transverse division of the sternum, division of the costal cartilages, 180° axial rotation of the sternum (sternal eversion), and suture reattachment. In essence, the concave deformity is made convex. The sternal plastron can be rotated on a mammary artery vascular pedicle or as a free graft. Although the series has not been updated recently, Wada and associates achieved satisfactory results with sternal eversion in 97 percent of 199 patients followed for 15 years.

Pectus Carinatum

The protrusion deformities of the sternum are much less common than pectus excavatum, accounting for less than 10 percent of patients presenting for repair. This group of “bird chest” deformities varies considerably in specific manifestations. The most common type is characterized by a deep depression of the costal cartilages along each side of the sternum, which accentuates the mild protrusion of the sternum by creating an illusion of greater anterior projection in relation to the ribs. The deformity usually is maximal below the nipple level; asymmetry is common, most often producing mild rotation of the sternum to the right.

Although symptoms reminiscent of pectus excavatum have been associated with the protrusion defects, it appears that most are asymptomatic, and the condition has seldom been studied physiologically. Operative correction is done through a curved submammary incision that allows broad exposure of the deformed cartilages and costochondral junctions (Fig. [16-20](#)). Subperichondral and subperiosteal resection of all deformed cartilages and ribs is performed throughout the length of their deformity. The excessive length of each perichondral bed is obliterated with reefing sutures, and the sternal contour is adjusted with a transverse osteotomy if necessary. In the only reported series of any size, Shamberger and Welch achieved 98 percent satisfactory results in 152 patients followed for 1 to 12 years.

Sternal Fissures

The sternum is formed when two lateral plates of mesoderm fuse in the midline during the tenth week of embryonic development. The clavicular heads also contribute primordia to the manubrium. Failure of fusion can be complete, or it can be confined to the superior end or the inferior end of the sternum.

Superior Sternal Cleft

In this type of defect the cleft is broad and U- or V-shaped, usually extending down to about the fourth costal cartilage (Fig. 16-21). The prominent pulsations of the heart, which is covered only by thoracic fascia and skin, create the illusion of cardiac displacement into the neck. In fact, the heart usually lies in approximately normal position, and the two separate halves of the sternum can be located at the periphery of the defect and reapproximated. Osteotomies in each half or distal transection of each half is usually necessary to bring them together. In some patients, especially those repaired after infancy, these techniques would not leave room for the heart, and coverage with prosthetic material is required.

Distal Sternal Cleft

A defect in the distal sternal is almost invariably part of a syndrome called *Cantrell's pentalogy*, which consists of the following five components: (1) a cleft distal sternum, (2) a ventral abdominal wall defect that may be a true omphalocele, (3) an anterior crescentic deficiency of the diaphragm, (4) communication between the parietal and peritoneal cavities through the diaphragm, and (5) congenital heart disease, usually with a ventricular septal defect and a left ventricular diverticulum.

Operative correction requires a staged approach taking into account the priorities of each defect. The omphalocele usually is repaired first. As with other forms of sternal cleft, early reconstruction offers the best chance for primary closure.

Complete Sternal Cleft

In this rarest form of sternal cleft, failure of midline fusion is complete, leaving the mediastinal contents bulging through a thin covering of skin and fascia. In the few cases described, an associated failure of midline abdominal fusion has been frequent and communication between the peritoneum and pericardium common. Repair in infancy is highly desirable and can be satisfactory.

Miscellaneous Anomalies of Rib and Costal Cartilage

The simplest anomalies consist of deformed, deficient, or enlarged cartilage or rib presenting as an isolated finding in an asymptomatic patient. More complex anomalies include absence or wide divergence of one or more lower ribs and are commonly associated with hemivertebrae, fused bony paravertebral bars, and progressive scoliosis. The chest wall defect can manifest obvious paradoxical respiratory motion and even true lung herniation, but the spinal anomalies usually are more functionally significant and demand more therapeutic attention.

Poland's syndrome consists of absence or hypoplasia of the pectoralis major and minor muscles, breast hypoplasia, and partial absence of the upper costal cartilages (Fig. 16-22). Brachysyndactyly, ectrodactyly, and ectromelia are frequently described associations. It is invariably unilateral. Depending on the extent of cartilage deficiency there may be an impressive lung hernia, paradoxical respiratory motion, or simple flattening of the anterolateral chest wall. When the anomaly is on the left side, the underlying heart and lung are significantly vulnerable because they are covered only by skin, fascia, and pleura. As the child grows, the concavity becomes more severe on either side.

Operative reconstruction is recommended for cosmetic reasons, to eliminate paradoxical motion, and to protect intrathoracic structures. Staged procedures involving split rib grafts from the contralateral side combined with Teflon felt or Marlex mesh have been advocated in the past. A logical outgrowth of the increasing popularity of pedicled myocutaneous flaps has been their application in the reconstruction of this anomaly. Urschel and associates described successful single-stage reconstruction in two patients using a latissimus dorsi flap and simultaneous augmentation mammoplasty.

Chest Wall Tumors

General Considerations

In reviewing this topic in 1949, Brian Blades observed, “. . . available statistical data concerning the exact incidence of thoracic wall tumors are incomplete and probably unimportant. Moreover accurate histological classification of the tumors is often confusing.” If he were writing today, he would probably add that the accurate histologic classification is unimportant. Now as then, most reports in the literature are limited case reports; the few larger series are reported from major tertiary referral hospitals with the highly selected patient population that characterizes those institutions. The available statistical data relating to the actual frequency of the various types probably remain inaccurate. Depending on the referral characteristics of the reporting institution, the incidence of primary malignancy of chest wall tumors ranges from 13 percent (Cavanaugh) to over 50 percent (Sabanathan et al.). It is likely that the true incidence of malignancy in the general population may be nearer the lower figure. Whatever the true frequency, malignancies are common, and clinical or laboratory findings are sufficiently uncertain that speculating about the probabilities of any given chest wall mass being benign or malignant usually is an unimportant exercise. It should be considered malignant until proved otherwise by detailed analysis by an experienced surgical pathologist.

The reported experience confirms that chest wall malignancies are often mismanaged. Inadequate biopsies are untrustworthy, fears about chest wall reconstruction difficulties may encourage inadequate local resection, and recurrence after inadequate initial resection is a common cause of failure. Most surgeons agree that an adequate biopsy should be undertaken early in the evaluation of the suspicious mass. Multimodality therapy increasingly has become a standard treatment for some adult soft tissue malignancies (e.g., Ewing's sarcoma). With advances in reconstruction techniques (e.g., myocutaneous flaps, improved synthetic materials), virtually any defect in the chest wall can be repaired. The current accepted approach is to obtain an accurate diagnosis in order to determine whether the patient should receive multimodality therapy or should undergo surgical resection as the primary treatment. Accurate diagnosis requires adequate tissue; fine needle aspiration should be avoided, and frozen sections should be performed on removed tissue before leaving the operating room, not to establish a diagnosis but to be sure suitable tissue for eventual diagnosis has been submitted. Metastatic tumors, especially to the ribs, and direct invasion of the chest wall from primary lung and breast carcinomas easily outnumber the tumors arising from the chest wall. While the biopsy is being processed, careful search for a primary neoplasm elsewhere should be made. Neoplasms originating in the thyroid, breast, and kidney are the most common to metastasize to the ribs.

The clinical manifestation of a chest wall neoplasm is most often either pain, a palpable mass, or an abnormality detected on a chest x-ray. With benign or malignant lesions, the discomfort is relatively mild, and patients often present with tumors that have been enlarging for months or years. Many patients attribute the tumor origin to some episode of localized trauma, or they state that they discovered the mass while rubbing their chest after a minor injury. A differential diagnosis includes the less frequent pulmonary infections that invade the chest wall, such as actinomycosis and nocardiosis, tuberculous chondritis, costochondral separation, and Tietze's syndrome (nonspecific chondritis). A suspicion of fluctuation in the mass and a corresponding pulmonary lesion may suggest that a diagnostic aspiration should be done anticipating probable infection. A true history of trauma and the ability to reproduce a clicking sensation with local pressure may reinforce the diagnosis of a suspected costochondral separation.

Work-up of the patient with a chest wall mass should focus on a search for other areas of neoplastic involvement by radioisotope studies and other imaging studies along with CT scans to map the local extent of the tumor invasion and to plan resection and reconstruction of the chest wall defect. It also must include evaluation of pulmonary function and assessment of the patient's ability to tolerate the physiologic deficit that might result from the procedure.

Benign Tumors

Among the more likely benign tumors are fibrous dysplasia, eosinophilic granuloma, osteochondroma, desmoid tumor, and chondroma.

Fibrous Dysplasia

The ribs are the most common site of solitary fibrous dysplasia (osteofibroma, bone cyst). Located most frequently in the posterior or lateral portion of a rib, it usually presents as a slowly enlarging, nonpainful mass. Diagnostic radiographs show expansion and thinning of the bony cortex, with a central trabeculated appearance. Fibrous dysplasia in ribs as well as other bones forms part of Albright's syndrome, a condition that includes skin pigmentation and precocious puberty in girls.

Eosinophilic Granuloma

The lesions of eosinophilic granuloma are sometimes part of a disease that includes pulmonary lesions called *histiocytosis X* or *eosinophilic granuloma of the lung*. When it occurs in a rib, the granuloma is a solitary destructive process, often associated with pain and localized tenderness. Radiographs reveal a punched-out osteolytic lesion, which, when subjected to excision and microscopic examination, is found to consist of a chronic granuloma. Healing may occur spontaneously, or a pathologic fracture may develop through the area of osteolysis.

Osteochondroma

These slow-growing tumors generally arise from the cortex of a rib. As with other neoplasms, the occurrence of pain may signal accelerated growth, which produces concern over the possibility of malignant change. The radiographic appearance is often that of a distorted rib cortex with an overlying mass that has a thin rim of calcification.

Chondroma

Chondromas occur at the costochondral junction, primarily in children and young people, and may be difficult to differentiate from chondritis or the sequela of traumatic costochondral separation. Chest and rib x-rays show an expansion of bone with thinned but intact cortex. Probably because of the abundance of cartilage in the chest wall, chondromas and chondrosarcomas are the most common benign and malignant tumors of the skeletal components of the thorax. Chondrosarcoma usually is a well-differentiated tumor easily misdiagnosed as a benign chondroma, resulting in inadequate local resection and consequent local recurrence.

Desmoid Tumors

These tumors are a form of low-grade fibrosarcoma. They have a high propensity to recur locally and should be resected with the same wide margins recommended for primary malignant tumors.

Malignant Tumors

Although the sarcomas arising in the adult chest wall usually are classified by the cell type of origin, prognosis is related to the histologic grade rather than cell classification. The grading system recommended by the American Joint Committee on Cancer no longer considers the cell of origin relevant and groups the wide variety of reported tumors under the general label of *adult soft tissue sarcomas*, although they may arise from any of the mesodermal tissues found in the chest wall. These tumors are potentially curable, usually by wide surgical resection.

Factors that influence prognosis include age, size of tumor, histologic grade, and the stage. If the patient is over 60 years of age and the tumor is more than 5 cm, has poorly differentiated cells, or has spread to the lymph nodes or distant sites, the prognosis is poor. If the tumor has a low mitotic index, is free of hemorrhage or necrosis, and is under 5 cm in largest diameter, it is likely to be curable by surgery alone. Higher-grade tumors are associated with a higher local treatment failure rate and a risk of distant metastases. The role of pre- or postoperative radiation or chemotherapy in preventing recurrence remains undefined.

These tumors occasionally can grow at extremely rapid rates. The case depicted in Fig. 16-23 and Fig. 16-24 was believed to be a walnut-sized breast mass 4 months before the CT scan was taken. Resection required complete removal of ribs 4 through 11 along with the lateral portion of the diaphragm and a generous wedge of lung.

Chest Wall Reconstruction

Because of the high rate of malignancy in chest wall neoplasms, there is need for an aggressive attitude toward management of any mass that likely represents a primary tumor. When malignancy is suspected, preliminary plans must be made for chest wall reconstruction that will allow resection of a generous margin of normal tissue around the neoplasm. The resection should include at least one normal adjacent rib above and below the tumor with all intervening intercostal muscles and pleura. In addition, it is often necessary to include an en bloc resection of overlying chest wall muscles such as the pectoralis minor or major, the serratus anterior, or the latissimus dorsi. When the periphery of the lung is involved with the neoplasm, it is appropriate to resect the adjacent part of the pulmonary lobe in continuity (see Fig. 16-24 C). Involvement of the sternum by a malignant tumor requires a total resection of the sternum with the adjacent cartilages. Techniques for postoperative respiratory support are sufficiently good that resection should not be compromised because of a concern about the patient's ability to ventilate adequately in the early postoperative period.

Reconstruction of a large defect in the chest wall requires the use of some type of material to prevent lung herniation and to provide stability for the chest wall (see Fig. 16-24 D). Mild degrees of paradoxical motion are often well tolerated if the area of instability is relatively small. Several authors, notably Pairolero and Arnold from the Mayo Clinic, have reported an extensive experience with chest wall reconstructions after removal of significant portions of the bony thorax. They emphasize that adequate resection and dependable reconstruction are essential ingredients to a successful operation and express the strong belief that a thoracic surgeon—plastic surgeon team is an important collaboration if these complicated problems are to be undertaken. Although historically a wide variety of materials has been used to reestablish chest wall stability, including rib autografts, steel struts, acrylic plates, and various synthetic meshes, current preference is either a 2-mm-thick polytetrafluoroethylene (Gore-Tex) patch or a double-layer polypropylene (Marlex) mesh sandwiched with methylmethacrylate. When soft tissue coverage is needed, this is provided by myocutaneous flap reconstruction.

DISEASES OF THE PLEURA AND PLEURAL SPACE

The inner surface of each hemithorax has a mesothelial lining, the parietal pleura, that is invaginated at each pulmonary hilum to form the visceral pleura. The two surfaces are normally in apposition, lubricated by a thin layer of serous fluid secreted by the mesothelium so that the steady motion of normal respiration is accomplished without friction. The pleural “space” is normally only a potential space lying between the visceral pleura investing the lung and the parietal pleura of the chest wall. The elastic recoil of the lung and the rapid continuous absorption of fluid from the pleural space create a balance of opposing forces that favors apposition of the visceral pleura to the parietal pleura. The introduction of fluid or air breaks this dynamic coupling and converts the potential space to a real space. Normal respiratory mechanics are impaired in proportion to the size of the space created and the pressure within it. Many of the processes affecting the pleural space are essentially mechanical, such as spontaneous pneumothorax or congestive heart failure, and are not associated with any pathologic alteration in either pleural surface. However, virtually any chronic form of pleural space disturbance is associated with pathologic changes that produce thickening and adherence of the visceral and parietal surfaces. The end results vary from a few filmy adhesions of no consequence to a dense fibrous and calcific obliteration of the pleural space with a permanent restrictive defect in pulmonary function.

Pleural Effusion

A pleural effusion is an accumulation of fluid in the pleural space. It is not a disease entity but signals the effect of pleural or systemic disease on the normal daily passage of fluid through the pleural space. Normally, the balance of hydrostatic and colloid osmotic forces favors movement of fluid from systemic capillaries in the parietal pleura to pulmonary capillaries. It is estimated that between 5 and 10 L of protein-free fluid traverses the pleural space in 24 h. Simultaneously, lymphatics drain smaller volumes of fluid containing protein, which would otherwise remain in the pleural space as a source of colloid osmotic pressure favoring retention of fluid. Alterations in systemic hydrostatic or colloid osmotic pressure that disturb the balance of forces across normal pleural surfaces produce an effusion consisting of a protein-poor ultrafiltrate of plasma classified as a *transudate*. Changes in capillary permeability caused by inflammation or infiltration of the pleura produce a protein-rich effusion classified as an *exudate*. Common causes of transudates and exudates are listed in Table 16-4 and Table 16-5. The distinction between transudate and exudate has diagnostic relevance, as noted in one series in which effusions were malignant in 42 percent of patients with an exudate and were caused by congestive heart failure in 83 percent of patients with a transudate.

Characteristics of fluid obtained by diagnostic thoracentesis that can help to make the distinction between transudative and exudative effusions are summarized in Table 16-6. Few findings are independently diagnostic, with the exception of positive cultures (empyema) and positive cytology (malignancy). Certain gross findings can be nearly diagnostic, such as the milky white fluid of chylothorax or the foul purulence of an empyema. Other findings can narrow the possibilities considerably. For example, grossly bloody fluid (red cell count > 100,000/mm³) is almost always caused by trauma, pulmonary infarction, or malignancy. A markedly elevated amylase level can be found in sympathetic effusions associated with pancreatitis, pancreatic pseudocyst, and esophageal perforation. Pleural fluid pH less than 7.20 (with an arterial pH > 7.35) strongly suggests bacterial infection and may appear before culture and Gram's stain are positive in some cases. Low pH also has been reported in some malignant effusions and in effusions associated with connective tissue disease.

There can be considerable overlap in the findings ostensibly separating exudate from transudate, and any chronic effusion tends to develop “exudative” characteristics. Too much can be made of laboratory distinctions, and it is rare for pleural effusion to be the sole manifestation of disease such that diagnosis hinges exclusively on pleural fluid analysis. The cause of most effusions is best recognized by simply looking carefully at the rest of the patient.

A concave meniscus in the costophrenic angle on an upright chest x-ray suggests the presence of at least 250 mL of pleural fluid. A lateral decubitus view can detect a smaller volume and confirms that the fluid is free in the pleural space if it is shown to layer out along a dependent surface. In some cases an effusion is completely contained between the base of the lung and the diaphragm (a subpulmonic effusion) and can be difficult to distinguish from an elevated hemidiaphragm or a subdiaphragmatic process. When this occurs on the left side, the position of the stomach bubble can provide a useful clue. On a supine film, a small to moderate effusion will be completely inapparent, and a large effusion only produces a uniform hazy appearance of the affected hemithorax that can be difficult to detect unless the process is unilateral. A very large effusion can produce complete opacification of one hemithorax that does not change in appearance with changes in position (Fig. 16-25). Adhesions can compartmentalize an effusion into loculations that assume a wide variety of radiographic configurations and that require CT scanning for definition. Presence of an air-fluid level has specific connotations because the air can only come from the tracheobronchial tree, from the esophagus, or directly through the chest wall.

Thoracentesis is the mainstay of diagnosis. Needle biopsy of the pleura can provide diagnostic tissue but has a high frequency of false-negative results because of sampling difficulties in diseases that do not involve the pleura uniformly. When clinical evaluation and thoracentesis fail to yield a diagnosis, videothoracoscopy with pleural and lung biopsies should be performed to determine the cause of the effusion.

Pleural effusions can produce dyspnea but also can be asymptomatic at rest. Therapeutic drainage is rarely indicated for transudative effusions because the fluid rapidly reaccumulates until the underlying condition is improved. Most exudative effusions warrant a more aggressive approach. The treatment of hemothorax was discussed earlier, and empyema, malignant effusion, and chylothorax are considered separately below. A number of nonmalignant, uninfected exudative effusions frequently are treated as if they were transudative; examples include collagen-vascular disease, pulmonary infarction, and sympathetic effusion secondary to abdominal pathology.

Malignant Pleural Effusion

More than half of all patients with malignancy will have a pleural effusion at some time in their course. The effusion is frequently massive and symptomatic. The pathophysiology is thought to be interference with venous and lymphatic drainage by direct tumor invasion. The fluid contains malignant cells in only about 60 percent of patients, and pleural biopsy, usually by videothoracoscopy, often is required to establish a diagnosis. Lung carcinoma is the most common primary, with breast and gastrointestinal malignancies close behind. The fluid is exudative in character and often bloody. Grossly bloody fluid (red cell count > 100,000/mL) has a 90 percent probability of being malignant, once trauma and pulmonary infarction are excluded. The presence of a malignant effusion is a poor prognostic sign, with mean survival after diagnosis of 3 to 11 months in most series.

Treatment

Treatment is palliative. Repeated thoracentesis has a high failure rate. Chest wall radiation, thoracotomy with decortication and pleurectomy, and even pleuropneumonectomy have been described but carry unacceptable mortality and morbidity to be considered standard treatment. At present, the standard therapy is tube thoracostomy or videothoracoscopy and pleurodesis.

Pleurodesis creates an inflammatory fusion between visceral and parietal pleura that eliminates the potential pleural space. An essential first step is complete evacuation of the fluid and reexpansion of the lung, accomplished by inserting a chest tube connected to a water-seal drainage system (Fig. 16-26). If the pleural effusion is large (i.e., greater than 1 L) or has been present for more than a few days, it should be drained slowly initially via the thoracostomy tube in aliquots of 200 to 300 mL/h in order to prevent re-expansion pulmonary edema. When loculations, inaccurate tube placement, or entrapment of the lung by a visceral pleural peel “trapped lung” prevent complete fluid removal and lung expansion, pleural symphysis will not occur uniformly, and pleurodesis will not succeed. This is probably more important than the choice of the chemical agent used in the next step. Innumerable agents have been used to induce the inflammation, including talc, nitrogen mustard, *Corynebacterium parvum*, doxorubicin, quinacrine, bleomycin, and tetracycline. Formerly, tetracycline was the agent most commonly used in the United States because of its low cost and easy availability. Because tetracycline is no longer commercially available, doxycycline, a newer antibiotic of the same type, is occasionally used. Talc, the preferred sclerosing agent in Europe for several decades, has become the most popular agent in the United States as well. Since talc is not soluble, it is administered as a suspension or “slurry” in saline via the tube thoracostomy or is insufflated as a dry powder “talc poudrage” across the pleural space by thoracoscopy. Following pleurodesis, the tube thoracostomy is left to underwater drainage until pleural fluid output is minimal, usually for approximately 72 h. The reported success rate of talc pleurodesis is 80 to 90 percent.

Use of an indwelling shunt connecting the pleural cavity to the peritoneum through a one-way valve has received attention recently. The system is analogous to the Denver shunt, except that the normal pressure gradient between the abdomen and chest is overcome with a subcutaneous squeeze- bulb pump. Although enthusiastically advocated by some authors, pleuroperitoneal shunts have the theoretical disadvantage of continuously circulating malignant cells. They also are easily clogged by proteinaceous debris and require the active participation of patients and families in compressing the bulb pump up to 100 times per day to maintain satisfactory function of the shunt. For the majority of patients with end- stage cancers, pleuroperitoneal shunts do not provide optimal palliation.

Empyema

Empyema is a suppurative infection of the pleural space. Empyema was studied carefully 2400 years ago by Hippocrates, who first described open drainage with rib resection. By the early 1900s empyema complicated pneumonia in 5 to 10 percent of cases. In the antibiotic era, empyema has become a less frequent complication of pneumonia, occurring in about 1 percent of cases, and the bacteriologic spectrum has shifted from *Pneumococcus* and *Streptococcus* to *Staphylococcus*, *Streptococcus*, gram-negative, and anaerobic organisms. Although empyemas are most frequently caused by pneumonia, they also can occur after trauma, pulmonary infarction, or pulmonary resection or can be caused by spread from an intraabdominal source.

Infection of the pleural space initially produces a large, exudative effusion with a high concentration of leukocytes. In hours to days, fibrinous adhesions succeed in limiting involvement to one or more loculated compartments. The ability of the lung to expand and obliterate potential space becomes very important in confining the infection and prevents formation of a fibrous “peel” over the visceral pleura that leads to a trapped lung. The pleura actually has remarkable ability to resolve infection when assisted by an expanded lung. A persistent air leak (bronchopleural fistula) potentiates infection by providing a route for constant inoculation of the pleural space and by promoting lung collapse. The difficulty of obliterating space after pulmonary resection, particularly pneumonectomy, accounts, in part, for the seriousness of postresection empyema.

Clinical Manifestations

Empyema should be suspected in a patient with a febrile illness and pleural effusion on chest x-ray. Thoracentesis with Gram stain and culture of the fluid obtained confirms the diagnosis and guides selection of antibiotics. The gross appearance of the fluid usually is unambiguous, although some seropurulent parapneumonic effusions are sterile. Pleural fluid with a pH below 7.20 and a glucose level below 40mg/dL strongly suggests empyema requiring drainage. Loculations or air-fluid levels on chest x-ray suggest empyema, but CT examination usually is required to distinguish simple empyema from an intraparenchymal process such as lung abscess, an infected congenital cyst, or an infected bulla (pyocyst).

Treatment

Successful treatment depends upon early recognition of the problem, selection of appropriate antibacterial therapy based on identification of the organism, and complete obliteration of the empyema space (Table 16-7). Thoracentesis alone provides adequate treatment in only about 10 percent of empyemas because the space rarely is obliterated. The first step should be insertion of a chest tube connected to a closed drainage system, applying suction as necessary to fully evacuate the space and promote lung expansion. Image guidance during tube or catheter insertion, with CT or ultrasonography, can be important when the empyema space is small or has complex loculations. Lung expansion is especially important in empyema associated with bronchopleural fistula. The success of streptokinase in lysing loculations to improve simple closed-tube drainage is controversial. In early empyemas, where simple debridement of the proteinaceous debris in the pleural space is needed to allow full expansion of the lung, videothoracoscopy is the fastest, most effective approach to treatment.

When tube thoracostomy successfully drains an empyema but there is a small residual space, the simplest option is to convert to open-tube drainage by cutting the existing tubes off near the skin, allowing chronic drainage into dressings. When this approach is successful, the cavity gradually will shrink and obliterate over weeks to months, slowly extruding the tubes, which are progressively shortened.

It is important that open drainage not be attempted before a secure pleural symphysis has occurred at the margins of the cavity, a process that requires at least 10 to 14 days. If this rule is violated, the resulting pneumothorax can cause a rapid spread of the infection throughout the pleural space. A simple test is to disconnect the tubes from the water seal and obtain a chest x-ray. If the space is ready for conversion to open drainage, the x-ray will be unchanged. Open drainage is most effective when the tubes are in a very dependent position, because suction cannot be used to augment gravity drainage. A combination of closed-tube and open-tube drainage is successful in at least 60 percent of patients.

Formal open drainage with rib resection (Fig. 16-27) was done more frequently in the preantibiotic era but is still useful today in the treatment of small, chronic, mature empyemas with a thick fibrous capsule (Fig. 16-28). Drainage is ensured by marsupialization of the empyema cavity. The same cautions important in conversion of closed-tube to open-tube drainage still apply—the cavity must be mature, the drainage site should be dependent, and production of a bronchopleurocutaneous fistula is best avoided. The larger wound allows easier access to the cavity, and drainage can be augmented with irrigation.

If drainage fails to expand the lung, a permanent restrictive defect in ventilation on the affected side is likely to result as the inflammatory membrane heals and contracts over the surface of the lung. Failure of expansion is frequent with a bronchopleural fistula. Between 4 and 7 days of high-suction drainage generally is considered an adequate trial, after which thoracotomy and decortication should be performed (Fig. 16-29). The empyema space is completely evacuated under direct vision, and drainage tubes are accurately placed in the most dependent position. The inflammatory “peel” is tightly adherent to the visceral pleura and should be entirely removed, a tedious process that must be done carefully to prevent development of new air leaks from tears in the lung. When an intraparenchymal abscess coexists with a large air leak, drainage or even pulmonary resection is necessary. Thoracoplasty and intrathoracic rotation of muscle flaps can be added to help obliterate the remaining space.

Decortication has been successful in 80 to 100 percent of patients in reported series and often shortens hospitalization. It has the disadvantage of requiring general anesthesia and a thoracotomy in patients who frequently have limited ventilatory reserve and are suffering the systemic consequences of chronic infection. Even so, in the long run, thoracotomy is often better tolerated than a chronic, draining infection.

Pleural Plaques and Calcification

Pleural plaques are thickenings of parietal pleura, usually smooth and white, and frequently calcified. They vary in size, are frequently bilateral and symmetrical, and do not occur at the apex or on the visceral pleura. They are often caused by exposure to asbestos but have no documented relationship to mesothelioma or other neoplasms. Localized inflammatory or traumatic events also can heal with production of calcified plaquelike lesions, but they are usually larger and unilateral.

Chronic pleuritis can result in diffuse, remarkably uniform thickening and calcification of parietal pleura. The original pleuritis may result from an unresolved hemothorax, from tuberculous or nontuberculous empyema, and from viral or bacterial pleuritis or pleuropneumonitis. When the wall of a chronic but active empyema becomes calcified, resolution by drainage alone never occurs, and resection, decortication, pleurectomy, and thoracoplasty are likely to be required.

Chylothorax

Leakage of lymphatic fluid (chyle) from the thoracic duct produces a characteristic milky effusion called a *chylothorax*. The most common cause is surgical trauma to the thoracic duct, most frequently seen after distal esophagectomy or procedures that involve dissection in the lower left cervical region at the confluence of the subclavian and internal jugular veins (Fig. 16-30). A mediastinal lymph node dissection is another less common cause. Traumatic chylothorax is almost always unilateral, usually on the left side. Nontraumatic chylothorax is less common, accounting for about one- third of patients in most series. Because venous hypertension in the brachiocephalic system is the most common cause of nontraumatic chylothorax, the process usually is bilateral. Underlying causes include superior vena cava thrombosis complicating central intravenous line placement and chronic elevation of central venous pressure after the Fontan procedure. The least common variety of nontraumatic chylothorax is that associated with malignancy, usually lymphoma. It is frequently accompanied by chylous ascites and is caused by neoplastic obstruction of lymphatic channels.

Aspiration of milky white, odorless fluid from the pleural space is virtually diagnostic. Pseudochoyle, which has a similar appearance, is a rare source of confusion seen in certain malignancies, infections, and connective tissue diseases. In comparison with chyle, pseudochoyle has a lower fat content and lymphocyte count, and its opalescent appearance is caused by the presence of lecithin-globulin complexes. If the patient is not eating, or if a coexisting problem could significantly dilute the chylous drainage, the gross appearance of the fluid may not be distinguishable from many other effusions. Table 16-8 summarizes characteristics of chyle that can be diagnostically helpful when gross appearance is ambiguous. The lymphocyte count and triglyceride level are most useful. Lymphangiography can define the site of the leak when it is not clinically obvious and is most useful in cases of nontraumatic chylothorax. It is rarely indicated in the traumatic variety.

Normal chyle flow ranges between 1.5 and 2.5 L/day but can vary much more widely depending on diet and on the fat content of the diet. During starvation or intravenous feeding, flow falls to about 250 mL/day of clear fluid. Chylothorax is frequently massive (Fig. 16-31) and symptomatic, and significant volume losses can occur through thoracentesis or chest tube drainage. Dehydration, nutritional losses, and a steady decline in circulating lymphocytes can produce significant disability and an increased susceptibility to infection.

Treatment

Until Lampson described successful treatment of chylothorax by ligation of the thoracic duct in 1948, mortality for the condition averaged 50 percent. Since that time, a better understanding of fluid and electrolyte management and the development of total parenteral nutrition have introduced additional options. Spontaneous resolution can occur, so a trial of nonoperative treatment usually is justified. Conservative treatment has two goals: One is to decrease chyle production, and the other is to keep the lung expanded against the mediastinum. Maximal reduction in chyle production is achieved by eliminating oral intake, while the patient is supported by total parenteral nutrition. A possible compromise is replacement of dietary fat with medium-chain triglycerides, which are not absorbed by lymphatics, but this often is unsuccessful. Fluid can be removed intermittently by thoracentesis, but continuous evacuation with a chest tube is much more effective. It is generally accepted that a 7- to 10-day trial of drainage and diet manipulation is justified. Experience in renal transplantation has shown that thoracic duct drainage produces measurable immunosuppression after 2 weeks. An occasional patient will have such massive drainage that persistence for more than a few days is unacceptably debilitating. A commonly accepted criterion is that drainage exceeding 500 mL/day in an adult or more than 100 mL/day/year of age in a child is an indication for abandonment of conservative therapy.

When conservative treatment fails, the operative approach is dictated by the cause and the location of the leak. For iatrogenic injury near the aortic arch or at the confluence of the subclavian and jugular veins, the left thorax or supraclavicular area is explored, the site identified, and the injury controlled with direct suture. If the site of injury cannot be clearly identified, the thoracic duct is ligated at the diaphragm where it enters the thorax, and a pleural abrasion is performed.

Ligation of the duct is most easily done through a right thoracotomy. If the problem is bilateral, the right side is approached first; ligation usually resolves the problem on both sides. Direct operative approaches through thoracotomy are successful in approximately 80 percent of patients. Treatment failures are most common in nontraumatic chylothorax. Based on early experience with thoracoscopy, thoracotomy may become a last resort for exploration.

The use of a pleuroperitoneal shunt has been added recently to the list of treatment options for chylothorax. Fluid is pumped from the pleural cavity to the peritoneal cavity with a small subcutaneous squeeze bulb on a one- way valve. Excellent results were obtained with Denver pleuroperitoneal shunts in 12 of 16 patients (75 percent) recently reported by Murphy and associates, and it was possible to remove the shunt in 10 of the 12 patients with good outcomes. However, pleuroperitoneal shunting should be considered only when other treatment options such as duct ligation are not possible or appropriate because they are potentially associated with risks of obstruction or infection.

Tumors

Mesothelioma

Mesothelioma is a neoplasm originating in the mesothelial lining of serosal cavities. Tumor presents in the pleura in 80 percent and in the peritoneum in 20 percent of patients. Although mesothelioma is a rare tumor (2.2 cases per million per year), an increased incidence has occurred since the association with asbestos exposure was recognized in the 1960s. In several large series, a history of asbestos exposure has been documented in 50 to 87 percent of patients. The disease is most common in geographic areas having local industries associated with high risk of exposure, such as shipbuilding or manufacturing processes using asbestos. Exposure to asbestos particles carried on the clothing of workers at risk has been implicated as a cause of increased incidence of mesothelioma in family members. The epidemiology is complicated by the fact that asbestos is nearly ubiquitous in any urban environment, and the characteristic refractile particles can be identified in many people without disease. Smoking is not an important etiologic cofactor, and the latency period from exposure to clinical disease is at least 20 years.

Mesothelioma previously was thought to occur in a benign and a malignant form. However, the term *benign mesothelioma* is now considered a misnomer. Such tumors, now more appropriately termed *benign fibrous tumors of the pleura*, are unrelated to asbestos exposure or to diffuse malignant pleural mesothelioma. They present as an intrathoracic mass on chest x-ray and usually are asymptomatic. Pleural effusion is rare. Pathologically, the tumor arises from visceral pleura as a discreet pedunculated mass (Fig. 16-32). Resection, performed via videothoracoscopy or thoracotomy, is curative and should be done to obtain an accurate diagnosis and to prevent further tumor growth.

In contrast, *malignant mesothelioma* is a locally aggressive neoplasm usually appearing after age 40, with a male predominance of more than 2:1. The tumor usually appears to be multicentric, with multiple pleural-based nodules ultimately coalescing to form sheets of confluent mass. There are four cell types: epithelial, mixed epithelial and fibrosarcomatous, fibrosarcomatous, and desmoplastic. Epithelial histology has the best prognosis, whereas desmoplastic and fibrosarcomatous have the worst and mixed tumors have an intermediate prognosis.

Although hematogenous and lymphatic spread occur in at least half of patients, the predominant clinical feature is local tumor growth. Involvement of lung, chest wall, diaphragm, and mediastinal structures is common. In one series of 69 patients, only 3 of 14 patients autopsied had disease limited to the thorax, and 9 patients developed tumor in a needle biopsy tract. Most untreated patients die of symptoms caused by the primary tumor rather than metastases. Thrombocytosis is frequently seen and is thought to be related to cytokine overexpression (interleukin 6). In one series the platelet count was more than 400,000/mm³ in 90 percent of patients and greater than 1,000,000/mm³ in 14 percent.

Clinical Manifestations

Chest pain, dyspnea, or both are present in virtually all patients with malignant mesothelioma. Pleural effusion is present at some time in 85 to 95 percent of patients, although as the disease progresses the pleural space tends to become obliterated with solid tumor. Radiographic findings other than effusion cover a wide spectrum including pleural thickening, lung nodules, chest wall masses, and mediastinal masses (Fig. 16-33). CT scan of the chest and upper abdomen is the most accurate means of non-invasive staging of the primary tumor (Fig. 16-34).

A tissue diagnosis is difficult to obtain without thoracoscopy or open pleural biopsy. In a series of 123 patients reported by Brenner and associates, thoracentesis in 60 patients revealed malignant cells in only 22, and a definitive diagnosis of mesothelioma could only be made in 7. Unless a representative specimen of adequate size is obtained, the epithelial cell type in particular can be easily confused with adenocarcinoma. Accurate pathologic diagnosis relies on immunohistochemistry. Malignant mesotheliomas rarely stain for carcinoembryonic antigen (CEA), whereas adenocarcinomas almost always do. When immunohistochemistry does not yield a definitive diagnosis, electron microscopy is required.

Treatment

The treatment of malignant pleural mesothelioma is controversial because the factors affecting prognosis are poorly understood. Prognosis is linked primarily to tumor stage and histology. The Butchart staging system (Table 16-9), developed in 1976, has been abandoned in favor of a new staging system proposed by the International Mesothelioma Interest Group (IMIG), which provides more accurate descriptors for tumor T and node N status (Table 16-10).

Recent information indicates that the natural history of malignant mesothelioma is more variable than previously thought. Survival in untreated patients ranges from 6 months for those with stage IV disease to 2 years or more for those with stage Ia tumors.

Patients who have very early stage tumors (stage Ia) are reported to have their survival prolonged by the intrapleural administration of gamma interferon, but most patients are not diagnosed until their tumors are more locally advanced. The role of surgical resection in the treatment of malignant pleural mesothelioma is not fully defined. Complete tumor resection by extrapleural pneumonectomy can now be performed with a mortality rate of 6 percent when patients are carefully selected and the operation is done by experienced surgeons. When coupled with adjuvant hemithoracic radiation, extrapleural pneumonectomy offers the best chance of local control. Patients who have stage I or II tumors of epithelial histology are the most likely to benefit from this approach. Although some centers routinely offer patients adjuvant chemotherapy, the benefit of chemotherapy is undefined, especially since no currently available drug has more than a 20 percent response rate.

Patients with stage I or II tumors who do not have the pulmonary function to tolerate an extrapleural pneumonectomy can be palliated by thoracoscopic talc pleurodesis or by pleurectomy/decortication. At Memorial Sloan-Kettering Cancer Center, experience with 105 patients managed by pleurectomy/decortication and adjuvant radiation (external-beam hemithoracic radiation with or without intraoperative brachytherapy) suggests that about one-quarter of operable patients may have their life expectancy prolonged by this treatment approach. Most patients develop locally recurrent disease within 2 years, and the risk of radiation-induced pneumonitis or pericarditis is significant.

Patients who have more locally advanced or metastatic mesothelioma have few treatment options. Radiation cannot be delivered in therapeutically effective doses in patients who have not had a pneumonectomy because of the sensitivity of the lung to high doses of radiation. The low response rates to currently available chemotherapy make it unattractive to treat patients routinely with standard agents. Other approaches such as immunotherapy or gene therapy are experimental.

Metastatic Pleural Tumors

Over 90 percent of pleural tumors are metastatic. Lung and breast carcinoma are the most common primaries. In more than half of all cases, gross tumor is not visible but produces a malignant pleural effusion. When multiple nodules or diffuse oblitative spread occur, differentiation from mesothelioma is impossible without biopsy.

Spontaneous Pneumothorax

Nontraumatic pneumothorax most commonly results from rupture of a pulmonary bleb or bulla. Negative intrathoracic pressure throughout the respiratory cycle favors movement of air into the pleural space with egress prevented by the ball-valve effect of collapsing tissue during expiration. The pneumothorax continues to progress until the leak seals with fibrin at a rate directly related to the size of the bleb. Large leaks can produce life-threatening tension pneumothorax. Spontaneous resolution can occur once the leak stops, but the gas in the space is mostly nitrogen and is very slowly reabsorbed by the pleural surfaces.

Up to 80 percent of patients with spontaneous pneumothorax are young adults, usually male, without clinically significant pulmonary disease. A tall, asthenic habitus is common. In 85 percent of patients, blebs or bullae of varying sizes are found in the lung apices (Fig. 16-35), and it is not known whether their origin is congenital or acquired. After the first episode, the chance of ipsilateral recurrence is 50 percent, and the risk rises with each recurrence to 62 percent after a second episode and 80 percent after a third episode. The risk of a contralateral pneumothorax after the first episode is about 10 percent.

In patients over age 40, significant pulmonary disease usually is present, most frequently emphysema in a tobacco addict. *Catamenial pneumothorax* is a rare condition in which pneumothorax occurs predictably within a few days of menses, usually in women over 30, and almost always on the right side. The mechanism is not known. The two most frequently cited possibilities are pleural endometriosis and small perforations of the diaphragm.

Clinical Manifestations

Chest pain is the most common presenting symptom, followed by dyspnea. If the lung is more than about 25 percent collapsed, a decrease in breath sounds is evident on auscultation, and the affected side is hyperresonant to percussion. Young patients without underlying lung disease can be asymptomatic at rest with nearly complete collapse of one lung, and arterial blood gases are nearly normal. A more dramatic presentation, including tachypnea, cyanosis, and hypoxia, is seen in patients with underlying lung disease and limited ventilatory reserve. An occasional patient with extensive lung disease and a pleural space obliterated with adhesions will present with massive subcutaneous emphysema and pneumomediastinum because air escaping from the ruptured bleb follows the path of least resistance retrograde through the peribronchial soft tissue.

The characteristic radiographic finding is absence of lung markings and a faintly visible line defining the edge of the lung. When the lung collapses almost completely, it is visible as an irregular density attached to the hilus (Fig. 16-36). Presence of a small amount of fluid with an air-fluid level is common. The fluid usually is serosanguineous and insignificant. On occasion, bleeding from a torn pleural adhesion produces a large and increasing hemothorax that can require urgent exploration. The lung fields must be examined closely for evidence of gross abnormalities, such as apical blebs or bullae. Although blebs and bullae frequently are obvious at thoracotomy, only about 15 percent are visible radiographically.

Treatment

An asymptomatic or mildly symptomatic pneumothorax with less than 30 percent collapse that is shown not to increase in size over 6 to 8 h can safely be observed. Simple needle aspiration of the airspace can nearly eliminate the space in a stable pneumothorax and greatly reduces the amount of time required for spontaneous resolution. In a report by Delius and associates, aspiration through an 8F Teflon catheter was successful in 69 percent of 114 patients and in 87 percent of patients with simple pneumothorax. The average cost was comparatively low. Needle aspiration of a tension pneumothorax can be a lifesaving temporizing maneuver.

Thoracostomy tube drainage is the most common treatment. The tube is inserted either anteriorly (second interspace, midclavicular line) or laterally in a lower interspace (middle to anterior axillary line), with the tip directed toward the apex. The tube is connected to water seal, to which suction can be added to increase the gradient favoring removal of air from the pleural space. Water seal alone suffices in many cases. As the lung reexpands, the patient feels pain as the visceral and parietal surfaces reoppose. The pain gradually subsides but usually is much more acute and severe when suction is applied initially. Rapid reexpansion occasionally leads to reexpansion pulmonary edema involving the ipsilateral lung, which was seen in 21 of 146 patients (14 percent) reported by Matsuura and associates. Those at greatest risk were patients 20 to 39 years of age with large pneumothoraces. Although the cause is not understood, the entity needs to be kept in mind because mortality has been as high as 20 percent. Some authors favor attaching the tube to a one-way flutter valve (Heimlich valve) that permits outpatient treatment of a pneumothorax in a reliable patient with a small leak.

Serial check x-rays are followed to assess reexpansion, and the size of the air leak is monitored by observing the rate of bubbling in the water-seal chamber. Air crosses the water seal only with cough or Valsalva in a pneumothorax caused by a leak that has already sealed, and the bubbling usually ceases altogether within 24 h. At the opposite extreme,

continuous bubbling occurring through both phases of respiration reflects a large, active leak that may take days to seal, if it will seal at all. With large air leaks, a single tube may be inadequate. If two tubes connected to suction still fail to expand the lung, thoracotomy is required. Even a large leak can seal if the lung can be expanded fully, which promotes adhesion formation between parietal pleura and the site of the leak in the visceral pleura. Intrapleural instillation of sclerosing agents such as talc appears effective in reducing the recurrence rate.

Operation is indicated for a massive air leak with failure of lung reexpansion or for a smaller leak that has persisted for more than a week. Because of the frequency of recurrence after one episode, operation is recommended after any second episode and in any patient with a previous contralateral pneumothorax. Operation might be recommended after a first episode to anyone with large apical bullae visible on chest x-ray, to persons likely to be exposed to dangerous changes in atmospheric pressure (airline pilots, scuba divers), or to persons living in remote areas. Complications such as empyema or hemothorax occasionally develop and mandate operation. Conservative treatment is continued as long as possible in older patients with underlying lung disease because of their limited ventilatory reserve.

At thoracotomy or thoracoscopy, the site of the leak can be identified and resected, oversewn, closed with staples, or ablated with laser energy. Pleural abrasion also should be performed to promote formation of adhesions between visceral and parietal pleura, an especially important maneuver if no leak site can be identified. Pleurectomy, accomplished by stripping all the parietal pleura off the underlying ribs and intercostal muscles, is undeniably effective but has substantially greater morbidity and is reserved for extreme cases. Either method is 90 to 95 percent effective.

LUNG

Development and Anatomy

In the 4-mm (3-week) embryo, an outpouching from the primitive foregut appears caudad to the paired pharyngeal pouches and bifurcates into the right and left primitive bronchial buds. Over the next 2 weeks, further branching occurs with 10 segmental tubes on the right and 8 on the left, providing an early indication of the lobar development that continues in each lung. Progressive branching of epithelial tubes results in a rich arborization of bronchioles and alveolar ducts and sacs. It is estimated that 300 million alveolar sacs eventually develop. As the structural maturation is taking place, histologic differentiation progresses from the cuboidal epithelium that lines the terminal buds during the first 4 fetal months to the flattened epithelium present at birth. It is likely that the basic architecture of the lungs is completely developed at birth. As the lungs grow, they bulge into the lateral pleural cavities, leaving a dorsal mesentery to encase the developing mediastinal structures. The most caudal pair of aortic arches (the sixth) gives rise to the pulmonary arteries, with the remnant of the left sixth arch persisting as the ductus arteriosus. Vascular sprouts from the unilocular atrium fuse with the developing capillary vasculature in the lung mesenchyma to become the pulmonary veins.

Although the number of respiratory units may not increase after birth, it does seem apparent that the newborn's lung is structurally immature. In place of alveoli, the lungs are made up of primitive air sacs that differentiate into alveolar ducts and sacs. Alveoli develop by outpouching and compartmentalization, and maturation continues throughout the first 8 years of life. The fully developed alveoli give a surface area of 70 to 80 m² at three-fourths maximal inflation of the adult lung.

Segmental Anatomy

The segmental anatomy of the lungs and bronchial tree is illustrated in Fig. 16-37. Although there is continuity of the pulmonary parenchyma between adjacent segments of each lobe, the separation of the bronchial and vascular stalks allows subsegmental and segmental resections whenever the clinical situation requires or allows preserving lung tissue. This may be particularly important in patients with impaired pulmonary function or in those with disease processes that are apt to become multifocal, requiring multiple resective procedures. Less than lobar resections are desirable when dealing with localized inflammatory diseases such as tuberculosis and bronchiectasis that characteristically involve segmental units of the upper and lower lobes, respectively, but often do so in a way that leaves one or more segments of the same lobe unaffected. Both these diseases, as well as metastatic pulmonary neoplasms, may involve more than one pulmonary lobe, synchronously or metachronously. Many surgeons doubt the necessity of extending the resection even of primary lung neoplasms beyond the field necessary for adequate margins around the tumor. The advantages of a segmental concept of surgical treatment are important in all these circumstances.

Lymphatic Drainage

Abundant lymphatic vessels are located beneath the visceral pleura of each lung, in the interlobular septa, in the submucosa of the bronchi, and in the perivascular and peribronchial connective tissue. The lymph nodes that drain the lungs are divided into two large groups, the pulmonary lymph nodes and the mediastinal nodes, referred to as N1 and N2 nodes, respectively, in the TNM system of staging of lung cancer (Fig. 16-38). In turn, the pulmonary (N1) lymph nodes consist of (1) intrapulmonary or segmental nodes that lie at points of division of segmental bronchi or in the bifurcations of the pulmonary artery, (2) lobar nodes that lie along the upper-, middle-, and lower-lobe bronchi, (3) interlobar nodes situated in the angles formed by the bifurcation of the main bronchi into lobar bronchi, and (4) hilar nodes located along the main bronchi.

The interlobar lymph nodes lie in the depths of the interlobar fissure on each side and have special surgical significance because they constitute a lymphatic sump for each lung, referred to as the *lymphatic sump of Borrie* (Fig. 16-39). This designation derives from the fact that all the pulmonary lobes of the corresponding lung drain into that group of nodes. On the right side, the nodes of the lymphatic sump lie around the bronchus intermedius bounded above by the right upper lobe bronchus and below by the middle lobe and superior segmental bronchi. The lymphatic sump on the left side is confined to the interlobar fissure, with the lymph nodes disposed in the angle between the lingular and lower lobe bronchi and in apposition to the pulmonary artery branches.

The mediastinal (N2) lymph nodes consist of four principal groups: (1) anterior mediastinal, (2) posterior mediastinal, (3) tracheobronchial, and (4) paratracheal. The anterior mediastinal nodes are located in association with the upper surface of the pericardium, the phrenic nerves, the ligamentum arteriosum, and the left innominate vein. Within the inferior pulmonary ligament on each side are found the paraesophageal lymph nodes that constitute a major part of the posterior mediastinal group. Additional paraesophageal nodes may be located more superiorly between the esophagus and trachea in the region of the arch of the azygos vein.

The tracheobronchial lymph nodes are made up of three subgroups that are located about the bifurcation of the trachea. Included are the subcarinal nodes, the lymph nodes lying in the obtuse angle between the trachea and each mainstem bronchus, and a few nodes that lie anterior to the lower end of the trachea. The paratracheal lymph nodes are located in proximity to the trachea in the superior mediastinum. Those on the right side form a chain with the tracheobronchial nodes inferiorly and with some of the deep cervical nodes above. A few of the latter are referred to as the *scalene lymph nodes* because they lie on the anterior scalene muscle. Lymphatic drainage of the right lung is ipsilateral except for an occasional incidence in which drainage to the superior mediastinum is bilateral. Drainage from the left lung to the superior mediastinum is as frequently ipsilateral as it is to the opposite side.

Diagnostic Tests

Although the importance of an accurate history and physical examination cannot be overemphasized, diagnostic tests play an integral part in the investigation and management of pulmonary disorders. Because the lung is an air-containing organ, relatively simple radiologic examinations can be used to great advantage. With increasing frequency, both chest x-rays and CT scans are used to investigate most pulmonary disorders. The communication between oropharynx and respiratory system allows secretions to be collected from the lung and airways for bacteriologic and cytologic examination and direct endoscopic examination of the tracheobronchial tree.

Sputum examination

In many of the acquired pulmonary disorders, sputum collection and examination are indicated as an initial diagnostic procedure. In inflammatory conditions, a specific etiologic agent can be identified by bacteriologic examination. Unfortunately, at times, the patient cannot expectorate sputum but provides saliva contaminated with oral flora, making a bacteriologic diagnosis difficult. When necessary, the oropharynx can be bypassed to obtain appropriate bacteriologic specimens. A percutaneous transtracheal or cricothyroid insertion of a sterile needle connected to an appropriate syringe can obtain secretions directly from the trachea. This is facilitated by injecting 5 to 10 mL of a sterile saline solution, which promotes coughing and allows aspiration of these secretions.

In investigating malignancies, sputum cytology is most appropriate when the tumor is in the proximal portion of the tracheobronchial tree (inner one-third of the lung) or in major airways (e.g., distal trachea and main bronchi).

The diagnostic yield from sputum samples can be increased by obtaining the specimen early in the morning when the patient is most likely to produce a large volume pooled from the peripheral airways. Serial specimens obtained on separate days also may improve diagnostic yield.

Imaging Studies

The standard posteroanterior chest film together with a companion lateral view remains the most frequent initial imaging study. When correlated with symptoms, physical findings, and, where available, previous radiographs, it can provide much of the information needed for the diagnosis and management of most lung disorders.

CT scanning has been used extensively in order to further define the abnormalities seen on chest x-ray. As well, CT scanning does allow investigation of the various mediastinal structures that cannot be isolated on a routine chest x-ray. This is especially important in investigating hilar abnormalities and assessing spread of malignancies to the lymph nodes in the mediastinum. Most patients now undergo CT scanning when surgical therapy is being considered in the management of their pulmonary disease.

Magnetic resonance imaging (MRI) does have value in investigating thoracic disorders, but in most instances of lung disease, this examination is unnecessary. MRI has its greatest value in assessing invasion of contiguous structures, including the vertebral bodies, spinal canal, brachial plexus, subclavian vessels, aorta, and chest wall.

Isotope studies are used less frequently. In assessing lung function, quantitative ventilation-perfusion scanning is of prime importance, especially when surgical resection of functioning lung in a pulmonary- compromised individual is anticipated. The percentage of functioning lung to be removed can be calculated and used in conjunction with pulmonary function tests to estimate the residual lung function after resection. In addition, perfusion scanning continues to be an important means of diagnosing suspected pulmonary embolism.

Other scans are used in investigating sites of metastases prior to the treatment of cancer patients. Routine organ scanning is not cost-effective before treatment, but when symptoms suggest abnormalities in distant organs, bone scans and CT or MRI scans of the brain are useful in detecting metastatic disease in these sites.

Positron emission tomography (PET) has been used to diagnose lung cancers and to detect metastases. This form of radionuclide scanning using fluorodeoxyglucose (FDG) is based on the principle that tumors take up and metabolize more glucose than do normal tissues and therefore appear as "hot spots" on FDG-PET scans. The proper application of this new imaging modality is being investigated. It has significant value in diagnosing cancer in an abnormality seen on chest x-ray and in identifying occult sites of metastases in

regional lymph nodes and other organs. In the future, it is possible that a single whole-body PET scan could replace doing multiple other scans in staging patients with thoracic malignancies (Fig. 16-40).

More invasive imaging plays less of a role today than it did previously. Although pulmonary angiography is still valuable, especially in confirming the diagnosis of pulmonary embolus and congenital vascular abnormalities, it has been supplanted largely by improved techniques of MRI and high- resolution CT. Similarly, imaging of the PP265">airway (contrast bronchography) has been replaced by thin section helical CT that can be spacially reconstructed to delineate airways.

Occasionally, bronchial arteriography has value in identifying and treating sites of bleeding from the airway. The bronchial arteries arising from the proximal descending aorta can be selectively catheterized, and abnormal bronchial arteries or bleeding bronchial arteries can be identified using routine percutaneous arteriographic techniques. This is valuable in diagnosis but also has become an integral part of the management of massive hemoptysis by embolizing these vessels to arrest the bleeding.

Bronchoscopy

Bronchoscopy is the most valuable invasive modality used in the investigation of pulmonary disease. With the advent of fiberoptic instruments 30 years ago, intubation of the tracheobronchial tree has become simple and expedient. Prior to this, rigid open tubes were required to visualize the tracheobronchial tree. These required general anesthesia and, because of their rigidity, limited the scope of investigation to the major airways (Fig. 16-41). The flexible fiberoptic equipment measures only a few millimeters in diameter and allows for intubation of the tracheobronchial tree using local anesthesia and mild sedation. These qualities extend the scope of bronchoscopy immensely (Fig. 16-42). Tiny channels within the bronchoscope allows for direct acquisition of secretions, cytologic brushings of abnormalities, and direct biopsy. This is especially important when investigating malignancies of the tracheobronchial tree and identifying the sites of bleeding when investigating hemoptysis.

Peripheral pulmonary nodules and diffuse lung disease can be diagnosed using fiberoptic bronchoscopic equipment combined with fluoroscopic imaging. Using fluoroscopic control, fine biopsy forceps and needles can be passed into the periphery of the lung to obtain biopsies of peripheral airways and subjacent lung tissue. As well, nodules of larger size (usually >3 cm) can be biopsied with this type of fluoroscopic control.

The bronchoscope not only plays an important role in diagnosis, it is also frequently required for therapeutic intervention. It is in these instances that the rigid "open" bronchoscope frequently is required, e.g., for removing foreign bodies or obstructing tumors or inserting or managing hemoptysis. In these situations, the fiberoptic bronchoscope is often used in conjunction with the rigid scope to remove secretions, inspect peripheral airways, or assist in laser therapy. The procedure is performed under general anesthesia with the patient ventilated via the rigid scope, and the flexible bronchoscope is passed through the rigid scope.

Transthoracic Biopsies

When investigating undiagnosed pulmonary lesions, percutaneous transthoracic biopsies using fine needles have proved to be exceptionally effective in obtaining material for bacteriologic and cytologic examination. In most instances, this is performed under fluoroscopic or CT-guided imaging by specially trained interventional radiologists. Diagnostic accuracy for malignancy approaches 95 percent when adequate specimens can be obtained (Fig. 16-43). Because this approach requires penetration of the lung, pneumothorax is a common complication (up to 30 percent) but usually is asymptomatic and requires no treatment.

Scalene Node Biopsy

Because of the predilection of lung cancer to spread to mediastinal lymph nodes and ultimately supraclavicular (scalene) lymph nodes (Fig. 16-44), in the past, before the newer imaging techniques previously discussed were available, biopsies of scalene lymph nodes (Daniel's procedure) often were done to rule out metastases that would contraindicate a surgical operation in dealing with patients with lung cancer. These "blind" scalene lymph node biopsies no longer are used. When physical examination or imaging reveals supraclavicular adenopathy, percutaneous needle aspiration biopsy or open scalene lymph node biopsy is necessary to identify metastatic disease in the palpable nodes.

Mediastinoscopy

When investigating diseases where the CT scan identifies enlarged mediastinal lymph nodes, mediastinoscopy has become the procedure of choice. This examination requires a suprasternal incision to expose the trachea and then insertion of an open tube instrument (mediastinoscope) into the mediastinum anterior to the trachea where the superior mediastinal lymph nodes draining the lung are located (Fig. 16-45). Because the results of surgery alone for patients with involvement of superior mediastinal lymph nodes are poor, most surgeons prefer to identify this before consideration of surgical resection of a lung cancer. Most physicians consider a 1-cm transverse diameter on CT scan as the highest limits of normal sized lymph nodes in this location.

This technique (mediastinoscopy) also is extremely useful in identifying other causes of mediastinal lymphadenopathy, e.g., sarcoidosis, lymphoma, granulomas, and other inflammations.

Parasternal Mediastinotomy

Mediastinoscopy cannot reach those lymph nodes which drain to the anterior mediastinum. This is extremely important in diseases of the left upper lobe, where the usual lymph node drainage is to the aortopulmonary window, and in diagnosing anterior mediastinal tumors. In this instance, parasternal mediastinotomy (Chamberlain procedure) can be used for diagnosis. A short transverse incision is made, usually in the second intercostal space or through the bed of the second costal cartilage (after removing it), in order to reach the paramediastinal area. The mediastinoscope can be introduced through this approach to biopsy lymph nodes along the aortic arch and in the aortopulmonary window just beneath the arch. Alternatively, the second costal cartilage can be excised, the pleura and lung retracted laterally, and the aortopulmonary window exposed directly. A similar approach can be used on the right side to biopsy tumors or lymph nodes anterior to the superior vena cava.

Thoracoscopy

Almost 100 years ago, thoracoscopy was performed using a cystoscope to examine the pleural space in order to diagnose the various causes of pleurisy. This technique was adapted to perform "collapse" therapy for pulmonary tuberculosis. Since that time, surgeons have used open-tube instruments (e.g., mediastinoscope) or cystoscope-like instruments to examine and biopsy the pleural space. With improved imaging, optical, and surgical equipment and the ability to unilaterally collapse the lung, video- assisted thoracoscopy has become an extremely valuable technique not only for investigating the pleural space but also for inspecting the mediastinum and obtaining lung biopsies. With advanced instrumentation, one, two, or three small intercostal incisions can be made, the pleural space and surface of the lung can be inspected, and using appropriate grasping and stapling equipment, biopsies can be obtained not only of the pleura but also of the lung and mediastinum. This has become especially valuable in investigating diffuse lung disease (e.g., sarcoidosis, interstitial pneumonia) and for removing peripherally placed pulmonary nodules for diagnosis.

Open Lung Biopsy

Before the advent of video-assisted thoracoscopic techniques, open lung biopsy was used extensively in obtaining lung biopsies for diagnosing interstitial lung disease. On occasion, especially in those patients in whom lung collapse is not appropriate (e.g., ventilated patients with acute disorders), open lung biopsy is the approach of choice. This can be performed very simply using a short intercostal incision directed to the area of interest in the lung and inserting stapling instruments to perform the biopsy.

Pulmonary Resections

In the surgical management of lung disease, diagnostic or therapeutic, portions of pulmonary parenchyma frequently are excised. Depending on the type of disease and the reason for removal of lung tissue, large or small portions of lung may be removed up to and including a complete ipsilateral lung (pneumonectomy).

After pulmonary resections, the remaining lung hyperexpands, and the diaphragm and mediastinum shifts in order to decrease the size of the hemithorax, thereby accommodating the loss of pulmonary tissue. Chest tubes attached to underwater drainage systems and, frequently, suctioning facilitate this and allow any parenchymal leaking areas to heal.

In the case of pneumonectomy, serum begins to fill the empty hemithorax and, over a few weeks, completely replaces the empty space created by the pneumonectomy. As with other resections, the affected hemithorax decreases in size by shifts in the mediastinum and elevation of the ipsilateral diaphragm.

Wedge Resection

(Fig. 16-46) This type of resection removes a small portion of peripheral parenchyma. It is performed most frequently for diagnosing diffuse lung disease or solitary pulmonary nodules. In many instances, video-assisted thoracoscopic techniques can be used. To maximize hemostasis and closure of air leaks, staplers are used to perform the biopsies. Larger portions of lung parenchyma also can be removed nonanatomically using this stapling technique. This is frequently used in the surgical treatment of emphysema (bullectomy and lung volume–reduction surgery).

Segmental Resection

(Fig. 16-47) Segments or subsegments of lobes can be removed in a more anatomic fashion by isolating and dividing the segmental bronchus and artery and then removing the lung in an intersegmental plane. This removal may be facilitated by using mechanical stapling equipment or dividing lung tissue and sewing the opened parenchyma. The intersegmental plane is defined by the pulmonary veins, and the segment to be removed may be stripped from the remaining lung along this intersegmental plane. Segmentectomy is best used in treating localized inflammatory diseases or small peripheral tumors limited to one segment where the patient cannot tolerate a larger resection.

Lobectomy

Any of the five lobes of the lung can be removed in an anatomic fashion. In all such resections, the lobar bronchus is divided, and the pulmonary arteries and veins to the lobe are individually ligated and divided. Frequently, the fissures between the lobes are incomplete and have to be divided before completing the resection. This is the most frequent type of resection used in treating localized lung tumors.

Pneumonectomy

Removing a total ipsilateral lung is reserved for those instances where lesser resections cannot be accomplished, e.g., tumors involving the hilum of the lung and inflammatory diseases where total destruction of the lung has occurred. In these resections, care must be taken to ensure that preoperatively the patient has been found to have sufficient lung function to tolerate such a resection. At the time of surgery, the main pulmonary artery must be divided and ligated as well as both pulmonary veins. In most instances, the final division is the main bronchus, which is divided and closed by suture or stapling devices. Because of the risk of bronchopleural fistula, this bronchial closure is sometimes reinforced with adjacent vascularized tissue.

Developmental Anomalies

Many developmental anomalies of the lung present at birth, resulting in stillborn infants or infants with severe respiratory distress. These include lobar emphysema, cystadenomatoid malformation, sequestration, pulmonary agenesis or severe hypoplasia, and giant bronchogenic cysts. These may require urgent or emergent treatment in the newborn period. Less severe anomalies are certainly compatible with life and may not present until later, even as late as adulthood. Many are mild anatomic variants and may never require treatment. An interesting and exciting development is the emergence of intrauterine diagnosis with ultrasound. Many of these life-threatening lesions may, in the future, be diagnosed and treated during intrauterine growth (fetal surgery).

Anatomic Variants

Many anatomic variants can occur because of abnormal intrauterine development. Most of these are interesting but inconsequential. The most common of these, the *azygous lobe*, occurs in 0.5 percent of individuals. The azygous vein lies in the substance of the right upper lobe on a pleural mesentery separating this “azygous lobe” from the remainder of the lung. This presents radiologically as a separate apical lobe appearing as an “inverted comma” in the medial apex of the right upper lobe. Occasionally, repeated infections can occur in this isolated area. *Situs inversus* is a rare entity in which the thoracic viscera (*situs inversus thoracis*) or the thoracic and abdominal viscera (*situs inversus totalis*) undergo complete mirror- image reversal in position during development. Although an important entity to recognize, this total reversal of organs rarely causes a problem unless associated with other conditions. *Kartagener's syndrome*, a familial association of situs inversus with chronic sinusitis and bronchiectasis, has been identified as being associated with abnormal ciliary anatomy and function causing repeated infections of sinuses and bronchi.

Occasionally, *aberrant bronchial origins* are present. Most frequently the right upper lobe bronchus originates from the lateral wall of the trachea. This is an important anatomic abnormality to identify at bronchoscopy before operative intervention.

Agenesis and Hypoplasia

Arrest in embryonic development can result in abnormalities of the lung varying from bilateral total pulmonary agenesis to hypoplasia of a portion of one lung. In about 50 percent of cases, other congenital anomalies coexist. Complete bilateral pulmonary agenesis is incompatible with life. Unilateral agenesis, when not associated with other life-threatening anomalies, is compatible with a relatively normal life. It usually occurs on the left side, with the right lung filling both hemithoraces.

Severe hypoplasia usually results in stillbirth or rapid death. In those patients presenting with severe respiratory distress and unassociated with other life-threatening congenital anomalies, neonatal pulmonary transplantation may offer hope for long-term survival. Unilateral hypoplasia often is associated with other space-filling congenital defects, e.g., diaphragmatic hernia that restricts intrauterine lung growth. An interesting variant of hypoplasia occurs in the right lung; the *scimitar syndrome* includes hypoplasia of the right lung, anomalous pulmonary venous drainage that enters the inferior vena cava instead of the left atrium, and an aberrant pulmonary arterial origin from the aorta. The venous drainage abnormality produces the “scimitar sign” outlining the venous drainage into the inferior pulmonary vein.

Cystic Adenomatoid Malformation

This anomaly is characterized by overgrowth of bronchioles resulting in cystic overgrowth of terminal ventilating units and usually presents as respiratory distress in the newborn. However, other congenital abnormalities, prematurity, and stillbirth are commonly associated. In the neonate presenting with respiratory distress, the chest x-ray shows a multicystic “swiss cheese” configuration with over-expansion of the involved area, shifting the mediastinum and compressing the normal lung (Fig. 16-48). The lesion can be diagnosed during intrauterine life and has been with increasing frequency using prenatal ultrasound examinations. Attempts have been made to treat this with prenatal intervention, either aspirating the cystic area or resecting it. There has been some success using this approach.

The postnatal management in surviving patients is resection of the diseased lobe. On occasion, these patients present beyond the neonatal period with slowly increasing respiratory problems, and the diagnosis and treatment are delayed. With a successful early operation, the prognosis is excellent, barring other life-threatening congenital anomalies.

Thoracotomy reveals a dense, meaty mass studded with cysts that may be partially aerated but have no ventilatory function. Anomalous vessels are very rare. Histopathology reveals multiple components of respiratory tissue, including a maze of irregular tubules resembling fetal bronchioles lined with disorganized respiratory epithelium that can resemble an adenoma. Lobectomy is the treatment of choice, although pneumonectomy has been necessary in some cases. The prognosis is excellent with a successful early operation.

Pulmonary Sequestration

During development, a portion of lung may be isolated from the remainder of the lung and receive its blood supply from an aberrant branch of the aorta instead of the pulmonary artery.

Intralobar sequestrations rest within a lobe and do not have their own visceral pleural envelope but usually have a communication with the tracheobronchial tree producing a cystic appearance. They occur invariably in the posterobasal portion of the lower lobes, most frequently on the left side. The sequestered lung is supplied by an anomalous branch of the aorta that usually is tortuous and disproportionately large, arising from the thoracic aorta in 70 percent of patients and from the abdominal aorta or its branches in the remainder. The vessel reaches the sequestered lung by passing through the inferior pulmonary ligament. Venous drainage is through the pulmonary veins. The radiographic appearance is that of a dense mass usually containing cysts with air-fluid levels, indistinguishable from cystic adenomatoid malformation or other congenital cystic abnormalities without an arteriogram (Fig. 16-49). Intralobar sequestrations frequently present as asymptomatic lesions or recurrent localized infections, often in the young adult. When these occur in the posterior basal areas of the lung, the surgeon should be suspicious. Confirmation can be made by CT scan or aortography to identify the anomalous artery (Fig. 16-50 and Fig. 16-51). When symptomatic, surgical resection is the treatment of choice, usually by lobectomy. Care must be taken to identify and ligate the anomalous arterial supply (Fig. 16-52).

Extralobar sequestration is a much less common entity in which the sequestered lung is enclosed by a separate pleural envelope sitting in the inferoposterior mediastinum adjacent to lung and esophagus, usually on the left side (Fig. 16-53). Association with other congenital anomalies, especially diaphragmatic hernia, occurs in over 50 percent of patients. Although tracheobronchial communication is said not to occur, an esophageal communication is seen occasionally. Extralobar sequestration is more likely to be detected early in childhood, appearing as an unexplained dense triangular mass in the posterior lower lung field (Fig. 16-54). Venous drainage is to the azygous or portal venous system. When this anomaly is symptomatic, resection of the abnormal lobe is indicated.

An *accessory lobe* is distinguished from sequestration by the fact that it communicates with the trachea or a major bronchial branch, most commonly on the left side. The accessory lobe can be supplied by the pulmonary or systemic circulation.

Congenital Cysts

These are a diverse group of abnormalities that can be single or multiple and vary greatly in size. They usually are confined to a segment or lobe and almost invariably present with infection. Their cause is poorly understood and may be equally diverse. Unilateral absence of a pulmonary artery branch may produce hypoplastic development of the lung, leading to cystic transformation. The lesions may begin as intrapulmonary bronchogenic cysts, which are thought to represent remnants of developing bronchial buds pinched off in the lung periphery. A region of cystic lung can develop distal to congenital or acquired bronchial obstruction.

The cysts are lined typically with respiratory epithelium and are filled with a viscid opaque fluid until they develop communication with the airway, after which they become partially air-filled and infected. The presence of respiratory epithelium is thought to indicate true congenital origin, but once chronic infection destroys the epithelium, it becomes impossible to separate a congenital cyst from a chronic pulmonary abscess or bronchiectasis, grossly or histopathologically.

Resection is indicated for large or chronically infected cysts. Preoperative evaluation includes bronchoscopy and occasionally arteriography to exclude sequestration. On occasion, massively enlarged cysts present as neonatal respiratory distress requiring urgent excision (Fig. 16-55).

These bronchogenic cysts also can present as mediastinal masses in the paratracheal or subcarinal regions. The diagnosis often is delayed until adult life. When they enlarge, they can produce airways obstruction. There is controversy as to whether or not such cysts should always be removed to avoid acute airway obstruction in the future. These asymptomatic cysts can now be approached through minimal-access surgery, e.g., video- assisted thoracoscopy or mediastinoscopy (see Fig. 16-50).

Arteriovenous Malformation

Pulmonary arteriovenous malformation is a fistula between pulmonary arteries and pulmonary veins. One or more thin-walled saccular channels with an endothelial lining are present without reaction in the surrounding lung tissue. The lesions are somewhat more frequent in the lower lobes. Multiple small (<1cm) lesions associated with capillary abnormalities elsewhere, a feature of hereditary hemorrhagic telangiectasia (Osler- Weber-Rendu syndrome), account for half of all reported cases. In the other half, the lesions are singular or few in number and larger (1 to 5 cm) in size. Although the vascular pattern is variable, one afferent pulmonary arterial branch with two or more efferent venous branches is the most common arrangement (Fig. 16-56). The lesions frequently are very superficial and vulnerable to erosion, and they can present with spontaneous hemothorax.

Diagnosis is easiest in the 20 percent of patients presenting with cyanosis, polycythemia, and clubbing. Cyanosis is said to develop when the shunt fraction exceeds 25 percent of the total blood flow and usually is not seen until adolescence or early adulthood.

There is an interesting difference between the right-to-left shunt seen in congenital heart disease and that seen with a pulmonary arteriovenous malformation. In the latter condition, vascular resistance in both the pulmonary capillary bed and the fistula is negligible, so the total volume returned to the left atrium is not increased—it is simply desaturated in proportion to the amount of flow going through the fistula. In contrast to the patient with an intracardiac shunt, the patient with the fistula has normal cardiac output, pulse, blood pressure, venous pressure, ECG, and heart size. No murmur is audible over the heart, but in over half the cyanotic patients a continuous murmur can be heard peripherally over the fistula. Patients with either condition have arterial desaturation and polycythemia.

Diagnosis is more difficult in the asymptomatic, acyanotic patient. Small, single malformations can be indistinguishable from all other solitary pulmonary nodules. Larger lesions may have a more characteristic lobulated appearance, and the afferent and efferent vessels often can be demonstrated on plane tomography or CT scan. Pulmonary angiography confirms the diagnosis (Fig. 16-57). Both lungs should be examined carefully for multiple lesions.

Significant complications occur in at least 25 percent of all patients and in a higher percentage of patients with hereditary telangiectasia and multiple fistulas. Complications can be local effects such as hemothorax, but consequences of polycythemia, such as cerebral thrombosis, are more common. Resection is indicated in all patients with solitary nodules and in selected patients with multiple nodules when adequate lung tissue can be preserved.

Although resection was the treatment of choice in patients with solitary nodules and in selected patients with multiple nodules when adequate lung tissue could be preserved, most

recently, invasive angiographic approaches, embolizing the fistulae with coils, balloons, and gel foam, are effective in most patients. Cyanotic patients with widespread, multiple, small fistulas are difficult to treat, although improvement with embolization has been reported in a few patients.

Lobar Emphysema

Lobar emphysema presents with massive distention of a lobe or segment that shifts the mediastinum and compresses the contralateral lung. It is the most common of the four structural lesions usually considered in the differential diagnosis of respiratory distress in the newborn. The other three are sequestration, cystic adenomatoid malformation, and bronchogenic cyst. Etiology has been a matter of continuing debate, and the clinical syndrome may represent the final common pathway of several distinct processes. Dysplasia of bronchial cartilage has been recognized most frequently, occurring in about 25 percent of patients. Acute bronchiolitis, extrinsic compression by lymph nodes or anomalous vessels, bronchial atresia, and several other possible causes of bronchial obstruction have been cited. No specific cause can be identified in more than 50 percent of patients. Associated malformations, mostly cardiovascular, are present in about 40 percent of patients, a fact that some authors interpret as support for a congenital etiology.

Respiratory distress typically appears from 4 days to 6 months postpartum. Half of all reported cases have occurred within the first 4 weeks of life. Physical findings of hyperresonance and decreased breath sounds mimic pneumothorax, which is a dangerous misapprehension if it leads to impulsive chest tube insertion. The chest x-ray also can mimic pneumothorax, because the distended lung is very hyperlucent. Another common misinterpretation occurs when the compressed normal lung is thought to be atelectatic and the distended lung compensatory. An important radiographic clue is that the diaphragm usually is depressed on both sides with lobar emphysema but is normal or elevated on the side of primary atelectasis (Fig. [16-58](#)).

In an infant with florid, progressive respiratory distress and a characteristic chest x-ray, emergency thoracotomy and lobectomy are indicated without further study. In such circumstances, the mortality without operation approaches 50 percent. Involvement of an upper lobe or the right middle lobe is the most frequent finding. Lower lobe involvement is rare. Resection is ordinarily straightforward anatomically and completely curative. When the clinical presentation is less fulminant, the decision is more difficult. There is no question that varying degrees of lobar emphysema can be produced by aspiration of mucus or amniotic fluid or by acute bronchiolitis. In such cases the emphysema almost always resolves in a few days with appropriate medical therapy.

Emphysema

Emphysema is characterized by enlarged air-spaces produced by a complex process of elastic tissue destruction resulting in alveolar wall breakdown and coalescence of damaged alveoli, resulting in impaired alveolar ventilation and gas exchange. The disease represents one manifestation of advanced *COPD, overlapping with other manifestations including chronic bronchitis and reactive bronchial asthma. Pathogenetic differences promoting a predominant pattern of alveolar breakdown (versus bronchitis) are difficult to isolate, and the response to a common mechanism of injury such as cigarette smoking is not predictable. An exception is the diffuse emphysematous pattern produced by the loss of normal restraints on tissue destruction as seen in α_1 -antitrypsin deficiency* (Fig. [16-59](#)).

Only a few aspects of this disorder are appropriately managed by surgical resection. Emphysema is often not diffuse, and involved areas may be localized into collections of small cysts (blebs) or very large ones (bullae). Blebs usually are subpleural, do not extend deeply into more central parenchyma, and may have little effect on gas exchange or overall pulmonary function, even when multiple, discrete collections of considerable size are present. Their main significance relates to their potential for rupture with production of pneumothorax. The localized collection of blebs frequently encountered in the apices of otherwise normal lungs in healthy young individuals with spontaneous pneumothorax bears an uncertain pathogenic relationship to emphysema and may be congenital. Although most blebs are apical, the blebs encountered in typical COPD are more likely to be multiple and in other parts of the lung.

Bullae result from a much larger coalescence of destroyed alveolar septa and develop deep within the lung parenchyma, compressing and distorting adjacent normal lung. They may assume the form of a single large cyst, or remnants of interstitium may remain to form a multiloculated space. Many bullae remain stable or increase in size slowly over many years, but they have the potential for rapid expansion, producing acute respiratory distress. An enormous single bulla may be very difficult to distinguish from a tension pneumothorax clinically or radiographically, completely compressing and obliterating the remaining normal lung.

Diffuse emphysema is characterized by a more uniform destructive process producing profound effects on pulmonary function and gas exchange. The full-blown clinical presentation includes extreme dyspnea, with a barrel chest and attenuation of intercostal and diaphragmatic musculature. Lungs with diffuse emphysema frequently contain areas of bleb or bullous disease.

Surgical Considerations

The surgeon confronts emphysema in two principal situations: in operations performed on patients with emphysema and in operations performed for emphysema. In the former category, patients with emphysema undergoing procedures with general anesthesia have an increased operative risk due to their abnormal gas exchange and are at higher risk for barotrauma during mechanical ventilation. Postoperative pulmonary toilet can be a major challenge in a patient with greatly reduced expiratory forces and chronic bronchitis whose ability to cough is compromised further by postoperative pain. Every surgeon has seen patients with marginally compensated emphysema become ventilator-dependent, with a tracheostomy and bilateral chest tubes, after routine abdominal surgery. Elective operation in such patients requires cautious assessment of risks and careful attention to preoperative pulmonary physiotherapy.

Thoracic operations designed to correct specific manifestations of emphysema carry similar risks but also offer the expectation of improvement. The history of operations for emphysema illustrates the danger of allowing surgical intuition to precede an understanding of pathophysiology. Some of the earliest procedures were designed to “make room” for the hyperinflated lung by further enlarging the barrel chest with sternotomy or chondrectomy. On observation that such procedures were ineffective at best, attempts were made to decrease lung volume by phrenic nerve destruction or thoracoplasty, with counterproductive results that would be considered predictable today.

Over the past 30 years, it has become evident that certain patients can be improved by surgical extirpation of a functionless portion of lung. Initially, surgery was only directed at areas of bullous disease compressing other relatively normal areas of lung. Resection of such bullae in selected patients appears to improve these patients. Spurred by the work of Brantigan almost 40 years ago and, more recently, by Cooper and associates, it has been identified that the hyperinflated lungs produce a mechanical dysfunction of the chest wall. *Lung-reduction surgery* for diffuse emphysema has resulted in maximizing chest wall function by decreasing the size of the lungs, thereby improving chest wall mechanics and diaphragmatic function. Short-term follow-up of such patients has resulted in a salutary effect.

In all patients, every effort is made preoperatively to maximize pulmonary function and eliminate chronic bronchial infection. Pulmonary rehabilitation programs have a decidedly beneficial effect. Unilateral disease can be approached through a posterolateral or anterolateral thoracotomy, and with increasing experience, video-assisted techniques can be used. For bilateral bullous or diffuse disease, median sternotomy or bilateral anterior thoracotomies can be used. Even in this disease, surgeons adept at video-assisted techniques have used bilateral *VATS to minimize postoperative pain*.

In performing surgery for emphysema, mechanical stapling devices are extremely helpful, often adding pledgets of bovine pericardium or artificial fibers to reinforce staple lines, because planes of division through emphysematous lungs are friable and prone to air leak. All attempts are made to eliminate any residual pleural space by careful placement of chest tubes and judicious use of volume-reducing maneuvers such as “pleural tents” or thoracoplasty.

Surgery for Bullae

Selection for operation is directed toward identifying patients in whom resection of localized bullous disease is likely to improve pulmonary function (Fig. [16-60](#)).

Ventilation-perfusion scans and fine-cut contrast-enhanced CT scans or angiograms can help define areas of “normal” lung that are compressed and non-ventilated but normally perfused (Fig. [16-61](#)) and are adjacent to large, compressing bullae. The most favorable patients are young (under 55 years of age), with unilateral disease and marked asymmetry of function, recently progressive symptoms, well-defined bullae, and evidence of crowded vessels in adjacent “normal” parenchyma. Large bullae displacing more than half the hemithorax are more likely to produce symptomatic improvement after resection than smaller bullae.

The resection is carefully tailored to preserve all adjacent vascularized “normal” lung parenchyma (Fig. [16-62](#), Fig. [16-63](#)). In carefully selected patients, resection of such large, compressing bullae can be extremely worthwhile.

Percutaneous drainage of expanding emphysematous bullae has been used effectively in patients for whom surgery is contraindicated. The emphysematous bulla is intubated with a large catheter, usually under direct vision using the techniques that have already been described in the open drainage treatment of lung abscess. A small rib resection is performed under local anesthesia, and the bulla is identified and intubated after a purse-string suture has been used to secure the catheter. Although a bronchopleural fistula results, the lung will expand and, ultimately, the fistula will close. This approach should be reserved for situations in which the risk of surgical resection is prohibitive.

Surgery for Diffuse Emphysema

Lung volume-reduction surgery (LVRS) is a relatively new approach to the treatment of severely incapacitating diffuse emphysema. The objective of this operation is to reestablish normal chest wall and diaphragmatic mechanics (Fig. [16-64](#)). Patients must be selected carefully based on their pulmonary function tests, arterial blood gases, exercise tolerance (6-min walk test), and the type and extent of bullous disease. Patients with irregular areas of bullous disease do better than those with very diffuse disease. Because most of the poorly ventilated, poorly perfused lung occurs in the apices and anterior portions of the upper lobe, these are the portions of lung that resected. Careful preoperative localization of the least perfused areas of lung is required using ventilation-perfusion and high-resolution CT scanning (Fig. [16-65](#) through [16-68](#)). Bilateral and unilateral resections have been performed. Because the procedure is new, long-term results are unknown. The improvement in pulmonary function and reduction in dyspnea last for at least 2 years. To determine the ultimate role of LVRS, a randomized national trial is under way in the United States comparing non-surgical pulmonary rehabilitation with LVRS in patients with incapacitating diffuse emphysema.

Lung Transplantation

During the past 20 years, lung transplantation has become an accepted *clinical procedure. In the management of COPD, it is reserved for patients with end-stage disease who are unsuitable for LVRS because of severe hypercarbia or other reasons. End-stage emphysema is the most common indication for unilateral or bilateral lung transplantation.*

Other forms of end-stage lung disease are indications for unilateral or bilateral lung transplantation, including primary or secondary pulmonary hypertension (often combined with septal defect corrections present), idiopathic and secondary pulmonary fibrotic diseases, and end-stage bronchiectasis (usually cystic fibrosis).

In well-selected patients, usually under age 60, the results of unilateral and bilateral transplantation are encouraging. Up to 60 percent of such individuals are alive and functioning normally after 5 years. Bilateral lung transplantation provides better pulmonary function, but unilateral lung transplantation is performed more frequently because of the lack of suitable donors. In those diseases marked by chronic pulmonary infection, however, bilateral lung transplantation is required. To improve donor availability, in certain circumstances, especially in pediatric patients, in whom a single adult lobe can replace a lung, living-related donors have been used to provide the needed organ.

Pulmonary Infections

As recently as the 1960s, thousands of patients each year in the United States required pulmonary resection for lung abscess, bronchiectasis, and chronic granulomatous disease. Since that time, effective antibiotics, aggressive methods for accurate early diagnosis, an increased standard of living, and public health programs are among the factors that have diminished the surgeon's role dramatically. Fifteen or twenty years ago it appeared that suppurative pulmonary infections would be a common surgical problem only in areas of the world with limited access to care and early treatment. Such problems are once again becoming increasingly frequent in developed countries; for example, patients immunosuppressed after transplantation or as part of cancer chemotherapy and patients with the acquired immunodeficiency syndrome (AIDS) commonly develop serious pulmonary infections.

The pathologic spectrum of "surgical" pulmonary infections is very broad, ranging from the indolent bronchiolar and peribronchial suppuration of bronchiectasis, to the contained parenchymal necrosis of lung abscess, to the pleural space infection of empyema. The clinical expression of pulmonary infection is determined by the route of inoculation, the competence of host defenses, and the specific organism(s) involved, which can include aerobic and anaerobic bacteria, viruses, and fungi, often in synergistic combinations. This broad spectrum of pathology has an equally broad spectrum of treatment in which surgical management is important.

Lung Abscess

Lung abscess is a focus of infection within the lung associated with parenchymal necrosis, usually with cavitation. Distinction between a lung abscess and a consolidated pneumonia is made as area(s) of cavitation appear on the chest x-ray and as the peripheral margins of the infection develop sharper definition. Causes of lung abscess are outlined in Table [16-11](#).

It is most commonly a complication of necrotizing pneumonia, often as a result of aspiration. Aspiration of gastric contents or infected saliva produces an infectious focus due to mixed aerobic and anaerobic bacterial contamination. Frequently concomitant aspirated particulate matter helps promote the abscess formation. Aspiration has a well-recognized association with altered states of consciousness (Fig. [16-69](#)), including alcoholic stupor, drug overdosage, head trauma, cardiopulmonary resuscitation, and after general anesthesia. Because most episodes of aspiration occur with the person supine, the abscess is characteristically located in the lung segments that are dependent in the supine position, i.e., the posterior segments of the upper lobes and the superior segments of both lower lobes. Bacteriologically, the infection usually is mixed, with anaerobic mouth organisms such as *Bacteroides* species frequently predominating.

The tissue necrosis that is the hallmark of "necrotizing" pneumonia is a function of the specific organism involved and is most prominent with *Klebsiella*, *Pseudomonas*, and other gram-negative organisms. Tissue necrosis is rare with Group B streptococcal pneumonia (*Pneumococcus*), whereas necrosis and abscess formation are frequent with *Staphylococcus aureus* and Group A streptococci.

Staphylococcal lung abscess is most common in the first year of life and has characteristic pathology, most frequently with pyopneumothorax and pneumatoceles. The latter are large cystic spaces, typically not containing true pus, that are thought to result from air trapping distal to bronchiolar obstruction. Staphylococcal lung abscess in infancy also is characterized clinically by a remarkable tendency to resolve completely with antibiotics alone, even when temporary drainage of the pleural space has been required.

Establishment of a gram-negative pneumonia begins with major alteration in the bacteriologic composition of upper respiratory flora. The defense mechanisms that reduce gram-negative organisms to transient visitors in normal individuals are seriously impaired in many hospitalized patients (nosocomial infections). For example, experiments in mice suggest that an *Escherichia coli* peritonitis interferes with recruitment of polymorphonuclear leukocytes in the lung, increasing susceptibility to gram-negative (*Pseudomonas*) but not to gram-positive infections. Over half the pneumonias seen in seriously ill hospitalized patients are gram-negative, and a significant proportion of such patients manifest a necrotizing infection leading to lung abscess formation.

Systemic sepsis can produce multiple bilateral foci of parenchymal infection that are radiographically discrete and are most frequently caused by *Staphylococcus* and other gram-positive organisms. One or more of the foci can become an abscess, although most resolve without a trace. Unlike staphylococcal pneumonia of tracheobronchial origin, hematogenous infection does not form pneumatoceles and can be seen in septic patients of any age. Lung abscess developing in a pulmonary infarction after pulmonary embolus is most frequently a special case of hematogenous infection seeding an area of devitalized or injured tissue.

A cavitory necrotizing infection also can form distal to an obstructive lung carcinoma or intrabronchial foreign body (Fig. [16-70](#)), a reminder that bronchoscopy is an important diagnostic maneuver. Not infrequently, a carcinoma becomes visible as the distal infection responds to antibiotic treatment.

In certain parts of the world, parasitic infection is a common cause of lung abscess. *Entamoeba histolytica* (amebiasis) can produce a lung abscess by hematogenous spread or by direct extension from the liver, in which case it is almost always associated with an empyema. Metronidazole usually is effective treatment, and operative intervention rarely is required. Hydatid infection (*Echinococcus* species) is associated with lung abscess in some cases when cysts are secondarily infected (Fig. [16-71](#)). In this disease, intraabdominal pathology (liver cysts) is much more prominent. Treatment with oral mebendazole or albendazole has been moderately successful, but resection frequently has been required.

Clinical Manifestations

The clinical presentation of lung abscess is relatively uniform. The patient appears ill, is likely to be febrile, and often will describe recent onset of copious foul sputum production, reflecting decompression of the abscess into the airway. Whether the initial infection originated from the airway or the bloodstream, the necrotizing process finds its way into the tracheobronchial tree, a development heralded radiographically by the appearance of cavitation on chest x-ray. Because of the necrotizing, erosive nature of the communication with the airways, hemoptysis can occur and can be massive, or the abscess can burst into the pleural cavity (pyopneumothorax). In contrast to pneumonia, dyspnea is not a prominent symptom. Auscultatory findings, if any, are more likely to be attributable to coexistence of pneumonia, a pleural effusion, or empyema. In the acute phase of abscess development, constitutional symptoms overlap with those of acute pneumonia. As the process becomes more chronic, symptoms frequently ameliorate as the abscess becomes walled off.

In a febrile patient with copious production of foul sputum, the differential diagnosis can be reduced to three entities: lung abscess, bronchiectasis, and cavitating carcinoma. Chronic copious sputum production is most characteristic of bronchiectasis; the other two entities have acute or episodic sputum production. A dramatic febrile illness is most consistent with lung abscess, reflecting its origins in a necrotizing pneumonia, although bronchiectasis and carcinoma can have febrile episodes associated with exacerbations of the inflammatory process surrounding the primary pathology. A chest x-ray showing a well-delineated cavity with an air-fluid level confirms the diagnosis but usually is of little help in distinguishing a cavitating carcinoma from lung abscess, for which bronchoscopy and biopsy are essential.

Treatment

The options for treatment of lung abscess are outlined in Table [16-12](#). Primary treatment consists of antibiotics and drainage. Antibiotics are administered intravenously in high doses based on the sensitivities of the infecting organism. In the most fortunate patients, spontaneous drainage by expectoration is adequate. Frequently, drainage must be achieved by other means, the least invasive of which is bronchoscopic aspiration. Responding patients require at least 8 weeks of antibiotics. Such methods are successful in more than 75 percent of all patients with lung abscess (see Fig. [16-69](#)), although convalescence can be prolonged. In one representative nonoperative series, the average duration of therapy was 4 months. Numerous surgical series have demonstrated that convalescence can be shortened dramatically in properly selected patients.

When antibiotics and internal drainage are ineffective or in very large abscesses (>5 cm), surgical intervention is indicated. There are three options for operative treatment: (1) tube pneumonostomy (catheter drainage), (2) pneumonotomy, and (3) pulmonary resection. Before antibiotic treatment, tube pneumonostomy and pneumonotomy depended on the development of a secure pleural symphysis between the parietal pleura and the visceral pleural surface closest to the abscess cavity. Both techniques established external drainage through the area of symphysis to avoid spilling a contained infection into the free pleural space.

Percutaneous catheter drainage usually is adequate and is having a resurgence in popularity, as recent reports indicate (Fig. [16-72](#)). The technique involves insertion of a relatively small percutaneous drainage tube that usually is connected to a water seal with or without suction. Tube drainage is theoretically limited by the viscosity and particulate content of the pus and by the presence of a foreign body. As reports from vanSonnenberg and associates and Yang and associates illustrate, fluoroscopic, CT, and ultrasound guidance can be used to localize the abscess and accomplish effective drainage in a single stage. With any form of external drainage, the possibility of erosive injury to large-caliber bronchioles and vascular structures that lie close to the soft inner surface of the abscess cavity imposes a theoretical risk of bronchopleurocutaneous fistula or hemorrhage. Most abscesses are more peripheral than central, which reduces this risk, and peripheral location helps promote the kind of aggressive pleural symphysis that favors external drainage when necessary.

Pneumonotomy is almost never used today but historically avoided the risk associated with an indwelling foreign body and was favored for the most organized cavities containing large volumes of especially viscid pus mixed with large amounts of necrotic debris. Drainage was achieved through a generous incision with rib resection. If inspection of the parietal pleura suggests that adequate symphysis had not taken place, the wound was packed open without opening the pleura. After several days, this resulted in an exuberant pleural reaction and symphysis, allowing safe access to the abscess cavity. This technique is now reserved for the rare patient who fails catheter drainage and cannot tolerate a resection.

The most definitive operative treatment for lung abscess is pulmonary resection. Standard indications for resection are failure of simpler approaches, serious hemorrhage, and suspicion of associated carcinoma. Lobectomy usually is required. Resection has the advantage of removing the entire infection promptly and is less hazardous than external drainage when the abscess is very large or centrally located. On the other hand, resection does not eliminate the risk of pleural space contamination. It can be technically difficult to remove a thin-walled abscess presenting close to the visceral pleura without spillage, and empyema after lobectomy is far more serious than primary empyema. Anesthetic technique and patient positioning are critical to prevent spillage of pus through the tracheobronchial tree across to the dependent lung. In the past, the patient was often positioned prone or supine. Currently, double-lumen endotracheal tubes, which can effectively isolate the two sides, generally allow use of the lateral decubitus position. Safety can be further augmented by frequent intraoperative bronchoscopy performed through the endotracheal tube, providing accurate irrigation and aspiration of the airways.

Life-threatening hemorrhage requires prompt resection when the bleeding site is unequivocally localized by bronchoscopy. This complication most frequently arises in patients least able to tolerate thoracotomy and who often are bleeding because of coagulopathy secondary to sepsis and multiple organ failure. Acceptable temporizing measures designed primarily to protect the uninvolved lung include insertion of a double-lumen endotracheal tube, placement of a bronchial blocker on the affected side, and aggressive toilet of the unaffected side with rigid or flexible bronchoscopy. Bronchial artery embolization is worth consideration but is limited by the rich collateral circulation of the lung.

Opportunistic Infections

Cancer chemotherapy and organ transplantation are creating a steadily increasing population of immunologically compromised individuals who would not have been alive 20 years

ago. Patients nursed through major trauma or complications of surgery exhibit a characteristic spectrum of immunologic compromise. Recently, AIDS has become epidemic. All categories of immunocompromised patients share a predilection for pulmonary infections caused not only by familiar agents but also by pathogens rarely seen in healthy individuals. Pulmonary infections are the most common infections seen in immunocompromised patients, perhaps reflecting the fact that the lung is the only organ capable of presenting pathogens to a delicate nonsquamous epithelium many times each minute.

AIDS is the most relevant model of pulmonary infection in the immunocompromised host. AIDS was first described in 1981 in a group of homosexual men with *Pneumocystis carinii* pneumonia and mucosal candidiasis. The causative agent, a retrovirus named the *human immunodeficiency virus* (HIV), was identified in 1983. Although improved medical treatment has lengthened the average survival time after diagnosis, mortality is high. The disease has escaped the confines of the originally recognized risk groups (homosexual males and intravenous drug abusers) to become a venereal scourge threatening the general population.

Numerous examples of transmission through blood transfusion during the 1980s accelerated development of techniques for blood conservation, although blood donors screened using available serologic testing for the presence of HIV infection pose a very small risk (about 1 in 100,000 per unit of blood).

Opportunistic infections and Kaposi's sarcoma are hallmarks of active disease. *P. carinii*, the most common pathogen, is present in 50 to 60 percent of all patients. This is a protozoan originally thought to be a trypanosome, and it was not recognized in human beings until 1938. Characteristic interstitial pneumonitis thought to be caused by *Pneumocystis* was recognized in epidemics among undernourished infants and among the very elderly. In the United States, *Pneumocystis* emerged as an infection confined to iatrogenically immunosuppressed patients on chemotherapy or after transplantation until its dominant role as a pulmonary pathogen in AIDS was recognized in 1981. The characteristic clinical presentation consists of diffuse interstitial infiltrates on chest x-ray, dyspnea, and an increased a-aO₂ gradient.

Trimethoprim-sulfasoxazole (TMP-SFX) is effective treatment in most cases and also is used as prophylaxis. Pentamidine is equally effective but usually is reserved for resistant cases or patients allergic to TMP-SFX. Medical treatment and medical prophylaxis with TMP-SFX or aerosolized pentamidine are effective in transplant recipients in part because the level of immunosuppression can be modulated. Medical treatment is considerably less successful in AIDS patients, with mortality approaching 50 percent.

The surgeon's role in the management of immunocompromised patients with pulmonary infection can be diagnostic and therapeutic. Transbronchial biopsy combined with bronchoalveolar lavage can establish a specific infectious diagnosis, which has markedly reduced the need for open lung biopsy. In a report by Bonfils-Roberts and associates, the need for open biopsy in AIDS patients dropped from 28 percent during 1983 to 0.7 percent in 1987, and a successful change in therapy based on the results of open biopsy was possible in only 1 of 66 patients biopsied (1.5 percent). Open lung biopsy and thoracoscopic biopsy are reserved for confusing mixed infections with inadequate response to empirical treatment.

In patients with AIDS, the most frequent therapeutic procedure is insertion of a chest tube for control of a pneumothorax, which frequently complicates this infection and may be difficult to control. Several tubes usually are required (Fig. 16-73), and on occasion, thoracotomy or thoracoscopy for direct control of the leak and pleural abrasion or pleurectomy are justified (Fig. 16-74). Gerein and associates illustrate that satisfactory palliation can be achieved with operation, but the overall prognosis is very poor and is dictated by the activity of the underlying lung disease rather than by the surgical treatment.

Operative therapy in immunocompromised patients without AIDS can be applied with greater optimism. The spectrum of infections includes *Pneumocystis* and the other organisms seen in AIDS but also includes a greater number of infections with more common pyogenic bacteria and *Aspergillus*. An open lung biopsy is required if other diagnostic attempts fail. Empyemas and intraparenchymal infections should be approached aggressively using indications for operation that are the same as those applied to normal hosts with similar infections. Although mortality and morbidity generally have been higher in immunosuppressed patients, it has been possible to perform major pulmonary resection, thoracoplasty, and decortication with excellent long-term results (Fig. 16-75).

Bronchiectasis

Bronchiectasis is characterized by dilatation of peripheral bronchi, recurring pulmonary infections, and a chronic course. Second- to fourth-order segmental bronchi in the basal segments of the lower lobes, the right middle lobe, and the lingula are involved most frequently. Isolated upper lobe involvement is very rare and usually is associated with tuberculosis or bronchial obstruction. Approximately one-third of bronchiectasis is unilobar, one-third is unilateral bilobar, and one-third is bilateral. Although the bronchial mucosa usually remains intact and is lined with pseudostratified columnar epithelium, the bronchi are filled with mucus, pus, and an occasional broncholith resulting in destruction and dilatation of the underlying bronchial wall. The changes vary in degree from mild tubular dilatation to cystic or saccular changes with almost unrecognizable gross architecture (Fig. 16-76). Collateral ventilation is only partially effective in maintaining expansion of alveoli distal to chronically obstructed segments. Hypertrophy of bronchial arteries occurs as part of the inflammatory process, producing a locally extensive precapillary left-to-right shunt into the pulmonary venous system and laying the substrate for erosive hemorrhage and hemoptysis.

In most cases, the disease has to be considered idiopathic, although, in the past, it was considered often to be due to suppurative diseases in infancy (e.g., whooping cough). It is occasionally associated with chronic bronchial obstruction by tumor, foreign body, or bronchostenosis. Immunodeficiency diseases have been implicated in certain instances. Kartagener's syndrome (situs inversus, pansinusitis, bronchiectasis) is a rare congenital disorder possibly related to a defect in ciliary structure and function. In many patients afflicted during childhood, a history of recurrent bronchitis and bronchopneumonia, presumed to be viral, is present. Progressive bronchiectasis is a hallmark of cystic fibrosis with progressive respiratory failure leading to death.

Clinical Manifestations

The clinical picture is dominated by cough and production of mucopurulent sputum, varying in volume from scant to as much as 500 to 1000 mL/day. Fever usually is low-grade with acute exacerbations. The systemic effects of chronic infectious illness can dominate the picture to produce a broad spectrum of constitutional symptoms, weight loss, and retarded development. The disease can occur at any age and is seen equally in both sexes. In the United States, an unusually high incidence has been identified in Alaskan native children, many of whom have required aggressive surgical treatment (Fig. 16-77). Dyspnea is not common except in diffuse disease or in progressive disease with cor pulmonale. Hemoptysis occurs in about 50 percent of patients, usually late in the disease, and is only major in about 10 percent. Serious hemoptysis is more frequent in association with lung abscess than with bronchiectasis.

Physical findings are dominated by stigmata of chronic disease and can include digital clubbing and pulmonary osteoarthropathy, even though cyanosis is rare. Auscultatory findings are primarily related to the presence or absence of associated pneumonitis and to the effectiveness of pulmonary toilet. A history of chronic profuse sputum production strongly suggests the diagnosis, and in children, associations such as cystic fibrosis, immune deficiency, and a α_1 -antitrypsin deficiency should be ruled out. Chest x-rays are nonspecific but may show linear streaking and atelectasis in the affected areas. Bronchiectasis is one possible explanation for the "middle-lobe syndrome," which is isolated middle-lobe atelectasis (Fig. 16-78).

Diagnosis

Bronchoscopy is done to exclude the rare case of correctable bronchial obstruction or carcinoma, to obtain accurate cultures, and to aspirate the tracheobronchial tree. Careful bronchoscopic pulmonary toilet can achieve surprisingly durable symptomatic benefit. Contrast bronchography used to be the definitive test in defining the anatomy when resection was contemplated but now has been replaced by CT scanning. A report by Munro and associates compared thin-section (3-mm) CT scanning with bronchography and found equivalent accuracy for the two techniques. With modern computer-generated reconstruction techniques, the CT scan can simulate a bronchogram.

Treatment

The majority of patients with bronchiectasis do not require operative treatment. Postural drainage and chest physical therapy (see Fig. 16-79) minimize retention of purulent sputum, and antibiotic treatment of all episodes of pneumonitis should be pursued indefinitely. When debilitating effects of chronic infection become prominent and surgery is contemplated, the anatomy should be defined carefully with CT scan before resection is planned. When extensive saccular disease is confined to one lobe or segment in a sufficiently symptomatic patient, resection is a clear choice. In children, interference with growth is often the sign of debility. Frequent hemoptysis associated with localized disease deserves operation. Patients with diffuse bilateral disease, of which cystic fibrosis is the best example, rarely benefit from resection and should be considered for lung transplantation as they approach end-stage disease.

Before resection, all patients should receive a maximal effort to reduce sputum volume and infection. Care must be taken during anesthesia to prevent spillage of infected secretions into uninvolved segments. A double-lumen endotracheal tube is used to protect the contralateral lung. As with operation for lung abscess, the risk of postoperative empyema is higher than for "clean" surgery, and considerable effort must be expended in postoperative pulmonary toilet to ensure that residual infected secretions are expectorated. The operative strategy is to remove as little normal lung as possible without entering the central focus of infection. This usually requires segmentectomy or lobectomy and depends on an accurate preoperative assessment of the diseased segments. Pneumonectomy is rarely indicated in this disease.

As with many clinical situations in which choice of therapy is based largely on quality-of-life decisions, there are no prospective, controlled series to compare relative benefits of medical versus surgical treatment. In general, isolated areas of bronchiectasis do well after resection. In a Turkish series of 487 patients treated over a 12-year period, including 190 treated with pneumonectomy, mortality was 3.5 percent, and 71 percent were asymptomatic (follow-up 4 months to 10 years). Surprisingly good quality of life has been described by Laros and associates from the Netherlands in 30 patients treated with unusually extensive bilateral resections (11 to 13 segments) and followed for 30 years. As a comparison, other authors have estimated that 70 percent of patients treated medically develop persistent or progressive symptoms.

Tuberculosis

Sanskrit written in 6000 b.c. refers to tuberculosis as the king of diseases. Tuberculosis, then called *phthisis*, was well known to Hippocrates. A generation beginning to face an uncertain battle with the AIDS complex would do well to recall that pulmonary tuberculosis was epidemic in Europe during the eighteenth and nineteenth centuries and took an extraordinary toll on young adults in the prime of life, much like the devastation of AIDS today. In the United States in the 1940s, pulmonary resection for tuberculosis carried a mortality rate of about 25 percent, and effective chemotherapy did not exist until streptomycin was discovered in 1944. Tuberculosis remained epidemic in parts of the United States (Alaska) as recently as the early 1960s. Until recently, the modern treatment of tuberculosis was largely reduced to a straightforward recipe of medical therapy using combinations of antibiotics.

The past decade has seen a recrudescence of tuberculosis as a significant public health concern. Noncompliance with drug therapy among those populations at particular risk, patients in low socioeconomic strata and drug addicts, has given rise to a more virulent multiple-drug-resistant (MDR) organism. The expanded population of immunocompromised patients, whether from AIDS or from posttransplantation drug therapy, has increased the pool of the highly susceptible. Many authorities are anticipating a return to the need for relatively long-term isolation of the MDR infected patient with active disease and a resurrection of the challenging, if nearly forgotten, surgical techniques characteristic of the

pre-drug treatment era.

Pathophysiology and Clinical Manifestations

A pulmonary infection with *Mycobacterium tuberculosis* behaves like a lung abscess, with notable differences based primarily on the peculiar growth characteristics of the organism and the nature of the host response. The primary infection usually is asymptomatic and “heals” spontaneously. The disease usually becomes clinically apparent when a previously acquired and quiescent infection is reactivated, usually in the apical or posterior segments of an upper lobe or in the superior segment of a lower lobe. In an immunocompetent host, the characteristic cycle of caseous necrosis and scar formation (healed primary infection) eventually produces what amounts to a chronic tuberculous lung abscess. Just as with pyogenic lung abscess, the smoldering central focus of infection tends to find communication with the tracheobronchial tree, providing a route for drainage and expectoration of purulent sputum loaded with tubercle bacilli and allowing ingress of air to produce cavitation. The ultimate extent of infection is determined by the size of the inoculum, the immune competence of the host, and the success of antituberculous drugs. Rapid progression can produce a tuberculous empyema surrounding a destroyed lung. If growth of the bacillus is controlled, the cavity may collapse and obliterate or may remain open indefinitely. Such cavities (“open negative”) are no longer sites of tuberculous infection but remain potential sites for secondary infection, the classic example of which is an *Aspergillus* “fungus ball” (mycetoma).

As with lung abscess and bronchiectasis, the intense inflammatory process in the periphery of a cavity tends to promote hypertrophy of bronchial arterial and pulmonary arterial branches. These may be eroded by the necrotizing process in the center of the cavity to produce hemoptysis, which can be life-threatening. The vessel responsible is most frequently a dilated bronchial arterial branch, referred to as a *Rasmussen aneurysm*. The management of massive tracheobronchial hemorrhage has been discussed in connection with lung abscess. Because a tuberculous cavity is likely to be chronic, when major hemoptysis occurs, the vessel involved is likely to be larger than that seen in a pyogenic lung abscess, and emergency pulmonary resection often is necessary.

Occasionally, the most intense inflammatory process is confined to regional lymph nodes, which can enlarge enough to produce bronchial stenosis and distal atelectasis, one cause of the middle-lobe syndrome. If this occurs distal to an evolving cavity, rapid expansion can occur as a result of air trapping to produce a “tension cavity.” The responsible nodes are choked with caseating granulomata. Discrete bronchial stenosis also can be seen without evidence of extrinsic compression, in which case it usually is ascribed to an intense tuberculous bronchitis occurring in a segment draining an active parenchymal infection.

In a typical case of pulmonary tuberculosis, the diagnosis is easily made on the basis of characteristic cavitary changes in an upper lobe on chest x-ray occurring in a patient with a positive purified protein derivative (PPD) test whose sputum has grown *M. tuberculosis*. A suggestive x-ray without positive cultures does not confirm the diagnosis, and a negative PPD test does not rule out active tuberculosis. Definitive diagnosis rests on growth of the organism in culture (Fig. [16-80](#)). A positive acid-fast stain provides a highly suggestive provisional diagnosis but cannot discriminate completely between *Nocardia* and *M. tuberculosis*.

Culture also allows identification of “atypical” mycobacteria, which deserve special mention. Clinically and pathologically, infection with an atypical *Mycobacterium* can be indistinguishable from infection with *M. tuberculosis*. Resistance to multiple antituberculous drugs is common among the atypical mycobacteria, and chances for a nonoperative cure depend on accurate assessment of appropriate medical therapy. Culture becomes important for identification of a specific species and for characterization of its drug sensitivities. Even with successful medical treatment, the use of three or four drugs for 2 to 4 years can be anticipated. Because of drug resistance, a higher proportion of atypical than of typical mycobacterial pulmonary infections require operation. *M. kansasii* and *M. avium-intracellulare* are the species most often associated with pulmonary disease (Table [16-13](#)).

Treatment

Operative treatment of tuberculosis is ordinarily an elective procedure performed after a period of treatment with antituberculous drugs. Emergency operation is only required for life-threatening hemorrhage or massive air leak from a tension pneumothorax. In these cases, the procedure of choice is almost always lobectomy or segmentectomy. The technical precautions necessary to minimize the risk of tracheobronchial or pleural spread of infection are the same as those discussed with regard to resection for lung abscess. Other indications for resection include (1) extensive pulmonary destruction with bronchopleural fistula and empyema, (2) persistently active disease with drug-resistant organisms, (3) inability to rule out coexisting bronchogenic carcinoma, and (4) posttuberculous bronchostenosis with recurrent nontuberculous infection. There has always been some controversy regarding resection of (5) an “open negative” cavity. In these patients with negative sputum, the goal of treatment is to ensure that the cavity itself is made truly negative. There is considerable evidence that well-managed long-term medical therapy can produce results at least as good as those following resection. Partial adherence to a drug regimen can encourage emergence of resistant strains, so noncompliant patients are poor candidates for medical treatment of large residual cavities and should have a resection. This discussion applies equally to typical and atypical Mycobacterial infections.

An occasional patient will have persistent active infection but such limited ventilatory reserve that resection would not be tolerated. Under these circumstances, lung-collapse therapy (e.g., thoracoplasty) is a valid alternative. Thoracoplasty is designed to collapse the affected portion of lung to promote healing, which can be remarkably effective. Collapse is achieved without entering the pleural space by performing an extrapleural resection of the first five ribs, followed in 10 to 14 days by resection of the sixth and seventh ribs. Although this procedure has its origins in the treatment of tuberculosis, the principle of chest wall collapse occasionally is used to obliterate the pleural space after a pulmonary resection as well, especially in managing tuberculosis.

Chronic Granulomatous Infections

By about 1900 all the major fungal pathogens had been isolated and named, but recognition of their role in disease underwent a very characteristic evolution. They were initially thought to be rare and fatal infections, but as diagnostic acumen increased, it became clear that mild asymptomatic infection was far more common. Now the pendulum is beginning to swing back somewhat, as fungal infections find their way into our enlarging reservoir of iatrogenically immunocompromised patients. Features common to all fungal infections include protean manifestations in compromised hosts, sensitivity to amphotericin B, and mimicry of carcinoma and tuberculosis. Amphotericin B is a very important drug that has rendered most fungal infections medically treatable, but it is also a highly toxic drug that cannot be administered as casually as antituberculous drugs are given. Certain bacilli (e.g., *Actinomyces* and *Nocardia*) also produce granulomatous infections.

Actinomycosis

For many years the *Actinomyces* were misclassified as fungi because they form branching hyphae and spores. Only in the past 20 years has it been recognized that the *Actinomyces* are bacteria. This taxonomic distinction has therapeutic relevance because the pathogens in this group are highly sensitive to penicillin and sulfonamides but not to amphotericin B.

Actinomycosis is caused by *A. israelii*, an anaerobic filamentous bacillus that is not found in nature but is a normal commensal inhabitant of the oral cavity and tonsillar crypts. It is not known what causes this organism to become an invasive pathogen, but in about three-fourths of cases some kind of predisposing factor can be identified, such as immunosuppression or breakdown of local tissue barriers (i.e., tooth extraction). About 60 percent of cases are cervicofacial, and only 15 percent are thoracic. Thoracic infection is presumed to result from aspiration of infected secretions. Classically, the disease is characterized by suppuration, abscess and sinus tract formation, and relentless invasion with complete disregard for tissue planes. Multiple sinus tracts are observed today in only one-third of cases, and the lesion is seen more commonly as a parenchymal process mimicking bronchogenic carcinoma. When involvement of ribs or extension into mediastinal structures is seen, without a cancer diagnosis, actinomycosis must be high on the list of possible causes (Fig. [16-81](#)).

Expectorated sputum, material from a sinus tract, and biopsy material can demonstrate sulfur granules, which are yellow-brown clusters of microcolonies. This finding is highly suggestive, but since *Nocardia asteroides*, certain fungi, and *S. aureus* are also capable of producing clumps of material resembling sulfur granules, diagnostic confirmation rests on identification of the bacillus within the granules, for which special stains are required. Cultures are positive in only about one-fourth of patients.

The organism is sensitive to penicillin, although large doses are required to penetrate the dense colonies, and medical treatment is most often quite successful. The surgical strategy is to make an accurate diagnosis at an early stage of disease. Because the disease can have gross resemblance to fungal infections and to carcinoma, and because tissue stains are essential to the diagnosis, operation frequently is required to obtain adequate biopsy material. Successful diagnosis is followed by high-dose intravenous penicillin and a long subsequent course of oral administration. Resection rarely should be necessary except in unusually advanced presentations with an inadequate response to penicillin.

Nocardiosis

Nocardiosis is caused by *N. asteroides*, an aerobic acid-fast filamentous bacillus widely distributed in nature as a saprophyte in soil and domestic animals. It is a rare pathogen except in an immunocompromised host and is most often manifested as a thoracic infection, beginning as a pneumonic process difficult to distinguish grossly from tuberculosis, fungal infections, and carcinoma. It also can closely mimic actinomycosis, with chest wall involvement, sinus tract formation, and production of sulfur granules. The acute infection is often much more aggressive than actinomycosis, with extensive pulmonic necrosis and abscess formation and metastatic dissemination to the central nervous system and elsewhere.

Nocardia is relatively easy to culture and to identify with standard stains, so the diagnosis frequently can be made by brush or needle biopsy and even from expectorated sputum. The organism is sensitive to sulfonamides, which usually provide successful therapy. Other drugs can be added in poorly responsive cases (trimethoprim-sulfamethoxazole, minocycline) with good results, and surgery is purely adjunctive in the majority of patients. Pulmonary resection, drainage of empyema, and similar procedures can be performed safely when necessary.

Fungal Infections Histoplasmosis

Histoplasmosis is the most common systemic fungal infection in the United States. *Histoplasma capsulatum* is a dimorphic fungus common in the great river valleys of the Midwest (e.g., Ohio and Mississippi), where it lives in mycelial form in soil, decaying organic material, and guano. It assumes yeast form in the cytoplasm of pulmonary alveoli after inhalation. It is extremely common in endemic areas as an asymptomatic infection; the severity of disease is determined by the size of the inoculum and the immune competence of the host. Release of a large inoculum can produce outbreaks of acute pneumonic illness in normal hosts and usually occurs after an environmental disruption such as excavation or demolition. Such infections ordinarily resolve without specific treatment but not before widespread lymphatic and hematogenous dissemination has occurred, apparent later as scattered calcific nodules in the lungs, mediastinum, spleen, and liver. In symptomatic patients, the disease can take many forms and often is distinguishable from tuberculosis only by culture. Skin testing reagents are available but are not as reliable as purified protein derivative (PPD). Serologic diagnosis is also available but is no more reliable and can be misleading if obtained following skin testing. As with tuberculosis, definitive diagnosis requires growth of the organism from pathologic specimens.

Amphotericin B is effective treatment in the majority of patients and is always the treatment of choice in a serious illness once the diagnosis is made. Most infections are asymptomatic or moderately symptomatic and self-limited, and chemotherapy is not recommended for skin test conversion as it is in tuberculosis.

Operation is applied much as it is in tuberculosis. Cavitory disease is common, and in a recent large series from an endemic area (Tennessee), this was the most frequent indication for resection. Large, thick-walled cavities that have failed to improve after a course of amphotericin B are likely to progress and can be resected with low morbidity and mortality. Another frequent indication for operative intervention is an inability to establish a definitive diagnosis, especially when the lesion presents as a solitary pulmonary nodule grossly consistent with carcinoma (Fig. [16-82](#)). As in tuberculosis, hemoptysis can require operation, and bronchostenosis produced by extrinsic nodal compression can require resection.

The lymphogenous phase of *Histoplasma* dissemination leads to remarkable nodal enlargement in some patients, producing symptoms related to compression of mediastinal structures and a radiographic appearance resembling mediastinal malignancies. Mediastinal involvement also can produce a sclerosing mediastinitis with obstruction of the superior vena cava, pulmonary arteries or veins, esophagus, or tracheobronchial tree. These may require surgical correction with autogenous venous bypass grafting to relieve symptoms of superior vena cava syndrome. The pathophysiology of this desmoplastic response to infection is not completely understood but is an idiosyncratic reaction.

Coccidiomycosis

Coccidiomycosis is the second most common fungal infection encountered in the United States. *Coccidioides immitis* is a dimorphic fungus found in mycelial form as a saprophyte in the arid soil of the American Southwest. Arthrospores released by the hyphae are inhaled and initiate the parasitic phase by becoming spherules that release infective endospores. In the normal host, most infections are asymptomatic, but some will manifest “valley fever,” essentially a mild pneumonic form of the illness. The organism is not difficult to recover from sputum or pathologic specimens. The skin test and serologic titers are almost always positive in active disease but are more ambiguous in the more chronic and indolent forms of infection. Except for a propensity to form thin-walled cavities, the spectrum of gross and microscopic pathology is similar to that seen in histoplasmosis, tuberculosis, and other fungal infections. In most instances, spontaneous resolution occurs.

For patients with symptomatic illness requiring treatment, amphotericin B is the primary therapy. As with histoplasmosis, the lungs provide an effective barrier against serious systemic illness in most patients, and specific treatment is frequently not required. Aggressive necrotizing pulmonary infection and disseminated disease usually are seen in immunocompromised hosts and require early and aggressive medical treatment.

Indications for operation are virtually identical to those applied to histoplasmosis. Resection of cavitory disease and resection for definitive diagnosis of a solitary pulmonary nodule are performed most frequently. Specific indications in cavitory disease include progressive enlargement, hemoptysis, rupture, and secondary infection.

Blastomycosis

Blastomycosis is caused by *Blastomyces dermatitidis*, a round, single budding yeast endemic in the southeastern United States and other scattered areas. Although there is a common cutaneous form, the disease always is acquired through aspiration of spores into the lungs, where it can assume a variety of appearances—pneumonic infiltrates, cavitation, solitary granulomatous nodules, and disseminated disease. The cutaneous form is characterized by crusty, ulcerative lesions from the margins of which the organism can be cultured readily. Cutaneous and pulmonary infection can occur together, and the cutaneous form has a better prognosis. Diagnosis rests on identification of the organism, which can be done with a sputum Papanicolaou stain.

Although it can mimic tuberculosis and other fungal infections, in endemic areas it most frequently mimics bronchogenic carcinoma, and resection frequently is required if a definitive diagnosis cannot be established (Fig. [16-83](#)). Aggressive infection is treated with amphotericin B. Cutaneous infection and mild pulmonary infection also respond well to 2-hydroxystilbamadine. As with other fungal infections, treatment with amphotericin B often can be avoided in mild presentations of illness, especially in normal hosts during outbreaks in endemic areas.

Aspergillosis

Aspergillus is a filamentous fungus with septate hyphae that is ubiquitous in nature. Inhalation of spores from *A. fumigatus*, *A. niger*, and other species initiates infection in susceptible individuals. Aspergillosis presents in three forms: allergic bronchopulmonary, saprophytic, and invasive. The first is characterized by asthmatic symptoms resulting from host response to fungus in the airways and is of little surgical importance other than diagnosis. The invasive form usually is seen in the immunocompromised host, can involve any organ system, and is almost always fatal. Robinson and associates and others have advocated early resection if disease is limited to one lobe with some encouraging results. Surgical attention focuses mainly on the saprophytic form, produced by colonization of a preexisting pulmonary cavity (an aspergilloma, mycetoma, or “fungus ball”). Hemorrhage can occur, requiring surgical intervention. On chest x-ray the aspergilloma appears as a solid, rounded mass within a cavity, surrounded by a crescent of air between the fungus and the cavity wall (Fig. [16-84](#)). *Aspergillus* precipitins are almost always detectable in patients with aspergilloma. Skin testing is available but is positive in only 30 to 75 percent of patients. The value of sputum cultures has been debated, but recent evidence suggests that two or more positive cultures carry excellent specificity and sensitivity.

For disseminated disease, amphotericin B is the mainstay of therapy. Penetration of the drug into a cavity containing an aspergilloma is very poor, so resection is considered the treatment of choice for a significant aspergilloma. Excellent results have been obtained with repeated intracavitary instillation of amphotericin B using fluoroscopic guidance. Operative treatment most frequently requires lobectomy, segmentectomy, or pneumonectomy. Percutaneous drainage or cavernostomy (open drainage through the chest wall) is occasionally performed in patients with poor ventilatory reserve and can be augmented by intracavitary instillation of antifungal agents. Repeated percutaneous instillations of amphotericin have been successful definitive therapy. Operation is most often justified as prevention for hemoptysis, which occurs in 50 to 83 percent of patients and can be life-threatening in a fraction of that total. Even so, operation remains somewhat controversial because it is associated with considerable mortality and morbidity. This is related to the poor health of most susceptible hosts and the technical difficulty of resection through dense inflammatory tissue. In a recent series from the Mayo Clinic, underlying lung disease or immunologic risk factors were present in 92 percent of patients, and complications occurred in 78 percent of patients with complex aspergillomas. In this series and others, operative mortality has been 5 to 10 percent, and complications in “simple” aspergilloma resection have ranged from 25 to 34 percent. Nonetheless, in the Mayo Clinic series the late results were excellent in about 75 percent of patients. It is probably prudent to observe small, asymptomatic aspergillomas, but in most cases, if intracavitary treatment fails, resection should be performed, accepting the increased risk in favor of potential benefits.

Cryptococcosis

Cryptococcosis is caused by *Cryptococcus neoformans*, a round, budding yeast found in soil and pigeon droppings. Infection occurs through inhalation of the organism and in most individuals produces a comparatively benign bronchopulmonary illness. The chief radiologic finding is a granulomatous complex with hilar node involvement, indistinguishable from the Ghon complex of tuberculosis. It is rarely of surgical significance except in the compromised host, when the entire spectrum of fungal pulmonary pathology seen in more inherently virulent infections can be seen on occasion (see Fig. [16-84](#)). The best known disseminated manifestation is meningitis. Infection can be controlled in many cases with amphotericin B and 5-fluorocytosine, even with meningeal involvement.

Innumerable other fungi can be associated with pulmonary disease in human beings, but as the list diverges further and further from the recognized pathogens, it becomes increasingly confined to immunocompromised hosts. *Candida*, mucormycosis, sporotrichosis, monospirosis, *Torulopsis*, even *Penicillium*—all have been described. Surgical treatment is rarely indicated and seldom definitive.

Lung Tumors

Primary Carcinoma of the Lung

Epidemiology

Cigarette smoking is the predominant factor in the cause of lung cancer. Each year in the United States there are 450,000 excess and preventable smoking-related deaths. Approximately 170,000 of these deaths are a result of lung cancer. Many industrial chemicals (e.g., nickel, chromium, uranium, and asbestos) are co-carcinogens.

From a trivial health problem at the beginning of this century and a minor one by 1930 (a death rate of 5 per 100,000), lung cancer has now become the main cancer killer in both men (70 per 100,000) and women (40 per 100,000). Reflecting the changing smoking habits in women that have occurred since the early 1950s and the long exposure required for the development of this malignancy, the rate in women is rising at an alarming pace (Fig. [16-85 A, B](#)). The histologic changes in the bronchial mucosa occur gradually over many years, evolving from metaplasia through dysplasia to carcinoma. Those who stop smoking reduce, but never eliminate, their risk. It is vital that primary care physicians educate patients and their families about the importance of smoking cessation and a smoke-free environment because even “passive” smoking has been implicated as an etiologic agent.

Pathology

Primary bronchogenic lung cancer is broadly divided into small cell and non- small cell variants. The World Health Organization Classification of primary lung tumors is shown in Table [16-14](#).

Non-small cell lung cancer accounts for approximately three-quarters of all tumors. In many countries, including the United States, adenocarcinoma rather than squamous cell has become the predominant cell type. It is hypothesized that the routine use of cigarette filters leads to deposition of carcinogens more peripherally in the lung, where adenocarcinomas tend to occur. Bronchioloalveolar carcinoma (BAC) is an uncommon form of adenocarcinoma. It develops in the very distal airways and lines the bronchioles and alveoli without invading through the basement membrane. Most frequently, it presents as an indolent solitary peripheral nodule. It also can present as a multifocal carcinoma (synchronous or metachronous), which is appropriately managed by surgical resection. Rarely, it causes diffuse lobar or pneumonic consolidation. In this situation, it is a more aggressive tumor best treated by chemotherapy.

Small cell lung cancer, accounting for approximately 20 percent of all lung cancer cases, arises from the neuroendocrine (Kultchitsky) cells lining the deeper layers of epithelium and has a more aggressive biologic behavior, frequently presenting with distant metastatic disease. It is rare for this variant to be considered for surgical treatment.

With increasing frequency, pathologists are identifying neuroendocrine cell tumors as part of the spectrum of non-small cell lung cancer. These large cell neuroendocrine carcinomas appear to have a prognosis worse than non-small cell lung cancer, approaching that of small cell lung cancer. Many of these were identified previously as “large cell undifferentiated tumors.” With immunohistochemical staining, neuroendocrine features can be identified and worsen the prognosis of this type of non-small cell cancer.

Stages of Lung Cancer

The prognosis of lung cancer is stage-dependent, and is influenced by the size and location of the tumor (T status), the presence or absence of lymph node metastases (N status), and the presence or absence of distant metastases (M status). For this reason, the initial clinical staging of the tumor is important not only for prognosis but also for decisions about treatment.

The most recent AJCC/UICC TNM Staging Classification is indicated in Table [16-15](#). As can be seen, with increasing stage, the 5-year survival rate after surgical resection

decreases.

Primary lung tumors arise for the most part in proximal or distal airways, resulting in the term *bronchogenic* carcinoma. It has been found that patients with tumors less than 3 cm (T1) fare better than those with tumors greater than 3 cm (T2). Tumors invading adjacent non-vital structures (T3) fare worse, but worst of all are tumors invading adjacent vital structures (T4), such as the mediastinal organs (heart, great vessels, etc.).

When tumors spread by lymphatic extension to intrapulmonary and hilar lymph nodes (N1), the prognosis worsens. Spread to the mediastinum is an even poorer prognostic sign and often contraindicates a surgical approach. Patients with ipsilateral mediastinal lymph node spread (N2), however, fare better than those with tumors with contralateral or supraclavicular lymph node spread (N3).

In the TNM staging, M0 indicates no evidence of metastases, whereas M1 indicates evidence of metastases whether they be single or multiple. When considering surgical treatment, on occasion, patients who have totally resectable primary tumors and solitary sites of metastases may be considered for a surgical approach to both lesions. Patients with metastatic disease usually are treated by systemic therapy (chemotherapy), with palliative radiotherapy used to control the primary locoregional tumor. Patients with metastatic disease, on the whole, fare poorly, with less than 50 percent surviving 1 year.

Surgical therapy is directed at those tumors for which a complete excision can be accomplished. These generally include patients who clinically have been staged I, II, or IIIa. For all the preceding reasons, it is important in assessing patients with lung cancer to attempt as accurate a clinical staging as possible before deciding definitive treatment.

Clinical Manifestations

Bronchogenic carcinoma is seen with increasing frequency in patients over age 50, with a peak incidence between the ages of 60 to 70. At one time, men predominated (10:1), but with increasing smoking among women, the incidence of carcinoma is now only 1.5:1 in favor of men.

Patients may be asymptomatic at diagnosis with a lung mass detected on a routine chest x-ray. These patients are the most likely to be cured because they have early-stage lung cancer. However, attempts at routine screening of smokers by annual chest x-rays have failed to improve the survival of the mass screened population because chest x-ray does not detect tumors at an earlier, more curable stage of the disease.

Clinical manifestations of lung cancer can be broadly divided into symptoms and signs related to local growth of the tumor within the airway and lung (chronic cough, hemoptysis, symptoms of obstructive pneumonia) and symptoms related to local extension of disease to surrounding structures (hoarseness from recurrent laryngeal nerve palsy, chest pain, symptoms of superior vena caval obstruction and dyspnea from pleural effusion).

Other symptoms include those resulting from metastatic spread, which occurs most frequently to the brain and bones or generalized manifestations of metastatic malignancy, including general debility, weight loss, and anorexia. Because carcinoma of the lung can metastasize to any organ, the symptoms and signs of metastatic disease vary.

A small percentage of patients with lung cancer present with extrapulmonary non-metastatic manifestations that are considered to be a consequence of the elaboration of hormone-like substances by the neoplastic cells. The occurrence of these signs and symptoms does not necessarily imply systemic spread of the tumor, and often resection of the primary tumor is associated with regression of the symptoms. The most common of these is the syndrome of clubbing and hypertrophic osteoarthropathy (Fig. [16-86](#)). Extrapulmonary nonmetastatic syndromes are listed in Table [16-16](#). Frequently, these are associated with small cell lung cancer, and it is felt that the neurosecretory type granules seen in these tumors have an important role in producing these non-metastatic manifestations. Examples of this are Cushing's syndrome and inappropriate antidiuretic hormone (ADH) secretion. Hypercalcemia, caused by a parathormone-like polypeptide, is seen most frequently in squamous cell carcinoma and has an unusually poor prognosis.

Diagnosis and Staging

When first seen, approximately two-thirds of patients have disease beyond that treatable by surgical excision. For this reason, diagnostic evaluation must include an effort to determine whether the disease is localized (stages I and II), locally advanced (stages IIIa and IIb), or metastatic (stage IV). The key to this effort is a meticulous history and physical examination to elicit symptoms and signs of local extension and distant spread. Frequently, symptoms alone suggest a diagnosis. The minimum imaging studies required for diagnosis and staging include a chest x-ray and a CT scan of the chest and upper abdomen—the latter to detect occult metastases in the liver and adrenals. In most instances, a diagnosis should be confirmed by non-invasive or invasive testing already outlined. This can include sputum cytology, needle aspiration biopsies, bronchoscopy, mediastinoscopy or invasive exploration of the hemithorax by video- assisted thoracoscopy or thoracotomy. Once a diagnosis has been established, a metastatic work-up is valuable. In addition to an accurate history and physical examination, imaging studies designed to detect that area of metastatic disease (e.g., CT or MRI of brain and bone scan) should be performed.

In order to determine whether or not a patient benefits from surgical removal of their tumor, accurate clinical staging is important. This often is accomplished by physical examination, chest x-ray, CT scan, and bronchoscopic examination. There is considerable debate as to how intensive the search for involved mediastinal lymph nodes (a very poor prognostic sign) should be. Any mediastinal lymph nodes that are enlarged on CT scan (>1 cm) are potentially malignant and should be biopsied by mediastinoscopy (Fig. [16-87](#)). However, because approximately 10 percent of normal-sized nodes contain microscopic metastatic disease and despite "normal" nodes on CT, some surgeons perform mediastinoscopy in all patients except those with very small peripheral tumors (clinical T1 N0). Because of the poor prognosis of clinical N2 disease, primary surgical resection is rarely indicated thus the intensive search for this preoperatively.

Local factors suggesting total inoperability include a malignant pleural effusion (T4) and contralateral or supraclavicular mediastinal lymph node involvement. When patients present with these suspected findings, histologic confirmation by invasive testing (e.g., mediastinoscopy, scalene lymph node biopsy, thoracentesis, or thoracoscopy) should be performed.

Treatment

Patients with clinical stages I and II non-small cell lung cancer should be considered for surgical treatment. Before surgical resection, patients must be assessed for their ability to withstand the proposed resection. A detailed preoperative assessment including history and physical examination, pulmonary function studies, and cardiac evaluation as indicated must be carried out. Lobectomy or pneumonectomy generally requires resection of the tumor. If local extension has occurred, en bloc resections of chest wall or adjacent airways may be required for complete excision.

Patients with small cell lung cancer rarely may be candidates for surgical resection. This applies only to those patients with clinical stage I or II disease (a rare event, <10 percent) in those patients presenting with small cell lung cancer (Fig. [16-88](#)).

It is worthwhile to discuss the management of non-small cell lung cancer according to the various stages of disease. The aim of surgical resection is to completely remove the primary tumor and all involved lymph nodes (Fig. [16-89](#)). There has been debate by surgeons on whether mediastinal lymph nodes simply should be sampled or should be completely removed at every surgical operation. When involved, surgical removal is indicated.

Stage I Disease

This early stage of lung cancer is afforded the best opportunity of long- term cure. In stage Ia disease, less than 20 percent of patients recur after surgical resection (Table [16-17](#)). Most frequently, a lobectomy is required for treatment. Less commonly, more proximal tumors require a pneumonectomy. Lesser resections (segmental resection, wedge resection) are reserved for those patients with extremely poor pulmonary function who cannot tolerate a lobectomy. It has been shown that these lesser resections carry a higher rate of local recurrence and decreased long-term survival, probably because of failure to remove occult intrapulmonary lymphatic spread.

Stage II Disease

Once the tumor has spread to intrapulmonary and hilar lymph nodes, the prognosis after surgical resection is worse. In these patients, pneumonectomy is more frequently required to extirpate all tumor. Since most tumors, when they recur, do so at distant sites, one would hope that adjuvant therapy, either chemotherapy or chemoradiotherapy, would have a beneficial effect. To date, several randomized trials have failed to show that adjuvant chemotherapy or radiotherapy improves survival.

When tumors directly involve adjacent structures (T3), en bloc excisions can be performed, removing the lung and the adjacent involved structure. In these cases, especially with apical (superior sulcus) tumors that involve the upper ribs and lower brachial plexus (Pancoast tumors: chest pain, T1 nerve root pain, and Horner's syndrome), the role of perioperative radiotherapy appears to be beneficial. Other T3 tumors, especially those involving proximal airways, can be treated with various plastic reconstructive techniques (sleeve resection of bronchi) such that ipsilateral lobes can be preserved.

Stage IIIa Disease

Management of tumors that have spread to ipsilateral mediastinal lymph nodes remains controversial. Historically, when surgeons identified preoperatively the presence of involvement of mediastinal lymph nodes, surgical therapy was not offered to the patient. These patients were treated primarily with radiotherapy and had a 5 to 15 percent chance of being cured using this treatment. During the past 15 years, multiple chemical trials have been performed to determine if induction chemotherapy or chemoradiotherapy improves resectability and survival. Results of these trials indicate that complete surgical resection is frequently possible, with up to 30 percent of patients being cured of their tumor. Similarly, a combination of chemotherapy and primary radiotherapy has been used in treating such tumors without the use of surgery. Patients treated in this manner also are provided a better chance of cure than with radiotherapy alone. Since both treatment strategies are effective in about 20 to 30 percent of patients, there are two randomized trials now being conducted, one in North America and one in Europe, in an attempt to determine which is the best approach in managing such patients. Both approaches presently appear to be valid.

Stage IIb Disease

Once lymph node involvement includes contralateral mediastinal areas (N3), it is highly unlikely that patients will be cured of their tumor by a surgical approach. In such instances, patients usually are offered chemotherapy and radiation to control their disease with a small chance of complete cure. Occasionally, T4 tumors that minimally invade adjacent vital organs of the mediastinum can be removed together with portions of that organ (e.g., left atrium, superior vena cava, aorta, esophagus). The results of such surgery can, on occasion, be gratifying when only minimal invasion of such structures has occurred and a complete resection is possible. Although not proven, it is routine that combined-modality therapy (e.g., radiotherapy and chemotherapy) is added in an attempt to improve the results of such treatment.

Metastatic Disease (Stage IV)

On occasion, patients with totally curable primary tumors present with a solitary metastasis (e.g., brain). In such instances, it is possible to effect a cure in 10 to 15 percent of patients by removing the primary tumor and the solitary site of metastasis.

When considering a surgical approach for a patient suffering from lung cancer, the surgeon must be aware of the results of such surgery—morbidity and mortality as well as long-term survival (Table 16- 18). The cost-benefit ratio of the procedure should be weighed before offering the treatment to the patient. The more advanced diseases with the more extensive resections result in increasing morbidity and perioperative mortality with a lesser chance of ultimate cure. Surgeons must be very selective in determining whether or not an individual patient should be offered a surgical procedure for treatment and must base that decision on the preoperative assessment of the patient and the clinical staging of the tumor.

Solitary Pulmonary Nodule

Among patients with lung cancer, the best survival can be expected from that group of patients in whom the cancer is first found as an asymptomatic solitary peripheral pulmonary nodule on the chest x-ray. Because of this relatively favorable outlook if the nodule is a cancer, and because of the variety of nonmalignant lesions that also present in this fashion, there is considerable interest in the differential diagnosis of these “coin lesions.” The *solitary pulmonary nodule (SPN)* has been defined by general agreement to be an abnormal density up to 4 cm in diameter, rounded or ovoid in appearance (Fig. 16-90 and Fig. 16-91), surrounded by a zone of lung tissue by x-ray, and free of cavitation or associated lung infiltrates. Eccentric flecks of calcium may be present, but lesions that are largely calcified or that have concentric calcium rings are not considered.

Earlier reports suggested a malignancy rate of about 40 percent in the SPNs; in more recent analyses, approximately 80 percent of all coin lesions were malignant in patients over 50 years of age. Only when the nodule is known to have been present for a long period with absence of growth and with a pattern of calcification characteristic of the several benign lesions that can occur (e.g., granuloma, hamartoma) should histologic diagnosis of these nodules be delayed.

Proof that the lesion has not developed recently requires inspection of previous chest x-rays because faint, small lesions are frequently overlooked in screening films and a “negative” official report often has been in error. Even when previous x-rays document radiologic stability of a solitary nodule for up to 2 years, malignancy must be suspected.

The differential diagnosis of an SPN includes many entities, among which are pulmonary hamartoma, granuloma, pulmonary arteriovenous fistula, pulmonary infarction, and several benign and malignant tumors. Surgery is rarely indicated for the nonmalignant lesions under consideration, but many clinics have recommended extensive diagnostic efforts to ascertain the correct diagnosis before thoracotomy. There is a significant false-negative rate in most of the studies short of excisional biopsy. With improving imaging techniques, the odds of a correct preoperative diagnosis are improving, but with the consequences of error so costly and with the reasonably good results after operative resection, many physicians feel that it is unwise to gamble on a determination of benignity unless the lesion is in a young (under age 35), nonsmoking patient with a known history of radiographic stability and advise surgical excision for diagnosis in all other patients.

Where calcification is present, CT is useful in selecting the rare patient who can be observed safely. CT scans have the capacity to measure absorption coefficients, which indicate tissue density. Siegelman and associates used CT with thin sections to assess tissue density in 91 apparently noncalcified pulmonary nodules in 88 patients. They established a separation between benign and malignant lesions on the basis of high attenuation values in the benign *SPNs*. The high values were presumably due to diffusely distributed calcium deposits within the lesions not visible on standard radiographs. In the absence of calcium, benign SPNs may have attenuation values in the same range as malignant lesions. Similarly, in a small proportion of patients, malignant lesions may have sufficient calcium to result in the high values characteristic of benign nodules.

For many years there has been a difference of opinion regarding the management of patients with SPNs, with some groups advocating early thoracotomy with resection of the lesion for all patients above 35 years of age and others urging a more conservative approach with greater emphasis on diagnostic studies and observation. Although the resection policy did result in a 50 percent frequency of removal of benign lesions, excellent cure rates could be expected if primary malignancies were found. With the sharply falling frequency of tuberculous granulomata and the continuing rise in lung cancer rates, current odds favor early resection unless there is strong evidence of a benign process. Sputum cytology, bronchoscopic washings and brushings, and percutaneous needle biopsies each can provide clear-cut positive information of both malignant and benign disorders. In many instances no diagnosis is made, and in these patients, malignancy cannot be excluded.

If previous films are available for comparison, or if a course of observation is elected for other reasons, calculation of the time necessary for doubling of the tumor volume is a useful indicator of the nature of the lesion. Serial radiographs provide the data for calculation of growth rate, and it usually is possible to detect that a lesion is growing within a few weeks. The doubling time of malignant nodules is usually between 37 and 465 days. If the lesion is growing more slowly or more rapidly than this, the evidence is in favor of benignity. Advocates of a conservative approach insist that present knowledge supports the concept that a pulmonary nodule can be watched safely for a period of time to determine whether it is growing.

A logical approach to the *SPN* is outlined in (Fig. 16-92). With the advent of video-assisted thoracoscopic techniques, resection of nodules in the periphery of the lung result in minimal morbidity and virtually no mortality. In patients known to be at high risk, including those with age over 50, smoking history, absence of certain knowledge, similar lesions on chest x- ray for more than 2 years, and failure to make a diagnosis by other means, resection of the nodule is indicated for diagnosis. Conversely, if the patient is under age 35 and a nonsmoker and the chance of malignancy is small, watchful waiting in close observation for growth or change may be indicated. This is especially true if the nodule is not easily accessible by video-assisted techniques.

Other Lung Tumors

Carcinoid Tumors

This group of tumors includes all neuroendocrine neoplasms arising from Kulchitsky cells. At the benign end of the spectrum, the “typical” carcinoid histologically resembles the carcinoid tumors of the small intestine. Along with cylindroma and mucoepidermoid tumors, these previously were termed *bronchial adenomas*. All of these tumors are in reality malignant, and the term *adenoma* has been abandoned. Even with “typical” carcinoid tumors, metastases to regional lymph nodes do occur on occasion. A more ominous variant is the “atypical” carcinoid, which demonstrates more mitotic figures and a higher potential for metastases and behaves much more like lung cancer. These tumors have a much poorer prognosis than typical carcinoids, which are almost always cured by surgical resection.

The term *bronchopulmonary neuroendocrine tumor* has been used to include the spectrum of tumors with neuroendocrine features from typical carcinoid tumor to the highly malignant small cell lung cancer.

Over 80 percent of carcinoids arise in proximal bronchi, but peripheral origin beyond cartilage-containing bronchi does occur. The tumors grow slowly and protrude into the bronchial lumen, causing signs and symptoms of bronchial obstruction as the principal clinical presentation. Unusual vascularity may cause hemoptysis as a presenting complaint (see Fig. 16- 91). The vascularity gives the tumor a deep pink or “cherry” red color when visualized through a bronchoscope.

The extent of bronchial wall involvement is variable, but there is usually invasion of the underlying cartilages. Rarely, direct extension through the bronchial wall results in invasion of mediastinal structures. In typical carcinoids, regional lymph node deposits are found in approximately 10 percent of patients. Distant metastases are rare. In keeping with the neuroendocrine origin of these tumors, a few patients with bronchial carcinoid have Cushing-like syndromes that seem attributable to the tumor.

Although the average age of patients with a carcinoid tumor is approximately 40 years, the neoplasm does occur in children. The clinical presentation usually is a result of bronchial obstruction with infection and pulmonary atelectasis. Sputum cytology is negative, but more than 80 percent of the lesions can be visualized by bronchoscopy. The carcinoid syndrome is seen rarely and in very large tumors can occur without extrathoracic metastases.

The treatment for bronchial carcinoid tumor is surgical resection. Neither the primary neoplasm nor lymph node metastases are sensitive to radiation therapy. Lobectomy is the accepted operation in most patients. In view of its low potential for spread, lung-conserving procedures, such as sleeve resection or local bronchial excision with bronchoplasty, are used whenever feasible (Fig. 16-93). The expected long-term survival rate is over 90 percent in typical carcinoid tumors after complete resection.

Tumors of Bronchial Gland Origin

Adenocystic carcinoma (cylindroma) and mucoepidermoid tumors are the most common neoplasms arising from the bronchial glands. Their location is predominantly central, and they are said to take origin only from bronchi containing cartilage and glands. Both neoplasms may show a spectrum of behavior from benign to malignant with regional and distant metastases. The treatment is surgical resection, including en bloc removal of regional lymph nodes when possible. Although the long-term cure rate usually is higher than that of primary carcinoma of the lung, it does not equal the results in typical bronchial carcinoid or benign adenomas. Other rare tumors of bronchial gland origin are occasionally reported; the majority seem to be forms of adenocarcinoma.

Carcinosarcoma

Making up less than 1 percent of lung cancers, carcinosarcoma consists of epithelial and mesenchymal types of tissue, and electron microscopy has confirmed that the sarcomatous elements are not simply transformed components of epithelial origin. The term *blastoma* recently has been used for some tumors that show histologic evidence of association with embryonal tissue.

Carcinosarcomas may be located in the lung periphery or in proximal bronchi, and they have been reported in a wide age range, including children. They are found most commonly in patients with tobacco addiction in the sixth decade. The overall survival of resected patients is worse than primary non-small cell lung cancer, with only about 20 percent of patients surviving 5 years.

Other Tumors

A variety of mesenchymal sarcomas and tumors of reticuloendothelial origin may occur in the lungs. As a group, these tumors represent approximately 1 percent of all primary neoplasms removed at operation. The age range of presentation is considerably wider than that for bronchogenic carcinoma, and the tumors may arise anywhere in the lung or bronchial tree. Precise histologic identification of these neoplasms can be difficult, and they may be mistaken for highly undifferentiated carcinomas or metastatic neoplasms.

The symptoms are the same as those of primary carcinomas, but there is no association with cigarette smoking. When the tumors develop as intrabronchial polypoid neoplasms, the symptoms of bronchial obstruction lead to earlier diagnosis and, therefore, a relatively higher cure rate after resection. Leiomyosarcomas, for example, had a 5-year cure rate of approximately 40percent in McNamara's report.

Lymphomas rarely may develop in the lung without evidence of tumor elsewhere. Routine chest x-rays discover an asymptomatic pulmonary lesion in a number of patients; other lesions become symptomatic because of pressure of the growing tumor or lymph nodes on adjacent structures. Although there is no pathognomic radiographic appearance, primary

lymphomas may present as an ill-defined pulmonary mass with central consolidation and air bronchograms. The diagnosis rarely is suspected from sputum cytology or bronchoscopy. Percutaneous needle biopsy may provide the diagnosis, but often this is made after resection. A sufficient number of lymphomas are localized to make the prognosis good after pulmonary resection. Often adjuvant chemotherapy is advised. A 5-year survival exceeding 50 percent may be anticipated.

Hodgkin's disease frequently involves the lung, and a rare patient is seen in whom a solitary pulmonary lesion is unassociated with other evidence of tumor. If resection has been performed, the patient should have complete staging of the disease so that decisions regarding additional therapy can be made.

Fibrosarcoma, rhabdomyosarcoma, neurofibrosarcoma, and other tumors of mesodermal origin may occur rarely in the lung but without specific clinical presentation. The treatment is operative resection, and the prognosis depends on the stage at which the neoplasm was discovered. High-grade sarcomas fare much worse than low-grade ones.

Benign Tumors

Primary or metastatic cancers make up 99 percent of all pulmonary tumors resected, and benign tumors are therefore a relatively small fraction of all lung tumors. Among that group of rare tumors, the hamartoma (chondroadenoma) is the most common. Although occasionally seen in children, they usually appear in men in their fifth to sixth decades, produce no symptoms, and are found in the periphery of dependent portions of the lungs (Fig. 16-94). The characteristic marble-like feel of these cartilaginous tumors makes it usually possible to simply enucleate them; wedge resection may be preferred if the physical findings leave the surgeon uncertain about the diagnosis. Epithelial elements are generally present, and there may be fat, muscular, or fibrous tissue interspersed.

Because benign tumors theoretically can occur wherever the cells from which they might arise are present, a wide variety of other exceedingly rare tumors occasionally is reported. They can be epithelial (tumorlet and papilloma), mesenchymal (fibroma, leiomyoma, lipoma, hemangioma, lymphangioma, neuroma, and rhabdomyoma), or lymphoid (plasmacytoma, lymphocytoma, plasma cell granuloma). Neurofibromas may occur, particularly in patients with neurofibromatosis. The significance of these tumors is almost exclusively related to the differential diagnosis from malignancies. When these neoplasms develop in a major bronchus, they may obstruct and present with the effects of chronic infection.

Metastatic Tumors

The lung is a common site of metastases from solid tumors arising in extrathoracic sites. Cells are shed into the vascular system and are trapped in the first capillary bed encountered; for primary sites not in contact with the venous portal system, this is the lung. Surgical manipulation of primary tumors might contribute to the shedding of cells, but metastases can appear at any time, even long after the primary seems controlled. Five-year survival rates after resection of one or more pulmonary metastases are 25 to 45 percent for patients with several types of carcinoma or sarcoma.

For the past 30 years, the treatment of solitary and even multiple but resectable pulmonary metastases in patients with controlled primaries has been operative resection. Randomized, prospective clinical trials comparing operative resection with medical management have not been done and might be considered unethical. Because of the relatively good results of resection and the absence of evidence that other therapeutic modalities are curative, surgical removal of isolated pulmonary metastases is the accepted treatment for many tumors.

There is some controversy about which tumor characteristics correlate with long-term survival. While it seems logical that long tumor doubling times (>40 days) should portend a better outcome, this has not been a consistent finding in reported surgical series, and shorter doubling times do not contraindicate surgery if other criteria are met. Five factors generally are considered important in selecting patients for pulmonary metastasectomy: The primary tumor has been controlled or is controllable; there is an absence of extrathoracic metastases; the lung metastases can be removed completely; the patient can tolerate the required pulmonary resection; and no better treatment (i.e., chemotherapy) for the pulmonary metastases exists. A recent report from an International Registry of Lung Metastases also emphasizes that the disease-free interval (greater or less than 36 months since control of the primary tumor) and single versus multiple metastases are important prognostic factors. The cell type of the original tumor is linked to prognosis (Fig. 16-95) when one considers that the four groups can be identified with different prognoses (Fig. 16-96).

A problem to be considered when a cancer patient presents with a solitary pulmonary nodule, synchronous or metachronous, is whether this nodule is a metastasis, a primary pulmonary tumor, or a non-neoplastic lesion. When lesions are picked up on routine chest radiographs after previous resection of a primary cancer, almost 90 percent are malignant. CT scans, which can locate lesions 2 mm in size, have a much lower specificity for tumor; only 45 percent of subcentimeter lesions picked up on CT scan are neoplastic. If a solitary nodule appears, 50 percent of patients with previous breast or colon cancers will have a primary lung cancer and not a metastasis. Conversely, patients with melanoma or sarcoma have an 80 percent risk of the lesion being metastatic. Because the type of surgical resection required depends on whether the lesion is primary or metastatic, this distinction is important but may not be available until the time of surgery.

Metastases usually can be removed adequately by wedge or segmental resection. Lobectomies or pneumonectomies are rarely required. A more extensive resection should be considered if the lesion is near the hilum and cannot be removed safely by a lesser operation. It is important to conserve as much lung tissue as possible because a certain percentage of these patients will undergo further resections in the future.

Some surgeons advocate a bilateral simultaneous approach for pulmonary metastatic disease in order to identify occult lesions on the contralateral side. Most surgeons use the preoperative CT scan to decide whether unilateral or bilateral exploration is indicated. Median sternotomy or bilateral anterior thoracotomy allows palpation of both lungs and provides adequate exposure for most resections. Proponents of bilateral approaches argue that in a certain percentage of patients, more metastatic disease will be found on the contralateral side and can be resected at the time of surgery. This is especially true in the case of metastatic sarcomas in which more than one lesion is found unilaterally. At the time of any thoracotomy or metastatic disease, systematic palpation of the collapsed lung is important; in 20 percent of patients, more lesions will be found than identified on CT scan.

With the increased effectiveness of chemotherapy for some malignancies, the role of surgery for pulmonary metastases is changing. With nonseminomatous germ cell tumors, chemotherapy has been so successful that the surgical resection of metastases is used primarily to establish the diagnosis, to resect metastatic disease unresponsive to chemotherapy, and to determine whether lesions that do not disappear totally after chemotherapy are malignant. Similarly, osteogenic sarcomas and Wilms' tumors usually are pretreated with chemotherapy, surgery being used to resect residual disease. Other tumors such as colon and renal cell cancers have yet to be treated preoperatively with chemotherapy in an effective manner.

Although resection is the standard treatment in a group of highly selected patients with isolated pulmonary metastases, this may change in the future as chemotherapy for many of these tumors improves.

TRACHEA

Anatomy

The trachea is a centrally located unpaired organ that conducts air from the oropharynx to the lung. It follows an oblique course from a vulnerable superficial position in the neck deep into the well-protected middle of the mediastinum. The adult trachea has an average length of 11 cm (range 10 to 13cm) segmented by 18 to 22 semicircular cartilaginous rings and has elliptical internal dimension averaging 2.3 cm in lateral diameter and 1.8 cm in anteroposterior diameter. The cricoid cartilage of the larynx, which has membranes attachments to the first tracheal ring, is the only complete cartilaginous ring in the upper airway. The membranous trachea is a flexible sheet of fibroelastic tissue forming the posterior wall of the trachea between the ends of the rings and directly abuts the posteriorly placed esophagus. The rigid rings of the anterior two-thirds of the trachea, combined with the flexible posterior third, impart great flexibility without collapse over a broad range of flexion, extension, and torsion of the neck and maintain patency of the lumen through the extremes of coughing and forced respiration. The loss of cartilaginous support that occurs in tracheomalacia allows dynamic collapse resulting in airway obstruction during the expiratory phase of breathing.

The important anterior relationships of the trachea are the thyroid isthmus, lying across the second to third rings; the innominate artery, crossing obliquely several more rings distally; and the aortic arch, crossing just above the carina. Laterally, the recurrent nerves lie close to the trachea in the tracheoesophageal groove, with the left nerve following a longer course and joining the trachea just above the carina after passing around the aorta and ligamentum arteriosum. Because its blood supply enters posterolaterally, dissection along the trachea is safest when confined to the anterolateral planes. The major arterial supply for the cervical trachea comes from the inferior thyroid artery. Lower portions of the trachea are supplied by branches of the bronchial arteries. Small branches from other mediastinal arteries supply the proximal bronchi and can assume importance after tracheal division, such as, for example, the coronary arterial branches that have been shown to provide blood supply to the tracheal anastomosis after heart-lung transplantation.

Congenital Lesions

Tracheoesophageal Fistulas

The most common congenital lesion involving the trachea is a tracheoesophageal fistula, which presents with many variations. It is discussed in detail in Chapter 37.

Tracheal Stenoses

Congenital tracheal stenosis presents as several variants, all of which are uncommon. Simple mucosal weblike diaphragms can occur, usually at the subcricoid level. Segments of functional stenosis as a result of tracheomalacia (cartilaginous softening) can be seen at sites of compression by a congenital vascular ring or an anomalous left pulmonary artery (pulmonary artery sling). Often associated with these anomalies is another variant characterized by absence of the membranous trachea with fusion of the cartilaginous rings posteriorly over a variable distance, thereby narrowing the trachea and presenting in three principal forms: (1) segmental stenosis, (2) funnel stenosis, in which the distal trachea tapers to a tight stenosis just above the carina, and (3) diffuse hypoplasia of the entire trachea. Frequently, a trifurcated main carina occurs in association with this; the right upper lobe bronchus arises at this level together with the two main bronchi.

Diagnosis

Congenital stenosis should be suspected in any infant with noisy breathing, wheezing, and inspiratory retractions occurring shortly after birth. In less severe forms symptoms may not occur until later in development. The necessary diagnostic evaluation can be exhaustive, reflecting the broad differential diagnosis and the association with other anomalies. Radiographic studies include chest films with magnification focused on the trachea, in inspiration and expiration, barium swallow, xeroradiography, CT scan of the neck and mediastinum, and angiography to identify associated vascular anomalies. Inspiratory and expiratory flow-volume curves, echocardiography, bronchoscopy, and rarely, bronchography also can be helpful. Great care is taken during bronchoscopy to prevent mucosal irritation and edema from converting partial to total obstruction.

Treatment

Therapy is individualized to suit the anatomy and the age of the child. Simple congenital webs often can be removed bronchoscopically. Occasionally, temporizing measures such as tracheostomy or repeated dilation allow resolution with growth. Operative treatment is indicated if these measures fail to allow such resolution, but every attempt is made to postpone reconstruction during early infancy. When possible, the stenotic segment is resected and the trachea reconstructed with an end-to-end anastomosis. Diffuse involvement presents a greater technical challenge in which, until recently, successful results have been rare. Satisfactory reconstructions can be performed using splints constructed from rib or costal cartilage to patch the length of the stenotic segment (Fig. 16-97) reinforced with a vascularized omentum pedicled flap. Innovative plastic procedure (slide tracheoplasty) have been used with success (Fig. 16-98). Perioperative airway management and the maintenance of luminal patency during healing and remodeling pose major challenges.

Relief of tracheal stenosis related to vascular anomalies requires more than simple correction of the vascular anomaly in about half of patients, the defect in the trachea also requiring correction.

Trauma

Blunt and penetrating trauma produce a spectrum of tracheal injuries ranging from simple laceration or contusion to complete transection. Much more common are injuries to the larynx. Hemoptysis, stridor, wheezing, or the presence of mediastinal and subcutaneous air (surgical emphysema) after trauma requires that the possibility of tracheal or proximal brachial injury be evaluated by careful bronchoscopy or exploration. Often a primary reconstruction is indicated, but the more conservative approach of inserting a tracheostomy tube at the site of injury may suffice if the injury is anterior and in the neck.

Post-intubation Injuries

The most common tracheal injury requiring treatment is that occurring as a complication of tracheal intubation for mechanical ventilation (Fig. 16-99). In the past, rigid rubber tracheostomy tubes and stiff tracheostomy cuffs frequently caused tracheal stenosis. Modern endotracheal and tracheostomy tubes have soft, low-pressure cuffs that have largely eliminated this problem. At the site of a tracheal stoma, exuberant granulations can form a bulky obstruction, or loss of cartilage combined with cicatricial healing may form an anterolateral stricture. Ischemic necrosis at the site of the tube cuff or the tube tip can produce a segment of ischemic stricture, a segment of tracheomalacia with functional obstruction during exhalation, or erosion and fistula formation with the esophagus or the innominate artery. Patients often present with airway symptoms long after the tracheal intubation (months or years).

Areas of stricture should be defined carefully with radiographic studies that include magnified air-contrast examination of the trachea, xeroradiography, and helical CT scans of the cervical region and upper mediastinum. Particular attention is paid to definition of laryngeal function. Bronchoscopy is essential to define associated laryngeal injury and preoperative assessment of the stricture.

Treatment

The operative approach for reconstruction of tracheal strictures is similar to that described below for the resection of tracheal neoplasms (Fig. 16-100). Endoscopic laser ablation can be useful for removal of granulation tissue but rarely has a place in the definitive treatment of stricture. A dreaded complication of tracheostomy is the occurrence of a tracheoinnominate artery fistula resulting from erosion by the tracheostomy tube through the anterior wall of the trachea creating a fistula with the overlying innominate artery. This produces sudden and often exsanguinating hemorrhage. A sudden hemorrhage through a tracheostomy tube should always make one think of this complication. Emergency surgery is required to divide and ligate the damaged innominate artery. Despite this division, postoperative neurologic sequelae are rare. Well-vascularized adjacent tissue (e.g., strap muscles) should be used to protect the ends of the divided innominate artery from the adjacent tracheostomy.

A tracheoesophageal fistula occurring during intubation and ventilation usually occurs because of pressure erosion of the cuff posteriorly through the membranous trachea creating a fistula with the subjacent esophagus. Whenever possible, repair of this problem should be delayed until the patient no longer requires mechanical ventilation. Definitive repair requires closure of the esophageal fistula and resection of the damaged trachea with reanastomosis of healthy tracheal ends and interposition of a pedicle of vascularized tissue between the injured sites.

Neoplasms

Primary tracheal neoplasms are uncommon and are vastly outnumbered by tumors that involve the trachea by direct extension from a bronchial, laryngeal, esophageal, or thyroid primary tumor. More than 80 percent of primary tracheal neoplasms are malignant, with squamous cell carcinoma and adenoid cystic carcinoma accounting for the vast majority. Adenoid cystic carcinomas usually are slow-growing, even when metastatic, so resection, if indicated, combined with radiotherapy can offer excellent long-term results even if considered non-curative. Squamous papillomas and fibromas are the most common benign tumors. A number of rare benign and malignant neoplasms have been identified in the trachea, including carcinoid tumors, chondromas, adenocarcinoma, mucoepidermoid carcinoma, and many others.

Diagnosis

Symptomatic patients with tracheal tumors present with some combination of dyspnea, cough, wheezing, inspiratory stridor, hemoptysis, and less frequently, recurrent respiratory infections. Chest x-rays can be misleading because the lung fields are clear, but an alert physician will obtain a CT scan of the cervical and upper mediastinal region to make the diagnosis. Standard pulmonary function testing may be normal, but flow-volume loops can detect upper airway obstruction. Bronchoscopy is an essential part of the evaluation and is best approached cautiously after maximum information has been obtained from noninvasive methods because of the potential for precipitation of acute airway obstruction. When approached carefully, most tumors can be biopsied endoscopically and a tissue diagnosis confirmed before proceeding with further treatment.

Treatment

Resection, airway stenting, and endoscopic ablation are the surgical options in the treatment of tracheal neoplasms.

Palliative Maneuvers

Airway stenting is palliative in patients with inoperable disease. Endoscopic ablation has been gaining more favor because of advances in laser technology. Developed in 1960, lasers produce coherent, low-divergence, high-intensity light capable of destroying tissue. As early as 1964, lasers were used experimentally to destroy tumor cells by thermal energy. The CO₂ laser was the first laser to be used for resection of airway neoplasms. This laser is very effective for tissue cutting and vaporization, but use in the trachea requires a rigid bronchoscope because the beam cannot be passed through fiberoptic systems. The neodymium-yttrium aluminum garnet (Nd-YAG) laser is favored because it is as effective as the CO₂ laser, can be used through fiberoptic systems, and allows cauterization of vascular tumors. In several large series, excellent results have been obtained in up to 92 percent of patients treated for unresectable obstructing tumors of the trachea (Fig. 16-101). Laser resection, however, is not always better than more traditional methods of palliative endoscopic resection using forceps and cautery. Use of laser ablation as the sole treatment for benign tracheal neoplasms is controversial. Once the airway is opened by stenting or endoscopic resection, radiation therapy usually is used as adjunctive therapy for long-term control.

Tracheal Resection

The ease of ventilation during tracheal reconstruction has been greatly facilitated by a variety of anesthetic techniques including the development of high-frequency “jet” ventilation, which is delivered to the distal airway through a small catheter passed through the endotracheal tube (Fig. 16-102). A small tidal volume is delivered at high frequency (60 to 150 breaths/min), maintaining lung expansion, alveolar ventilation, and oxygenation in the normal range. The catheter is small enough to pass through most stenoses and interferes little with surgical exposure.

The choice of incision for tracheal reconstruction depends on the level of tracheal involvement. In a young patient, hyperextension of the neck brings more than half the trachea above the suprasternal notch, accessible through a cervical incision. In older patients, it can be difficult to bring more than the first few tracheal rings above the notch. Lesions involving the upper half of the trachea usually are approached through a cervical collar incision, augmented as necessary with a midline upper sternal extension. Lesions involving the lower half of the trachea can be approached through a midline sternotomy incision or, when near the carina, through a posterolateral thoracotomy.

Surprising lengths of trachea (up to one-half its total length) can be resected and reconstructed with an end-to-end anastomosis. During the operative procedure, frozen-section analysis identifies clear resection margins. Minimizing tension on the anastomosis can be facilitated by releasing the larynx above the hyoid bone (suprahyoid release) and mobilizing one or both hila of the lung (hilar release). Both these maneuvers allow additional lengths of trachea to be resected. In the postoperative period, tension on the anastomosis is prevented by maintaining the neck in flexion, loosely suturing the chin to the anterior chest. For proximal tumors, a variety of complex reconstructions can involve the subglottic area and larynx and, in distal lesions, the carina and both main stem bronchi. The use of prosthetic materials and allografts for tracheal reconstruction generally has been unsuccessful.

Radiotherapy

Both adenoid cystic carcinoma and squamous cell carcinoma are highly radiosensitive. In instances where tracheal resection cannot be accomplished, primary radiotherapy can be curative (squamous cell carcinoma) and palliative (adenoid cystic).

MEDIASTINUM

The mediastinum is the central cavity of the thorax, bounded on either side by the pleural cavities, bounded inferiorly by the diaphragm, and merging superiorly with the thoracic inlet. No compartment of the body carries more physiologic traffic. Many liters of blood pass through the mediastinum each minute, as is true of liters of air, all ingested material and saliva, most autonomic nervous activity, and all the body's lymphatic fluid. Much of the embryologic development of the circulatory, respiratory, and digestive systems takes place within the mediastinum. Congenital, traumatic, inflammatory, and neoplastic processes all find frequent expression in this complex compartment and produce a broad spectrum of pathology in which anatomic relationships assume paramount importance.

The mediastinum is conveniently divisible along rough anatomic boundaries into subcompartments that contain characteristic lesions. The most traditional classification recognizing four spaces has largely given way to a system recognizing three spaces, which divides the highly overlapping contents of the superior compartment between the more surgically relevant anterior and posterior compartments (Fig. 16-103). In this system, the anterior mediastinum lies anterior to the heart and extends cephalad into the anterior half of the thoracic inlet, where it meets the posterior mediastinum. The posterior mediastinum lies behind the heart, extending cephalad into the thoracic inlet where the anterior borders of the upper thoracic vertebrae form its boundary with the anterior mediastinum. The middle mediastinum is the wedge in between with its base lying on the diaphragm and its apex at the top of the aortic arch.

The anterior mediastinum contains the thymus, along with a variable amount of adipose, areolar, and lymphatic tissue. The middle mediastinum contains the heart and pericardium, aorta, trachea and main stem bronchi, and associated lymph nodes. The posterior mediastinum contains the descending aorta, the esophagus, autonomic nerve trunks, and the thoracic duct.

Most mediastinal lesions appear as mass lesions radiographically, and most are neoplasms or cysts. A small number of mediastinal mass lesions are inflammatory or infectious. Vascular lesions, such as aneurysms, are considered elsewhere.

Tumors and Cysts

Mediastinal tumors and cysts in adults are distributed by type with similar frequencies in most large series. Among 400 patients with mediastinal masses reported on by Davis and associates, 25 percent had primary cystic lesions; thymic neoplasms were the most common primary tumors (17 percent), followed closely by lymphoma (16 percent), neurogenic tumors (14 percent), and germ cell tumors (11 percent). Malignant neoplasms have increased to 42 percent of the total over the 56 years encompassed by the series. Among the 62 percent of asymptomatic patients, the fraction of benign neoplasms has decreased from 93 percent before 1967 to 76 percent. This trend toward more frequent detection of occult malignancies probably reflects improved sensitivity of diagnostic techniques. In childhood series, the distribution of neoplasms is skewed toward malignancy, with nearly 50 percent having Hodgkin's or non- Hodgkin's lymphoma, while neurogenic tumors are a distant second. Lymphoma is the most common malignant neoplasm in all age groups.

Clinical Manifestations and Diagnosis

Mediastinal masses produce a wide variety of signs and symptoms, and one-half to one-third of patients are asymptomatic. The most common symptoms are nonspecific (chest pain, cough, dyspnea), and most can be ascribed to compression of adjacent structures, the trachea and esophagus in particular. Superior vena caval obstruction, recurrent nerve palsy, and Horner's syndrome are less common examples, but their presence focuses diagnostic attention on the mediastinum. Certain mediastinal tumors are associated with symptomatic endocrine syndromes, such as hypertension (pheochromocytoma), hypercalcemia (parathyroid tumor), thyrotoxicosis (intrathoracic goiter), and gynecomastia (choriocarcinoma). In such cases, symptoms have nothing to do with the mediastinal location but are systemic consequences of the disease. Pel-Ebstein fevers associated with Hodgkin's disease are a similar example.

The presence of symptoms correlates with malignancy. Ninety-five percent of mediastinal masses that are discovered as incidental radiographic findings are benign, whereas symptomatic lesions are about half benign and half malignant. This correlation is less meaningful in children, whose airways are more vulnerable to compression. In a large series (188 children) from the Mayo Clinic, 78 percent of patients with benign mediastinal masses under age 2 had symptoms and signs of tracheal compression. Signs and symptoms of nerve compression, such as Horner's syndrome, vocal cord paralysis, or hemiplegia, usually reflect aggressive direct invasion and carry a poor prognosis.

Diagnostic evaluation begins with chest radiography. Localizing the mass to one of the three subcompartments of the mediastinum narrows the possibilities (Fig. 16-104) and guides selection of further studies. In most patients the next step is CT, which can sort out the uniform radiographic densities of the mediastinum, identifying normal vascular and soft tissue structures with great cross-sectional clarity. CT of the mediastinum is most diagnostic of benign pathology, such as a cystic mass with an attenuation coefficient close to that of water. The CT appearance of solid malignancies is less definitive, but malignant characteristics such as extension, compression, and invasion are often readily demonstrated. The diagnostic power of CT is enhanced by oral and intravenous contrast material. In one series of children with mediastinal abnormalities, CT provided additional diagnostic information in 82 percent of patients, and in 65 percent the CT findings contributed to a change in clinical management.

MRI is occasionally of additional benefit in imaging the mediastinum, mainly for vascular lesions or for tumors associated with the heart or great vessels. Remarkable definition of vascular structures is obtainable in several views, without the need for contrast material injection (Fig. 16-105). The powerful magnetic field employed contraindicates the use of MRI in patients with pacemakers or cerebrovascular metal clips and complicates examination of critically ill patients on monitors and elaborate life support systems. Fortunately, most metallic hardware likely to occur in the mediastinum (prosthetic valves, vascular clips, sternal wires) does pose a major hazard.

Plane tomography has been replaced by CT and MRI. A barium swallow can demonstrate invasion, compression, or displacement of the esophagus, resulting from intrinsic or extrinsic lesions. Arteriography rarely is necessary in addition to CT and MRI, but contrast material injection of the aorta or pulmonary artery provides information regarding blood supply and anatomic relationship to critical vascular structures that is sometimes not obtainable by any other method. For preoperative evaluation of major vascular disorders (aneurysms), angiography is the diagnostic standard. Venous angiography can provide specific information about the extent of involvement and nature of collateral channels in superior vena caval obstruction but is difficult to justify unless operation and reconstruction are anticipated. Myelography, previously considered an essential part of the evaluation of posterior mediastinal tumors lying very close to the vertebral foramina, has been replaced by CT and MRI of the spine.

Radioisotope scanning can provide very specific information when an anterior mediastinal mass is suspected of being a substernal goiter. Endoscopy of the esophagus or tracheobronchial tree can add observations on displacement, compression, or erosion by adjacent mass lesions and occasionally provides biopsy material. Percutaneous transbronchial or transesophageal needle biopsy sometimes can be used to obtain a diagnosis. Mediastinoscopy and parasternal mediastinotomy are frequently also used for diagnosis. These are the preferred approaches to anterior mediastinal masses suspected to be lymphomas or thymomas because fine-needle aspiration usually does not yield a large enough specimen for definitive tissue diagnosis.

Small, anatomically discreet and encapsulated mediastinal masses are best managed by definitive resection without preoperative biopsy. The operative mortality for resection of such mediastinal lesions is very low. In a large series reported by Davis and associates from Duke, mortality has been 0.8 percent since 1930, without a single death in 236 patients over the most recent period of 26 years. For small mediastinal masses, operation provides definitive diagnosis and simultaneous definitive treatment. Large mediastinal masses, especially those which appear on CT to involve adjacent mediastinal structures, should be biopsied first because most of these will be treated non-operatively (e.g., lymphomas) or with a combined modality approach using preoperative chemotherapy (e.g., germ cell tumors or thymomas).

Neurogenic Tumors

Neurogenic tumors arise from sympathetic ganglia or intercostal nerves and are almost always found in the posterior mediastinum lying in the paravertebral gutter. The peak incidence is in adulthood. Because only 10 to 20 percent of adult neurogenic tumors are malignant, presentation as an incidental finding in an asymptomatic young adult is common. A higher proportion (20 to 40 percent) of childhood tumors are malignant. Chest wall pain caused by nerve compression or bony erosion is the most common symptom. Hemiparesthesia, hemiparesis, and other signs of spinal cord compression can be seen in tumors with “dumbbell” extension through the intervertebral foramina. Hormonally active tumors are most often childhood malignancies, which can produce hypertension, flushing, diarrhea, diaphoresis, anorexia, and fever.

Neurilemoma

Neurilemmomas (schwannomas) account for 40 to 60 percent of all neurogenic tumors. They arise from mature Schwann cells in intercostal nerves and have a hard, yellowish, well-encapsulated gross appearance consistent with the fact that most are benign. Some form “dumbbell” extensions through the intervertebral foramina (Fig. 16-106).

Neurofibroma

Neurofibromas contain elements of both nerve sheath and nerve cells and account for about 10 percent of all neurogenic tumors. They are poorly encapsulated but resemble neurilemmomas radiographically. Mediastinal neurofibromas can be one feature of generalized neurofibromatosis (vonRecklinghausen's disease), in which case the risk of malignant degeneration to neurosarcoma is increased. Advanced age also increases the risk of malignancy. Malignancy is present in 25 to 30 percent of tumors of this type and carries a poor prognosis because of rapid growth and aggressive local invasion.

Neuroblastoma

Neuroblastomas are the most poorly differentiated tumors arising from the sympathetic nervous system. Only about 10 percent occur as a primary lesion in the mediastinum. More than 75 percent occur in children under 4 years of age, and many are hormonally active, producing vanillylmandelic acid in sufficient quantity to present with a systemic symptom complex often consisting of hypertension, fever, vomiting, and diarrhea. Bone, liver, and lymph node metastases, as well as direct spinal cord invasion with neurologic deficits, are not infrequent at the time of diagnosis. Tumors presenting in such advanced stages usually are unresectable, but the tumors are generally radiosensitive, and debulking followed by radiation therapy can produce long-term survival. Tumors presenting in the mediastinum and those presenting in the first year of life have a more favorable prognosis.

Ganglioneuroma, Ganglioneuroblastoma

Ganglioneuromas arise from mature nerve cells in sympathetic ganglia and are benign tumors that usually present in a younger age group than tumors of neural sheath origin. Radiographically, ganglioneuromas have a triangular configuration, with the base toward the mediastinum, and may be completely obscured by the vertebrae in the lateral projection. They are poorly encapsulated and can be difficult to resect because of adherence to adjacent structures. Ganglioneuroblastomas consist of a mixture of mature and immature cells and are rare tumors that share features of neuroblastoma. These usually are seen in patients who are under 3 years of age and are rare in adults.

Paraganglionic Tumors

Pheochromocytomas are chromaffin paraganglionic tumors that characteristically secrete catecholamines. Intrathoracic primaries are unusual, occurring in about 1 percent of all pheochromocytomas. As with all extraadrenal locations, intrathoracic tumors are more frequently “silent” (nonsecreting) than their adrenal counterparts but are also more often malignant—about 30 percent of extraadrenal pheochromocytomas are malignant. Chemodectomas are nonchromaffin paraganglionic tumors that rarely secrete catecholamines and arise from chemoreceptor tissue around the aortic arch, vagus, and aorticosympathetics. They are quite rare, and 15 to 30 percent are malignant.

Treatment

Operation is indicated in most posterior mediastinal neurogenic tumors. The region is best approached through a standard posterolateral thoracotomy. Benign tumors should be excised completely. Preoperative evaluation of all posterior mediastinal tumors includes careful evaluation of the intervertebral foramina and vertebral bodies, which is most easily done initially with a CT scan. MRI is required to confirm intraspinal extension (see Fig. 16-106). When intraforaminal extension exists, resection is performed as a combined thoracic surgical and neurosurgical procedure with spine resection as necessary to provide exposure to the origin of the tumor at the level of the cord.

Malignant tumors are excised if possible. Radical operations for neuroblastoma are approached selectively, keeping clearly in mind the age of the patient, the radiosensitivity of the tumor, and the possibility of spontaneous maturation. Resection of an active (secretory) pheochromocytoma requires attention to the perioperative medical management of paroxysmal hypertension.

Thymoma

In adults, thymoma is the most common anterior mediastinal mass and ranks second in frequency among tumors and cysts of the mediastinum. Thymoma is rare in children and has equal sex distribution, with a peak age incidence between 40 and 60 years. About one-third of patients are asymptomatic at the time of diagnosis. Symptomatic patients present with mass effects on adjacent organs or with systemic effects referable to one of the paraneoplastic syndromes associated with thymoma. Of the former, common examples include cough, chest pain, dyspnea, and superior vena caval obstruction. Of the latter, myasthenia gravis is the most common, although hypogammaglobulinemia and red cell aplasia have

been described. It is most often stated that the incidence of myasthenia gravis is 10 to 50 percent in patients with thymoma. Conversely, thymoma is seen in only 8 to 15 percent of patients with myasthenia gravis. Myasthenic patients with thymoma have a poorer prognosis than patients without thymoma and are less likely to benefit from thymectomy.

Thymoma does not have a characteristic radiographic appearance, and diagnosis usually is made when the mass is excised (Fig. 16-107). The most prevalent histologic classification is based on the relative proportions of lymphocytic and epithelial elements, so the tumor is described as lymphocytic, epithelial, or mixed. Histology does not contribute to the distinction between benign and malignant, which is based on invasive gross characteristics. Distant metastases occur but are uncommon. Local tumor growth with involvement of surrounding mediastinal structures usually is followed by the development of pleural metastases. The pattern of disease progression is reflected in the staging system used for thymoma (Table 16-19).

CT scanning provides important assessment of the extent of the primary tumor. Biopsy should be performed when the tumor is large and is not encapsulated so that preoperative chemotherapy can be given. Smaller tumors that can be removed completely (stage I or II) should be managed by surgical resection alone.

This usually is accomplished via a median sternotomy. Fifty to sixty-five percent of thymomas are benign and subject to curative resection, which should encompass the entire thymus and all adjacent mediastinal adipose tissue. Postoperative irradiation is of unknown benefit and does not compensate or substitute for a complete surgical resection (Fig. 16-108).

Lymphoma

Mediastinal involvement is present in about 50 percent of patients with Hodgkin's and non-Hodgkin's lymphoma, and lymphoma is the most common mediastinal malignancy. Lymphoma is located most frequently in the anterior mediastinum (Fig. 16-109). Hilar nodes in the middle mediastinum are involved less commonly, and posterior mediastinal location is rare. Chemotherapy and radiation are the standard treatment for lymphomas, and resection is almost never indicated. Surgery is performed primarily as a diagnostic procedure, either as an initial biopsy before treatment or to determine if residual active tumor remains after chemotherapy and radiation.

Teratodermoid Tumors

Teratomas account for less than 10 percent of all mediastinal tumors, with almost all found in the anterior mediastinum. By definition, teratomas consist of multiple tissue types not normally found at the site of the tumor. They often are partially cystic and consist primarily of ectodermal elements that can include hair, teeth, and sebaceous glands. Teratomas are thought to arise from branchial cleft and pouch cells associated with the thymus. The mediastinum is second to the gonads as the most frequent location of teratomas in adults. The sex ratio is roughly equal, and age distribution peaks in early adulthood.

In modern series, about two-thirds of patients are asymptomatic at presentation, and the majority of symptoms are nonspecific mass effects such as chest pain, cough, and dyspnea. The classic pathognomonic presentation with cough productive of hair and sebum has become a rarity, since most tumors are detected before eroding into the tracheobronchial tree. As with other neoplasms of the region, malignant teratocarcinomas are more likely to present with symptoms related to aggressive invasion of adjacent vital structures.

Typical radiographic appearance is that of a large, well-circumscribed anterior mediastinal mass. Twenty to forty percent of teratomas are calcified, most often appearing as a nonspecific opacity in the cyst wall, although occasionally due to the presence of teeth or bone. CT scanning is very helpful in delineating involvement of adjacent structures and in confirming fat density in the center of the cystic mass (Fig. 16-110). Elevated serum levels of alpha-fetoprotein (AFP) and human chorionic gonadotropin (hCG) suggest malignancy.

When the mass is small and discreet and likely to be a benign teratoma, surgical excision through a median sternotomy is the best method of diagnosis and treatment. Eighty percent are benign, and resection is curative. Even with benign forms, resection can be difficult because of the tendency for the tumors to be adherent to surrounding structures, most commonly pericardium, lung, great vessels, and thymus, and incomplete resection is occasionally necessary. For benign tumors, recurrence is rare even after partial excision.

Germ-Cell Tumors

Primary extragonadal germ cell tumors are rare. Although they can be seen in the pineal, sacrococcygeal, and paraaortic regions, they are found most often in the anterior mediastinum, where they comprise less than 1 percent of all mediastinal tumors. The histogenesis of germ cell tumors outside the gonads is poorly understood, but a theory of origin from pluripotential primordial germ cells in the mediastinum is favored. Mediastinal teratoma probably should be viewed as the end point of benign differentiation in this germ cell line but usually is considered separately because clinical behavior is different.

Five distinct cell types are recognized. Seminoma and embryonal cell carcinoma are most common, followed by choriocarcinoma, malignant teratoma, and endodermal sinus (yolk sac) carcinoma. These tumors usually are seen in young adults, with a male-to-female ratio of at least 4:1. Because the tumors are highly malignant, it is not surprising that 80 to 90 percent of patients are symptomatic when the diagnosis is made. The most frequent symptoms are nonspecific and result from tumor expansion encroaching on adjacent structures to produce cough, dyspnea, chest pain, or superior vena caval syndrome.

Standard posteroanterior and lateral chest x-rays detect over 90 percent of such tumors. A CT scan provides important information about tumor extent and invasion of adjacent structures. Serum tumor markers suggest the diagnosis and are important to obtain before treatment as a basis for monitoring relapse and response to treatment. All patients with choriocarcinoma have elevated serum human chorionic gonadotropin levels, as will some patients with seminoma and embryonal cell carcinoma. Alpha-fetoprotein levels can be elevated, most commonly in embryonal cell and yolk sac tumors.

The possibility of metastasis from a gonadal tumor must be excluded before a mediastinal germ cell tumor is declared primary. Primary gonadal tumors rarely metastasize only to the mediastinum and most often spread through retroperitoneal lymphatics. A gonadal primary can be excluded with reasonable accuracy if there is no evidence of retroperitoneal involvement by CT scan or lymphangiography and if a gonadal mass is not detectable by palpation and ultrasound examination.

Previously, most patients with mediastinal germ cell tumors underwent exploration through a median sternotomy and an attempt at complete resection. In a large series from the Mayo Clinic, complete resection was achieved in 44 percent of 56 patients. Because of improved chemotherapy during the past decade, most patients are now managed with chemotherapy initially. Surgical resection is used to excise the residual mediastinal mass after chemotherapy and to make a determination about the need for additional treatment postoperatively. Long-term survival is linked primarily to the tumor response to the initial chemotherapy.

Mesenchymal Tumors

Tumors of mesenchymal origin constitute about 7 percent of all mediastinal tumors and cysts, with most occurring in the anterior mediastinum. Lipomas are most common and are characteristically soft masses without fixation to surrounding structures that can reach enormous size without producing symptoms. Fibromas are more dense and less common but have similar clinical behavior. The malignant forms (liposarcoma and fibrosarcoma) are seen rarely.

Tumors of lymph-vascular and blood-vascular origin also are classified as mesenchymal neoplasms. Tumors of blood-vascular origin consist of hemangiomas (capillary, cavernous, and venous) and rare malignant hemangiopericytomas. The most common lymph-vascular tumor is a lymphangioma (cystic hygroma). Most vascular tumors present as smooth, often lobulated masses of uniform density on chest x-ray and appear as cystic masses on CT scan.

The complete list of mesenchymal mediastinal tumors also includes mesothelioma, hamartoma, myxoma, mesenchymoma, leiomyoma, and leiomyosarcoma, xanthogranuloma, and rhabdomyosarcoma.

Endocrine Tumors

Thyroid and parathyroid tumors appearing in the mediastinum are most properly considered within the context of their usual cervical manifestations. Less than 10 percent of parathyroid adenomas are located in the mediastinum, and most are approachable through a cervical incision. Because of their embryologic origin from the third branchial cleft, they usually are in close association with the upper pole of the thymus gland. Parathyroid tumors rarely present as a mediastinal mass.

Mediastinal thyroid tissue usually is a direct substernal extension of the cervical gland. Aberrant mediastinal thyroid tissue with agenesis of the cervical gland is exceedingly rare but does provide the rationale for obtaining a radionuclide thyroid scan in any patient with an undiagnosed mass high in the anterior mediastinum.

Mediastinal Cysts

Congenital cysts constitute approximately 20 percent of all primary mediastinal mass lesions and account for the vast majority of middle mediastinal primary lesions. On chest x-ray they appear as opaque densities that may be indistinguishable from neoplasms except on the basis of typical location. On CT scan a mass with near water density occurring in a characteristic location is virtually diagnostic and provides a strong rationale for routine use of CT scanning in mediastinal lesions. In a recent review of experience with mediastinal cysts in 34 children, Snyder and associates found that the accuracy of their preoperative diagnosis increased from 50 percent before the use of CT scanning to 100 percent thereafter.

Pericardial Cysts

These cysts are the most common type occurring in the mediastinum. They usually are detected as an incidental finding in an asymptomatic patient and very frequently appear at the right costophrenic angle as a smooth-walled cystic mass 3 to 6 cm in diameter. They contain a clear fluid and occasionally communicate with the pericardium. Histologically, they are lined with a single layer of mesothelial cells. The location and appearance of pericardial cysts are so characteristic, especially on CT scan, that close observation is becoming a defensible option, although most are still resected for diagnosis.

Bronchogenic Cysts

Bronchogenic cysts are most frequently located just posterior to the carina or main stem bronchi, although they can be found elsewhere in the mediastinum or more peripherally in the lung (Fig. 16-111). Communication with the tracheobronchial tree can occur to produce an air-fluid level, serving to distinguish them completely from pericardial cysts but allowing for confusion with lung or mediastinal abscess in certain cases. Chest x-ray and CT scan usually demonstrates a cystic mass in the characteristic location, although bronchogenic cysts can contain a viscid fluid difficult to distinguish from a solid mass by CT scan alone. A contrast esophagram may show compression of the esophagus by an anterior mass. Histologically, they are lined with ciliated respiratory epithelium and contain varying amounts of cartilage, smooth muscle, and mucous glands. They are most frequently symptomatic in children, producing cough, dyspnea, and stridor in more than half. All bronchogenic cysts should be resected and usually are approached through a posterolateral thoracotomy. When they have formed a communication with the tracheobronchial tree, the chronic infection that frequently results can make resection through dense

inflammatory adhesions very difficult.

Enteric Cysts

Enteric cysts are located in the posterior mediastinum adjacent to the esophagus. They are occasionally embedded in the muscularis of the esophagus but rarely communicate with the esophageal lumen. The cysts have a smooth wall with a muscular coat and a lining recognizable as intestinal mucosa, although it may be ciliated, and they contain a clear, colorless mucoid fluid. When lined with an aberrant gastric mucosa, peptic ulceration can lead to perforation of adjacent bronchus or esophagus, producing hemoptysis or hematemesis, and erosion into adjacent lung can produce a lung abscess. A rare association with vertebral anomalies has been described in which the enteric cyst is attached to the spinal cord of meninges, and a patent tract may exist that can be demonstrated by myelography.

Approximately 60 percent of enteric cysts are recognized in patients under 1 year of age when symptoms of tracheal and esophageal compression are prominent. Less than one-third of children with enteric cysts are asymptomatic. Complete evaluation of children with a suggestive presentation includes chest x-ray and esophagram followed by a CT scan with contrast material in the esophagus. Resection is always indicated. The lesions are approached through a posterolateral thoracotomy, with the choice of side determined by the level of involvement and the appearance of projection into either hemithorax.

Mediastinitis

Acute Mediastinitis

Acute mediastinitis is a fulminant infectious process with high morbidity and mortality characterized by rapid spread through the areolar planes of the mediastinum. The mediastinal pleura confines the process to the mediastinum only temporarily, with a breach occurring into one or both pleural cavities early in the course of the infection in most cases, after which the negative pressure of the pleural space helps to rapidly spread the infection throughout. The rapid spread of infection is promoted by several factors. One is the separation of tissue planes produced by air forced into soft tissues adjacent to a perforated hollow viscus, most often the esophagus, further promoted by the digestive action of salivary and gastric enzymes. Another is the pressure gradient established from the atmosphere to the negative pressure of the pleural space once the pleura is penetrated, which pulls the infection through the mediastinum from its source and into the pleural space. A third factor is the presence of naturally continuous fascial planes connecting the deep cervical compartments with the mediastinum, along which oropharyngeal infection can spread.

The infection is initiated most frequently by esophageal perforation, resulting from instrumentation, trauma, foreign body, suture line leak, or spontaneous postemetic rupture (Boerhaave's syndrome). Tracheal rupture or perforation is a less common cause in which dissemination of air through the soft tissues is massive, and infection is likely to be a secondary development. Direct necrotizing spread of infection without violation of an intrathoracic viscus is seen most commonly with aggressive oropharyngeal infections involving the deep cervical space but also has been described in association with infections of ribs, sternum, and vertebrae.

Chest pain, dysphagia, respiratory distress, and cervical upper thoracic subcutaneous crepitus are the chief hallmarks of the process during the earliest stages of infection when it is most important to diagnose the problem and begin treatment. Evidence of fulminant systemic infection is certain to appear within 24 h, and florid sepsis with hemodynamic instability supervenes rapidly in untreated patients.

The chest x-ray may be normal very early in the process, although mediastinal and subcutaneous air becomes apparent in most patients. The mediastinal contour is usually wide, and pleural effusion with or without pneumothorax appears very frequently. A contrast esophagram, for which water-soluble contrast material usually is recommended, is essential when esophageal perforation is known or suspected. Esophagoscopy rarely is indicated in acute perforation. Infections resulting from esophageal perforation and those descending from a perioral source usually are caused by a mixture of gram-positive and gram-negative aerobic and anaerobic organisms representing the spectrum of oral flora. Initial antibiotic coverage should be broad enough to cover all possibilities until cultures are available.

Treatment must be early and aggressive because mortality is directly linked to length of time between injury and esophageal repair or diversion. Antibiotics and fluid resuscitation are begun immediately. Chest tubes are placed for pneumothorax or effusion. The primary problem, such as esophageal perforation, is treated according to accepted principles, either separately or in combination with drainage procedures. For preservation of the cervical esophagus, direct drainage of the neck is required, entering the deep cervical space through an incision parallel to the sternocleidomastoid muscle and retracting the muscle laterally to expose the carotid sheath and pretracheal and retrovisceral spaces. Perforations of the thoracic esophagus are approached via a thoracotomy, which allows primary repair of the site of perforation and buttressing of this area with adjacent well-vascularized tissue (e.g., intercostal muscle or pericardial fat pad). The thoracotomy should be performed via the pleural space into which the esophageal perforation has drained, usually the right side for perforations in the middle or upper thoracic esophagus and the left side for perforations of the distal esophagus. Thorough debridement and drainage of the pleural space and mediastinum in conjunction with closure of the perforation are essential. Esophageal diversion by cervical esophagostomy, gastrostomy, and ligation or division of the gastroesophageal junction is required only when primary closure has failed or cannot be performed because of severe mediastinal inflammation related to a delay in diagnosis (usually 48 h or more).

Mediastinitis is seen in 1 to 4 percent of patients after open heart surgery and has accounted for an increasingly large proportion of all cases of mediastinitis as open heart procedures have increased in frequency. It follows a more indolent course than the entities discussed above, is rarely associated with crepitus and mediastinal air on x-ray, and has the bacteriologic spectrum of other wound infections, with *S. aureus* and *Streptococcus epidermidis* predominating. Several techniques have improved the treatment of this complication, which include sternal debridement and reclosure with mediastinal irrigation for infections diagnosed early and the rotation of bilateral pectoralis major muscle flaps into the sternal defect for more severe infections.

Chronic Mediastinitis

Chronic inflammation and fibrosis in the mediastinum (sclerosing mediastinitis, fibrosing mediastinitis) are thought to result most often from granulomatous infection such as tuberculosis or histoplasmosis, although identification of an organism in individual patients is rare. It has been postulated that the process begins as an inflammatory reaction in the tissues surrounding involved lymph nodes. The process is likely to remain clinically silent unless it progresses to produce obstruction of the esophagus, airways, superior vena cava, or other mediastinal vascular structures. The chest x-ray may show mediastinal widening but often is normal. CT scanning combined with angiography may be necessary to define the process. Operative exploration frequently is required to establish a diagnosis and also can be undertaken to relieve obstruction. In a series of 22 patients, medical treatment with the antifungal agent ketoconazole was surprisingly effective at controlling progression of disease when combined with operation.

Superior Vena Caval Obstruction

Superior vena caval obstruction is caused by bronchogenic carcinoma in 85 percent of cases. In the remainder, the cause is another mediastinal tumor, fibrosing mediastinitis, thoracic aortic aneurysm, or caval thrombosis secondary to chronic indwelling catheters or instrumentation. At least 40 percent of bronchogenic carcinomas producing superior vena caval obstruction are small cell tumors. Obstruction can be caused by compression or direct invasion. The clinical syndrome produced is easily recognizable, consisting of venous distention, facial edema, and plethora, often accompanied by headache and respiratory symptoms. In rare patients, associated airway compression or laryngeal edema can be life-threatening, but there is otherwise little evidence to support the commonly held notion that superior vena caval obstruction is inherently dangerous. Seizures, intracranial venous thrombosis, and other nonspecific cerebral consequences are unusual and highly associated with the presence of brain metastases. Survival in patients with obstruction due to carcinoma usually is measured in weeks to months, and it can be difficult to separate the dismal prognosis and aggressive behavior of the primary disease from the effects of superior vena caval obstruction alone. As with venous obstruction elsewhere in the body, compensatory venous collaterals develop promptly and largely ameliorate the condition, a fact that also complicates objective assessment of treatment modalities.

The vascular diagnosis can be confirmed by venography, but CT scanning with venous contrast material is equally effective and provides additional information regarding surrounding structures that can be diagnostically valuable. Invasive diagnostic procedures, such as mediastinoscopy, bronchoscopy, and lymph node biopsy, may be more difficult because of elevated venous pressure. Respiratory complications related to venous engorgement and edema of the tracheobronchial mucosa can occur but are almost always manageable in the hands of a careful anesthesiologist. The clinical tradition favoring emergency radiation therapy for the clinical syndrome before performing a biopsy is no longer accepted. A tissue diagnosis should be obtained before starting treatment.

Because the majority of cases are caused by an incurable neoplasm, palliative radiation with or without combination chemotherapy is by far the most common treatment modality. Rare cases of benign etiology are treated occasionally with venous bypass, but without large numbers of reportable patent conduits. Bypasses from the jugular vein to the atrium or distal superior vena cava have been accomplished with femoral vein and with a spiral graft constructed from excised saphenous vein (Fig. 16-112). Saphenojugular bypass also has been described, in which the saphenous vein is routed to the neck through a subcutaneous tunnel and left attached at the saphenous bulb for outflow. All invasive treatments have in common the difficulty of predicting which patients will be unable to establish sufficient venous collaterals over time without operation.

CHAPTER 17 - Congenital Heart Disease

Aubrey C. Galloway
Michael Artman
Stephen B. Colvin

GENERAL CONSIDERATIONS

Introduction

Congenital structural malformations of the heart or great vessels constitute the most common form of heart disease in children. The incidence of congenital heart disease is nearly 1 percent of live births (approximately 8/1000). Despite major advances in diagnosis, medical therapies, and operative treatment during the past decade, congenital heart disease is a leading cause of morbidity and mortality in infants and children. The highest proportion of deaths from birth defects in the first year of life is attributable to congenital heart defects. Although this chapter focuses on congenital malformations, acquired diseases also can occur in children, including conditions such as rheumatic fever (mitral and aortic valve regurgitation), Kawasaki's disease (coronary artery aneurysms) and others that may require operative intervention.

Given the intricacy of the embryonic development of the heart and cardiovascular system, it is not surprising that structural malformations occur frequently. A functioning cardiovascular system is essential to the survival of the fetus, and consequently the heart and vasculature develop early in gestation. Most fetal heart structures are formed between the third and the eighth week of pregnancy. The primitive fused heart tube undergoes looping, the first break in symmetry of the developing embryo, and septation in a highly ordered and tightly controlled fashion to form a normal four-chambered functioning heart during this 4- to 5-week period. Cellular commitment, differentiation, and migration are genetically controlled processes that may be affected by environmental or epigenetic influences. The developing heart receives important contributions from neural crest derivatives, and signals from the extracellular matrix are probably involved in directing cell migration. The developing branchial arch system contributes to the development of the aorta and ductus arteriosus. Disturbances in any of these processes may have profound effects on the final structure of the heart and great vessels after development is complete. The wide spectrum of congenital heart defects underscores the complexity of these normal cardiovascular developmental processes.

It is increasingly apparent that disordered developmental mechanisms are likely to be responsible for a high percentage of congenital cardiac defects. Basic developmental errors in the genes regulating cardiac development result in primary malformations that may be lethal to the embryo. Defects may arise from environmental influences during intrauterine development such as teratogens (e.g., retinoic acid), toxic agents, infections, and alterations in blood flow. Embryos with the most severe malformations are not viable, and only a fraction of all embryos with cardiovascular malformations survive to birth. Single-gene mutations may account for a large proportion of congenital heart defects. The role of chromosomal abnormalities such as trisomy 21, Down syndrome with frequent atrioventricular septal defects, has been known for some time, but the specific gene(s) involved has yet to be determined. Examples of recognizable single-gene defects include Marfan syndrome, supravalvular aortic stenosis, long QT syndrome, familial hypertrophic cardiomyopathy, Williams syndrome, Holt-Oram syndrome, and Noonan's syndrome. Considerable interest has been focused on the finding of a strong relationship between monosomy of a locus on chromosome 22 and conotruncal malformations. Deletions in the 22q11 region have been associated with DiGeorge syndrome, velocardiofacial syndrome (Shprintzen's syndrome), and conotruncal anomaly face syndrome. These syndromes share common features, and the phenotypic abnormalities represent a spectrum of disorders attributable to a related developmental field defect. Patients with microdeletions of chromosome 22q11 exhibit a variety of conotruncal and aortic arch anomalies, including truncus arteriosus, interrupted aortic arch, and tetralogy of Fallot. Although the specific genes involved remain to be identified, studies of the molecular genetics of congenital heart defects hold great promise for improved understanding, diagnosis, and treatment of affected infants.

The fetal circulation has several distinctive features that may allow the fetus to grow and develop normally during intrauterine life with a congenital heart defect that is lethal if untreated after birth. During fetal development, the lungs are collapsed and have a high vascular resistance, and pulmonary blood flow is low. Much of the oxygenated blood returning from the placenta through the inferior vena cava to the right atrium flows through the foramen ovale into the left atrium and the left ventricle. Most of the blood expelled from the right ventricle into the pulmonary artery is shunted through the ductus arteriosus into the descending thoracic aorta. Fetuses with severe right ventricular or left ventricular outflow tract obstruction, ventricular septal defects, or aortic arch anomalies thrive in utero. Shortly after birth the circulatory patterns change as a consequence of the normal transition to extrauterine life. It is during this transition time that many structural congenital abnormalities become apparent. At birth the lungs expand to assume the role of oxygenation. There is normally a rapid fall in pulmonary vascular resistance, and the ductus arteriosus closes in the first few days after birth. The ductus remains patent in only a small proportion of individuals but is one of the most common forms of congenital heart disease. The foramen ovale becomes functionally closed within a few days or weeks, although it may remain open anatomically for several months. The foramen ovale is a slitlike channel that seals when left atrial pressure becomes higher than right atrial pressure. Persistent patency of the foramen ovale, usually an innocuous defect, occurs in perhaps 10 to 20 percent of adults and has been implicated occasionally in thromboembolic stroke. With elevation of right atrial pressure above left atrial pressure from any cause, the foramen ovale may be stretched open and create a right-to-left shunt from the right atrium to the left atrium. Right-to-left shunting can be of sufficient magnitude to produce cyanosis from shunting of unoxygenated blood into the systemic circulation in infants with critical pulmonary valve stenosis.

Although a broad spectrum of congenital heart defects has been recognized and characterized, in large pediatric cardiac clinics several of the most common malformations comprise the majority of the abnormalities seen. Isolated ventricular septal defect is the most common anomaly, representing 20 percent or more of all patients. Other relatively common malformations (each occurring in 10 to 15 percent of patients) are patent ductus arteriosus, atrial septal defect, pulmonic stenosis, aortic stenosis, coarctation of the aorta, tetralogy of Fallot, and transposition of the great arteries.

Classification

Congenital heart disease may be classified by the type of anatomic abnormality present, which in turn produces a distinct physiologic disturbance. Five major groups exist: (1) *obstructive left-sided lesions* that restrict systemic blood flow; (2) lesions producing *increased pulmonary blood flow* by left-to-right shunting of blood across a cardiovascular defect; (3) lesions producing *cyanosis* by shunting right-to-left away from the lungs into the systemic circulation; (4) *complex malformations with mixed physiology*; and (5) *anomalous origin of vessels and vascular rings*.

Pathophysiology

The physiologic consequences of congenital heart disease vary from mild to severe, depending on the anatomy. The mildest forms consist of abnormal physical findings with minimal derangements of physiology. In some instances, such as with mild pulmonic stenosis or a small ventricular septal defect, treatment may be unnecessary or may be delayed until later in life. With more severe defects, symptoms may be more consequential. Physiologic abnormalities, such as pressure gradients across stenotic valves, shunts through septal defects, and elevated pulmonary artery pressure, can be detected by echocardiography or measured by cardiac catheterization. If untreated, patients may develop congestive heart failure or severe hypoxemia. Eventually physiologic abnormalities worsen and corresponding anatomic changes occur, such as cardiac hypertrophy, irreversible ventricular dysfunction, or pulmonary vascular disease.

Obstructive Left-Sided Lesions

The most common disorders are aortic valvular stenosis and coarctation of the aorta. These lesions impede emptying of the left ventricular chamber, resulting in systolic pressure overloading and corresponding hypertrophy of the ventricle. As the ventricular response is predominantly concentric hypertrophy, cardiac enlargement may be difficult to detect by clinical examination, and the chest radiograph may be normal or only slightly abnormal. The electrocardiogram (ECG) is helpful in identifying the presence of left ventricular hypertrophy. The echocardiogram not only can assess wall thickness and myocardial mass but also can provide a noninvasive estimate of the pressure gradient across the stenotic aortic valve. Similar information can be obtained with magnetic resonance imaging (MRI) techniques. MRI is helpful in defining the aortic anatomy in cases of coarctation of the aorta. MRI often provides superior images of the aorta, especially in older children and adolescents in whom echocardiographic imaging of the aortic arch and descending aorta is limited when using conventional transthoracic approaches.

With progressive left ventricular hypertrophy, susceptibility to ventricular arrhythmias develops, and sudden death may occur in patients with aortic stenosis, often during exercise, when myocardial oxygen demands increase disproportionately to oxygen delivery. Newborn infants with critical aortic stenosis or coarctation of the aorta may exhibit severe, life-threatening heart failure. In these cases, emergency intervention is indicated. Otherwise, cardiac failure is uncommon in older children and, if present, usually is a late and preterminal manifestation. Surgical intervention should be timed to prevent the development of severe hypertrophy and ventricular dysfunction. Left-sided obstructive lesions are managed in close cooperation with the interventional cardiologist in order to provide optimal surgical and catheterization-based treatments.

Left-to-Right Shunts

The direction and magnitude of flow through an unrestrictive ventricular septal defect or patent ductus arteriosus depends on the relative vascular resistances in the pulmonary and systemic circulations. Because systemic vascular resistance is normally greater than pulmonary vascular resistance, a defect in the ventricular septum or a connection between the aorta and the pulmonary artery (e.g., patent ductus arteriosus) results in a shunt of oxygenated blood from the left-sided circulation to the right side (hence the term left-to-right shunt). Shunting through an uncomplicated atrial septal defect is also left-to-right because of differences in ventricular compliance that favor flow into the right atrium and pulmonary circulation. A left-to-right shunt produces an increase in pulmonary blood flow. Systemic blood flow often is preserved unless there is marked pulmonary blood flow with significant signs and symptoms of congestive heart failure. Cyanosis is not a feature of isolated left-to-right shunts. The most common defects producing left-to-right shunts are ventricular septal defect, atrial septal defect, patent ductus arteriosus, and atrioventricular septal defects.

Pulmonary Congestion

A left-to-right shunt becomes physiologically significant when the pulmonary blood flow is 50 percent to two times greater than the systemic flow (see Cardiac Catheterization section for calculation of Q_p/Q_s). Large shunts may produce a pulmonary blood flow three to four times greater (or more) than systemic blood flow, with a pulmonary blood flow exceeding 10 to 15 L/min/m² of body surface area. During infancy and early childhood, the resulting pulmonary congestion increases the work of breathing and basal energy expenditure. Infants with large left-to-right shunts may tire during feeding and be unable to achieve sufficient caloric intake for normal growth. The predominant presentation in infancy is failure to thrive with signs of increased respiratory effort. Pulmonary congestion is associated with increased susceptibility to lower respiratory tract infections, and recurrent bouts of pneumonia may occur in the first few years of life. Beyond early childhood, however, high pulmonary blood flows often produce surprisingly little disability for a period of time. With careful questioning of the family, it often becomes apparent that the child has diminished exercise tolerance with easy fatigability relative to his or her playmates. Sometimes the degree of impairment is subtle, and it is only in retrospect after surgical correction that the family recognizes a change in the child's exercise capacity.

With the increase in pulmonary blood flow there is a corresponding enlargement of the left ventricle because of increased pulmonary venous return to the left atrium, and the right ventricle becomes volume overloaded in the presence of a large atrial septal defect. Volume overloading of the ventricle generally produces chamber dilation, rather than hypertrophy, which can be recognized on clinical examination and on the chest radiograph. Changes in the electrocardiogram are often less prominent than those seen with concentric hypertrophy. Echocardiography is useful for evaluating chamber sizes more precisely.

Medical management of large left-to-right shunts with pulmonary congestion includes vasodilator and diuretic therapy, often with digoxin therapy in addition, although the value of digoxin is uncertain unless left ventricular failure is present. Left ventricular afterload reduction with angiotensin-converting-enzyme inhibitors decreases the amount of left-to-right shunting, while the diuretics decrease fluid retention and limit pulmonary congestion by diminishing *volume* overload. In many cases, shunting through a left-to-right shunt diminishes with time as the child grows and the defect becomes smaller. Medical therapy may be used to temporize, and not all children with a left-to-right shunt need surgical repair. However, if an infant fails to grow despite medical therapy or if there are complications because of a large left-to-right shunt, then operative intervention is indicated.

Increased Pulmonary Vascular Resistance

It is important to distinguish between pulmonary hypertension and pulmonary vascular disease. Infants and children with a large unrestrictive ventricular septal defect have essentially equal pressures in the left and right ventricles, because the ventricles are functionally connected by the septal defect. Consequently, the pressures in the right ventricle and pulmonary arteries are elevated to systemic levels, a condition defined in its strictest sense as pulmonary hypertension. The pulmonary vascular resistance normally is low, and there is markedly increased pulmonary blood flow even though the patient has pulmonary hypertension. It is more meaningful from a physiologic and prognostic perspective to characterize each patient with respect to their pulmonary vascular resistance rather than the pulmonary artery pressure.

Elevated pulmonary blood flow and pressure ultimately produce changes in the pulmonary vasculature, resulting in a progressive increase in pulmonary vascular resistance. Pulmonary vascular resistance is calculated with the following formula (in which Q_p is measured in L/min/m² body surface area):

$$PVR = \frac{\text{Mean pulmonary arterial pressure} - \text{Left atrial pressure}}{Q_p}$$
 (Pulmonary blood flow)

- Left atrial pressure / Q_p (Pulmonary blood flow)

Normal pulmonary vascular resistance is less than 2.5 Wood units by this formula. Pulmonary hypertension resulting from an increase in pulmonary blood flow subsides as soon as the cardiac defect producing the increase in blood flow is corrected. Elevated pulmonary vascular resistance may take longer to resolve because it is a result of abnormal reactivity of the pulmonary vascular bed with thickening of the media and intima. If corrected early, pulmonary vascular disease progression is halted and the vascular changes may regress. If left untreated, children and adolescents with large left-to-right shunts can develop irreversible pulmonary vascular disease. When pulmonary vascular resistance is fixed above 10 Wood units and the shunt is balanced or changes to predominantly right-to-left, a condition known as Eisenmenger's syndrome, the operative risk becomes exceedingly high. In evaluating pulmonary hypertension, the significant physiologic measurement is the degree of change in the pulmonary vascular resistance, as calculated from the relation between flow and pressure, and not the absolute level of the pulmonary artery pressure. If the pulmonary resistance is elevated, it is helpful to determine whether or not the vessels are reactive to oxygen, nitric oxide, or other pulmonary vasodilators. Even if the baseline resistance is high, a child may be considered a good candidate for surgery if the pulmonary vascular bed remains reactive and is capable of dilating in response to appropriate stimuli.

It is rare for permanent pulmonary vascular changes to occur before 1 to 2 years of age in uncomplicated ventricular septal defect or patent ductus arteriosus, but there is significant individual genetic variation in susceptibility to the development of these changes. Some children with a large ventricular septal defect and a large increase in pulmonary blood flow do not develop any increase in pulmonary vascular resistance, while others with smaller defects develop significant pulmonary vascular changes at an early age. Infants with trisomy 21 and ventricular septal defect or atrioventricular septal defect are at increased risk for early development of fixed pulmonary vascular disease, so repair at approximately 2 to 3 months of age is advised. Similarly, defects such as truncus arteriosus or transposition of the great arteries with ventricular septal defect may produce permanent pulmonary vascular disease in some infants before 6 months of age. Most lesions associated with an increase in pulmonary vascular resistance should be surgically corrected in the first 3 to 12 months of life. More complex defects, such as transposition or truncus arteriosus, generally require operation in the first few weeks of life. With a simple atrial septal defect, the early onset of pulmonary vascular disease almost never occurs, and repair in infancy generally is not necessary.

Cyanotic Lesions

Right-to-left shunting of systemic venous blood directly back into the systemic circulation results in arterial hypoxemia and cyanosis. Cyanosis usually occurs because of the combination of an anatomic obstruction that results in *decreased pulmonary blood flow* and an intracardiac defect that allows right-to-left shunting of unoxygenated blood. The classic example is the tetralogy of Fallot, a combination of ventricular septal defect and right ventricular outflow tract obstruction. Other cyanotic disorders with decreased pulmonary blood flow include pulmonary atresia with intact ventricular septum, tricuspid atresia, and, in many cases, Ebstein's anomaly. Some more complex malformations, such as transposition of the great vessels, double-outlet right ventricle, truncus arteriosus, and single ventricle, produce mixing of unoxygenated and oxygenated blood, with bidirectional shunting and cyanosis, despite normal or increased pulmonary blood flow.

Cyanosis resulting from significant right-to-left shunting produces a large number of physiologic disturbances because of the tissue anoxia resulting from chronic hypoxemia. Most disturbances result from deficient oxygen transport to tissues of the body. Cardiac failure is rare in an uncomplicated cyanotic patient, in contrast to its more frequent occurrence in patients with large left-to-right shunts. The combination of cardiac failure and cyanosis can occur with complex lesions that produce mixing of blood with bidirectional shunting, yet have nonrestricted pulmonary blood flow. These lesions include transposition of the great vessels, double-outlet right ventricle, truncus arteriosus, and single ventricle.

The degree of cyanosis depends on the degree of anoxia and the blood hemoglobin concentration, since the visible intensity of cyanosis is determined by the amount of reduced hemoglobin in the circulation. It has been estimated that about 5 g of reduced hemoglobin is required to produce visible cyanosis. Normally in the capillaries about 2.25 g of reduced hemoglobin is present. With an average hemoglobin concentration of 15 g/dL of blood, a decrease in arterial oxygen from the normal range of nearly 95 to 75 percent is needed to produce visible cyanosis. In the presence of anemia, a more severe degree of anoxia is required to produce visible cyanosis, while with polycythemia and hemoglobin concentrations of 20 g/dL or more, severe cyanosis occurs with lesser degrees of anoxia. Cyanosis may be difficult to detect in newborn infants because of physiologically high levels of fetal hemoglobin.

Central cyanosis results from a defect in oxygenation of blood in the lungs or from an intracardiac right-to-left shunt. Cyanosis resulting from a pulmonary abnormality usually can be suspected because of the presence of signs and symptoms of respiratory distress. Cyanosis due to lung disease generally improves when the patient breathes 100% oxygen. This is a quick and helpful test to perform when confronted with a newborn baby with cyanosis. A rise in the arterial partial pressure of oxygen to above 150 mmHg makes the diagnosis of cyanotic congenital heart disease much less likely, though it does not rule it out. In the catheterization laboratory, pulmonary disease is suspected if the oxygen saturation of blood in the pulmonary veins is less than 95 percent. Pulmonary insufficiency from cardiac disease occurs only with severe pulmonary congestion from cardiac failure or far-advanced pulmonary vascular disease.

In contrast to cyanosis from pulmonary causes, cyanosis from an intracardiac shunt permits direct entry of venous blood into the systemic circulation, causing cyanosis that is unresponsive (or only minimally responsive) to an increase in the fraction of inspired oxygen. The intensity of the cyanosis is related to the volume of pulmonary blood flow, for ultimately cyanosis depends on the relative proportions of unoxygenated and oxygenated blood in the arterial circulation. Even though a large intracardiac shunt is present, an increase in pulmonary blood flow to produce a larger amount of oxygenated blood can substantially reduce cyanosis and improve oxygen transport. This was the rationale for palliative systemic-to-pulmonary artery shunts to increase pulmonary blood flow.

Clinical features of chronic cyanosis are seen much less commonly now that early diagnosis and effective surgical treatment are available for most forms of cyanotic congenital heart disease. There are still children who escape early detection and present with many of the classic features of chronic cyanosis. Two distinctive changes that appear with chronic cyanosis are clubbing of the digits and polycythemia, and the triad of cyanosis, clubbing, and polycythemia is a familiar one in children with congenital heart disease. Clubbing of the digits, or hypertrophic osteoarthropathy, is an unusual change in the appearance and structure of the digits, consisting of a rounding of the tips of the fingers and toes and a thickening of the ends, associated with deposition of fibrous tissue. In addition, there may be a pronounced convexity of the fingernails. Histologically, the fingers have increased numbers of capillaries, with a large number of tiny arteriovenous aneurysms. Clubbing usually is not prominent until a cyanotic child is 1 to 2 years of age, but in some instances of severe anoxia it may evolve within several weeks. Clubbing gradually subsides after correction of the intracardiac defect.

Polycythemia is a normal physiologic response of the bone marrow to chronic anoxia. Up to a point this response is beneficial; an increase in red cell and hemoglobin concentration increases the ability of the blood to transport oxygen. Hematocrit concentrations of 60 to 70 percent are not uncommon with chronic cyanosis; values exceeding 80 percent are noted in extreme cases. There is a parallel rise in viscosity of the blood, with restriction to the flow of blood as the hematocrit level rises. Once the hematocrit level exceeds 75 to 80 percent, the blood's increased viscosity may constitute a significant hazard for the development of cerebral venous thrombosis and neurologic injury. In chronic polycythemia defects in blood coagulation may develop, with abnormalities in several components of the blood-clotting mechanism. These patients may have increased susceptibility to hemorrhage after surgical procedures.

A decrease in exercise tolerance, with dyspnea on exertion, is a characteristic feature of cyanotic heart disease, because the circulation is unable to increase oxygen transport during exercise. The severity of the disability or its progression can be measured with formal exercise testing. Cyanotic children quickly learn that dyspnea on walking can be lessened by assuming a squatting position. Physiologic studies indicate that squatting produces an increase in peripheral vascular resistance with a corresponding increase in pulmonary blood flow by diminishing the degree of right-to-left shunt. Squatting is most commonly seen in older children with unrepaired tetralogy of Fallot, but it may occur in other cyanotic conditions.

Periodic episodes of unconsciousness, termed *hypercyanotic spells*, are a sign of cerebral anoxia. They often appear in the third or fourth month of life in severely cyanotic children. These episodes characteristically occur at different times, not always associated with exertion, and evolve as episodes of crying, deepening cyanosis, and loss of consciousness lasting a few minutes to a few hours. Emergency treatment to improve the oxygen content of the arterial blood is indicated if hypercyanotic spells occur. Medical treatment includes placing the infant in the knee-chest position, administration of oxygen, morphine for sedation, and phenylephrine to increase systemic resistance and reduce the magnitude of the right-to-left shunt. Urgent surgical placement of a systemic-to-pulmonary shunt or early total correction of the defect is indicated once hypercyanotic spells develop. In selected cases, pulmonary blood flow can be increased in the catheterization laboratory by dilating a stenotic pulmonary valve.

Another cause of neurologic injury in cyanotic children is brain abscess. The increased susceptibility may be partly related to direct access of bacteria in the venous circulation to the arterial circulation through the right-to-left shunt in the setting of polycythemia and sluggish capillary flow. A localized infarct with subsequent bacterial infection may explain the evolution in some patients. Cerebral injury may occur because of paradoxical thromboembolism through an intracardiac defect. In this instance, a thrombus migrating through the venous circulation, which would normally lodge in the pulmonary bed, traverses an intracardiac defect and reaches the cerebral circulation.

In older children with severe cyanosis there is a striking increase in the bronchial circulation through the development of aortopulmonary collateral vessels as a compensatory response to the chronic decrease in pulmonary blood flow. The myriad of collateral vessels, often constituting a mass of varicosities in the mediastinum, are of surgical significance because of the risk of bleeding during operation, and because they produce overperfusion of the lungs if left in place once a surgical shunt is created. It is helpful in this setting to

coordinate the operative intervention with the occlusion of aortopulmonary collateral vessels in the catheterization laboratory. The use of specially designed coils delivered through a catheter to occlude the major collateral vessels can reduce the time in the operating room and minimize flooding of the lungs once a controlled surgical shunt is created. In patients undergoing total definitive operative repair, preoperative occlusion of major aortopulmonary collateral vessels simplifies the operative procedure and minimizes flooding of the field during cardiopulmonary bypass.

Examination

History

A thorough history and physical examination are important components of the evaluation of an infant, child, or adolescent with known or suspected heart disease. The parents or caretakers are the source of most of the essential information related to the child's health. The family often is very concerned because they lack information or they harbor inaccurate perceptions regarding the prognosis of heart disease in a child. The thought of heart surgery being performed on their child provokes extreme anxiety. It is essential to establish good rapport and close communication with the patient and the parents in order to minimize these anxieties and ensure proper treatment and compliance. Most parents want to be well informed in order to participate in decisions that may dramatically affect their child.

Initial historical information should be collected regarding pertinent maternal and familial factors. The general state of the mother's health during pregnancy should be ascertained along with questioning about medications, infections, and lifestyle. A careful family history is essential to provide clues as to possible hereditary disorders. The perinatal history should include questions about birth weight, illnesses at birth, length of hospital stay after birth, and whether or not a murmur or cyanosis was detected in the newborn nursery.

Significant congenital heart disease often presents in infancy, so a careful analysis of the first few weeks and months of life is essential. Often the presence of heart disease in infants may go unrecognized because the signs of heart disease lack specificity. For example, feeding difficulties may result from a variety of conditions other than congestive heart failure. Significant arterial desaturation can be present without obvious cyanosis. If the infant is the first child, new parents may not recognize abnormal infant behavior since they have no previous experience with a normal baby. Specific questions about feeding include the type of feeding (formula versus breast milk), frequency of feeds, amount consumed with each feeding (or time spent at each breast), and duration of each feeding should be recorded. It is important to ask if the infant seems to breathe harder or perspire during feeding. The pattern of growth (height, weight, and head circumference) should be ascertained. It is useful to plot the child's growth parameters on an appropriate growth chart in order to determine the pattern of growth. The age at which a cardiac murmur was detected for the first time should be noted. The time of appearance of cyanosis is significant as well as an assessment of whether or not the degree of cyanosis is progressing.

A decrease in exercise tolerance, manifested by dyspnea on exertion, is a common symptom and an indication of the severity of the disorder. This may be subtle, so it is important to ask the parents to compare the child's activity level with that of his or her playmates. Sometimes the school can provide useful information. Often the parents indicate that the child does not exhibit exercise intolerance, but on careful questioning it becomes apparent that the child's activity is self-limited and the child fails to engage in strenuous forms of play activities. Frequent squatting while playing can be readily identified by the parents, although they may think of this as normal for their child and usually do not volunteer this information. Older children and adolescents should be allowed to participate in the history gathering and answer questions related to activity and exercise tolerance. Older children should be asked about the presence of symptoms such as shortness of breath, chest pain, palpitations, pre-syncope, and syncope. Previous signs or symptoms of neurologic episodes such as cyanotic spells, cerebral embolism, brain abscess, or other signs of cerebral injury should be noted. An inquiry should be made about infections such as pneumonia, bacterial endocarditis, or rheumatic fever.

Physical Examination

General inspection should be performed to assess the overall appearance of the infant or child looking for phenotypic features characteristic of common syndromes associated with congenital heart defects (e.g., trisomy 21, Turner's, Noonan's, velocardiofacial, or Williams syndromes). The examiner should be alert to evidence of cyanosis, respiratory difficulties (respiratory rate, effort, and use of accessory muscles), diaphoresis, or whether the infant is resting comfortably. The approach to the physical examination depends on the age of the patient. It is often helpful to examine the infant while the mother or father holds the baby to provide a familiar, warm, and comforting environment. Every effort should be made not to disturb the infant because crying complicates auscultation of the heart.

The vital signs, including blood pressure, should be recorded. Height, weight, and head circumference should be carefully measured. On examination of the chest, any deformity of the left hemithorax, indicating long-standing cardiac enlargement, should be noted. The chest is palpated for precordial activity and to determine whether a thrill is present. A palpable thrill is particularly important, as it indicates significant underlying cardiac disease. A finger placed in the suprasternal notch is used to feel for the thrill associated with left ventricular outflow tract obstruction. It is imperative to carefully feel the pulses in all four extremities and to simultaneously palpate the upper and lower extremity pulses. It is sometimes easier to feel the pedal pulses than the femoral pulses in infants. Diminished intensity of the lower extremity pulses provides evidence of coarctation of the aorta. Bounding pulses suggest patent ductus arteriosus or aortic regurgitation. Cyanosis may be obvious or may require close scrutiny for detection. Inspection of the nail beds is more reliable when performed using natural light. The fingers should be carefully inspected from above and from the side for evidence of clubbing.

Auscultation should be performed in a consistent, systematic fashion. Patience is required with infants and toddlers. The entire precordium should be evaluated, as well as both sides of the back and the midaxillary areas bilaterally. The first and second heart sounds should be characterized and the presence or absence of additional sounds should be noted. A single second sound often is found in pulmonary valve atresia and tetralogy of Fallot. An excessively loud second heart sound signifies pulmonary hypertension or transposition of the great arteries. When a loud murmur is present, it should be characterized with regard to the type of murmur, intensity, location, and transmission. Many of the common defects produce characteristic murmurs. For example, a harsh holosystolic murmur loudest at the lower left sternal border is typical for a ventricular septal defect. An ejection systolic murmur at the upper left sternal border with radiation into the lungs and a preceding ejection click is diagnostic of pulmonary valve stenosis. A pulmonary ejection murmur with a fixed widely split second heart sound is characteristic of an atrial septal defect. Diastolic murmurs are less frequent in infants but when present are especially significant. A diastolic inflow rumble may result from increased pulmonary blood flow from a large ventricular septal defect. The murmur of a patent ductus arteriosus typically has a diastolic component. Less commonly, a diastolic murmur may be due to aortic or pulmonic regurgitation.

Auscultation of the lungs usually is normal in infants and children in the absence of pulmonary infection, even in cases of congestive heart failure due to a large left-to-right shunt. The presence of rales from cardiac failure in children suggests impaired left ventricular function with elevated pulmonary venous and capillary pressures. Characteristically, no abnormalities are found in the lungs with right-to-left shunts producing cyanosis. The hallmark of congestive failure in children is hepatic enlargement, developing and regressing rapidly as the degree of circulatory failure changes in response to therapy. Estimation of the presence and extent of hepatic enlargement is of particular importance. In contrast to adult forms of cardiac disease, hepatic enlargement occurs more commonly than the rales or peripheral edema found in adults with heart disease. If an infant or child presents with peripheral edema, it is more likely to be a result of renal disease (e.g., nephrotic syndrome) than to a structural cardiac defect.

Diagnostic Tests

The use of diagnostic tests should be goal-directed, based on the history and physical examination. The chest radiograph, electrocardiogram, and echocardiogram are not used as screening tests because of the lack of sensitivity and specificity (chest radiograph and electrocardiogram) or the expense (echocardiogram). Echocardiography has assumed a predominant role in the diagnosis and management of heart disease in infants and children, but the chest radiograph and electrocardiogram continue to be useful.

Chest Radiograph

On the chest radiograph, cardiac position, size, and contour, aortic arch position, and vascularity of the lung fields should be noted. The lungs and pleural spaces should be examined. Bony abnormalities may occur in certain syndromes or may be secondary to previous thoracic operative procedures. In older children with coarctation of the aorta, rib notching caused by collateral flow may be apparent. Cardiac size is best expressed as the cardiothoracic ratio, with a ratio greater than 0.5 (0.6 in infants) suggesting cardiac enlargement. Enlargement of specific cardiac chambers can be estimated, but this is more precisely done with echocardiography. Enlargement of the left atrium occurs with mitral insufficiency, ventricular septal defect, patent ductus arteriosus, or any form of left ventricular failure. Left ventricular enlargement is characteristic of aortic disease, mitral insufficiency, coarctation of the aorta, patent ductus arteriosus, and ventricular septal defect. Right atrial enlargement is especially prominent in Ebstein's malformation and also occurs in tricuspid atresia. Selective enlargement of the right ventricle is seen frequently with atrial septal defect.

Characteristic changes in cardiac contour may be seen in certain malformations. The boot-shaped heart of tetralogy of Fallot results from hypertrophy of the right ventricle in association with a right ventricular outflow tract. The egg-shaped heart of transposition of the great vessels is caused by enlargement of the right ventricle and right atrium, with a narrow mediastinal shadow due to the anterior-posterior relation of the aorta and pulmonary artery. With total anomalous connection of the pulmonary veins to the superior vena cava, a characteristic figure-of-eight or snowman appearance has been described. The size of the pulmonary vessels and the pulmonary vascularity also are important. With left-to-right shunts producing a significant increase in pulmonary flow, the vessels are enlarged with engorgement of the lung fields. The appearance may be strikingly different from conditions with a normal or decreased pulmonary blood flow, such as in tetralogy of Fallot.

Electrocardiogram

The electrocardiogram is the best tool for determining the cardiac rhythm. The normal ECG changes significantly during the first few days and weeks after birth, with continued changes progressing throughout adolescence. It is important to interpret the ECG in an age-appropriate fashion, since what appears to be markedly abnormal for an adult might be completely normal for an infant or child. A considerable amount of information can be gained on the presence and degree of hypertrophy, although the ECG in infants and children is not highly sensitive. Selective hypertrophy of the left ventricle, as in aortic valvular stenosis, or selective hypertrophy of the right ventricle, as in pulmonic valvular stenosis, can be identified and roughly correlated with the degree of stenosis. A large ventricular septal defect generally produces electrocardiographic features of biventricular hypertrophy. An atrial septal defect usually produces evidence of right ventricular enlargement. Evidence of ischemic changes or infarction can be provided by the ECG, especially if serial tracings are available for comparison.

Echocardiogram

Echocardiography is the cornerstone of noninvasive assessment of infants and children with congenital heart disease. Two-dimensional imaging and a thorough Doppler evaluation provide information on the structure and function of the heart. In contrast to adults, infants and children generally have excellent acoustic windows, so that conventional transthoracic imaging provides high-quality diagnostic information. Often views from the subcostal approach are extremely helpful, which usually is not the case in adults. The patient must be still during the examination; sedation is sometimes necessary in infants and young children in order to obtain diagnostic images. Because transthoracic and subcostal imaging generally provides all of the necessary information, transesophageal echocardiography is not required in children nearly as frequently as it is in adults.

Transthoracic echocardiography has emerged as an important tool in the operating room during pediatric cardiac surgery to confirm preoperative diagnoses, monitor ventricular function, and assess the adequacy of the repair. With the newer, smaller probes, transesophageal echocardiography can readily be applied to infants weighing as little as 3 kg. Intraoperative transesophageal echocardiography has become the accepted practice in most large centers providing cardiac surgery for infants and children. Fetal echocardiography is useful for detecting significant cardiac structural defects before birth. This has proved to be helpful in preparing for the immediate management of newborns

with congenital heart disease. Newer techniques of three- and four-dimensional echocardiography are used in selected pediatric patients but have yet to gain widespread application.

An echocardiogram and Doppler study generally can provide information regarding cardiac and great vessel anatomy, including cardiac situs, atrioventricular concordance, ventriculoarterial concordance, ventricular and septal wall thickness, chamber size and configuration, and aortic or pulmonary artery size. Doppler evaluations are helpful in detecting and quantitating intracardiac or great vessel shunts and the presence and severity of atrioventricular and semilunar valve regurgitation or stenosis. The pressure gradient across a stenotic valve or coarctation correlates well with pressure measurement obtained at catheterization. The magnitude of a left-to-right shunt can be estimated by a variety of techniques. In the presence of a ventricular septal defect or patent ductus arteriosus, estimates of systolic right ventricular and pulmonary arterial pressure are relatively straightforward. Many children have a small amount of tricuspid valve regurgitation, often inaudible but detectable by Doppler, which allows convenient estimation of right ventricular pressure.

Because of the reliability, accuracy, and ease of modern echocardiography, many infants and children are treated medically or surgically without the need for invasive studies (e.g., cardiac catheterization). Patients with straightforward obstructive lesions, atrial septal defect, ventricular defect, or patent ductus arteriosus are often in this category. Even infants with complex defects such as transposition of the great arteries, atrioventricular septal defect, hypoplastic right heart syndrome, truncus arteriosus, and interrupted aortic arch usually are taken to the operating room without undergoing cardiac catheterization. MRI may be helpful in defining the anatomy, especially extracardiac features (aortic arch, coarctation, pulmonary arteries, systemic and pulmonary venous connections).

Cardiac Catheterization

Pediatric cardiac catheterization is becoming more of an interventional procedure than a traditional diagnostic procedure. In most centers, the proportion of diagnostic catheterizations is declining as the number of interventional procedures increases. Cardiac catheterization is increasingly used in children for the diagnosis and treatment (e.g., radiofrequency catheter ablation) of simple and complex arrhythmias. Many common malformations can be treated safely and effectively in the catheterization laboratory. Balloon dilation generally is the preferred treatment for uncomplicated isolated valvular pulmonic stenosis. Patent ductus arteriosus usually is treated with coil occlusion of the ductus in the catheterization laboratory. Although not yet approved for general use, catheterization techniques likely will be used in the near future in closing most secundum atrial septal defects. Balloon dilation of stenotic pulmonary arteries (including placement of stents in the pulmonary arteries) plays an important role in the comprehensive management of patients with complex lesions. The role of interventional techniques continues to emerge for more complicated cases such as aortic stenosis, mitral stenosis, and coarctation of the aorta. Coordination and planning of complementary catheterization- based and surgical approaches is necessary to provide optimal care for infants and children with heart disease.

Diagnostic cardiac catheterization may be helpful when, for example, precise measurement of pulmonary vascular resistance is necessary. During cardiac catheterization, intracardiac pressures and pressure gradients from obstructive lesions can be determined, shunt magnitudes can be calculated, ventricular or vascular morphology can be visualized, and vascular resistances can be calculated. Diagnostic catheterization should be considered in complicated postoperative patients, such as infants being prepared for stage 2 and 3 reconstruction for hypoplastic left heart syndrome, in whom uncertainty exists regarding the cardiac status.

In the normal heart, depending on the age of the child, the right atrial systolic pressure is less than 5 mmHg, the right ventricular systolic pressure ranges from 15 to 30 mmHg, the left atrial pressure and the left ventricular diastolic pressure each range from 5 to 10 mmHg, and the left ventricular systolic pressure ranges from 80 to 120 mmHg. Accurate quantification of intracardiac shunts is based on the Fick principle. Normally pulmonary blood flow (Q_p) equals systemic blood flow (Q_s) and the Q_p:Q_s ratio is 1. In patients with left-to-right shunts the Q_p:Q_s ratio is increased.

Q_p/Q_s =Aortic oxygen sat. - Mixed venous oxygen sat. / Pulmonary venous oxygen sat. - Pulmonary arterial oxygen sat.

A Q_p:Q_s ratio of 1.5 or less is associated with mild physiologic disturbances and may not require operative intervention. A Q_p:Q_s ratio of 1.5 to 1.8 is on the borderline, and usually a Q_p:Q_s ratio greater than 1.8 to 2.0 is an indication for operative correction. It is important to consider all information, especially the pulmonary vascular resistance, and not just the pulmonary artery pressure or Q_p:Q_s ratio alone, when considering a patient for operative intervention.

The physiologic evaluation of the degree of valvular stenosis is obtained by calculating the functional cross-sectional area of the stenotic valve orifice. This is done by measuring the flow rate and pressure differential across the involved orifice. A valvular diameter more than 50 to 75 percent below the predicted normal for the child's body surface area is markedly abnormal. For example, a normal cross-sectional aortic valve area is 2 cm²/m² body surface area, while an area less than 0.5 cm²/m² represents severe aortic stenosis. Similar calculations are possible for the mitral valve, which has a normal area of 2.5 to 3.0 cm²/m². Significant symptoms are noted with a mitral valve diastolic gradient greater than 10 mmHg and with a mitral valve area of less than 0.8 cm²/m².

PRINCIPLES OF PREOPERATIVE, INTRAOPERATIVE, AND POSTOPERATIVE CARE

Preoperative Management

In cases of newborn infants with life-threatening congenital heart disease the initial diagnosis usually is made in the referring hospital, usually by echocardiography. Immediate initiation of proper preoperative therapy in the referring institution and careful transport are essential for optimal results. Close attention should be given to oxygenation, acid-base status, fluids, body temperature and respiratory mechanics before and during transport. Metabolic acidosis should be corrected immediately in patients with severely restricted systemic or pulmonary blood flow. Patients who are dependent on a patent ductus arteriosus should be started on an intravenous infusion of prostaglandin E₁ (0.05mg/kg/min). Treatment with digitalis, diuretics, or inotropic agents also is frequently necessary. If the infant is hypoventilating or severely tachypneic with respiratory distress, mechanical ventilation should be initiated. Close attention should also be paid to body temperature, oxygen saturation, and respiratory mechanics during transport.

Once the seriously ill infant arrives in the neonatal or pediatric cardiac intensive care unit, vigorous critical care management is initiated. It is no longer advisable to rush the patient to the operating room early in unstable condition. Instead, correction of the underlying heart failure and metabolic defects is carried out over 2 to 3 days, improving perfusion, correcting acidosis, and stabilizing hemodynamics before surgery. This approach allows the child to arrive in the operating room in stable metabolic and hemodynamic condition, which significantly lowers the operative risk.

Intraoperative Management

On arrival in the operating room general anesthesia is induced and central venous access and arterial pressure monitoring are secured. A percutaneous, double-lumen internal jugular central venous catheter usually is inserted. Secondary sites for central venous access are the subclavian or femoral veins. Similarly, a percutaneous radial artery line is inserted for arterial monitoring if feasible. Otherwise, a radial, brachial, or femoral artery cutdown is performed.

The patient is placed in the supine position with a roll or sandbag between the shoulders. A small Foley catheter is placed into the bladder and rectal and tympanic membrane temperature probes are placed. Close attention must be given to the patient's temperature, fluid status, and oxygenation. Intraoperative transesophageal echocardiography usually is performed to confirm the diagnosis and to rule out any unsuspected lesions.

After the preparation and sterile draping of the patient, a sternotomy incision is made. Special pediatric cannulas are available for arterial and separate vena caval cannulation. Cardiopulmonary bypass is established with moderate (22 to 25°C) or profound (15 to 17°C) hypothermia. The heart usually is arrested with cardioplegia for myocardial protection, and the intracardiac repair is performed.

A major advance responsible for the excellent results obtainable with total correction of congenital heart problems is the frequent use of profound (deep) systemic hypothermia during cardiopulmonary bypass. Lower temperatures give a measure of end organ protection and allow perfusion with lower flow rates. In patients with complicated anatomy, deep hypothermia and total circulatory arrest may be used, allowing the surgeon excellent visualization to perform a precise, complex intracardiac repair. The techniques used are based on the principle that the energy requirements and oxygen consumption of the body are reduced relative to decreases in body temperature. For example, at normothermia, systemic flow rates during cardiopulmonary bypass must approach the normal cardiac index of 2.5 to 3.5 L/min/m² to supply the oxygen demands of the body. At 25°C total-body oxygen consumption drops by more than 50 percent and pump flow rates of 1.5 to 1.7 L/min/m² are adequate for tissue and organ perfusion. More strikingly, at 15°C oxygen consumption is less than 25 percent of normal. At this temperature low pump flow rates of 1.0 to 1.5 L/min/m² are adequate, and total cessation of flow (circulatory arrest) is safe for 45 to 60 minutes. The use of low systemic flow rates or total circulatory arrest has allowed safer, more precise intracardiac correction of complex abnormalities in small infants or neonates with a still, dry, bloodless field.

After the cardiac defect is repaired, the child is rewarmed. Before discontinuing bypass, additional central venous, left atrial, or pulmonary artery pressure monitoring catheters are placed as necessary. Temporary pacemaker wires are routinely placed on the right atrium and right ventricle, often placing two atrial and two ventricular pacemaker wires if atrioventricular pacing is required. Inotropic agents are used as necessary for impaired cardiac function. Once all monitoring is in place and the child is warm and ventilated, bypass is discontinued.

The hemodilution and systemic inflammatory effects of cardiopulmonary bypass have been found to result in significant postoperative total-body volume overload because of increased capillary leakage. This may lead to transient dysfunction of the heart, lungs, and kidneys. Several centers have advocated the use of ultrafiltration to prevent massive postoperative volume overload, minimize edema, and hasten myocardial functional recovery. Ultrafiltration during or immediately after cardiopulmonary bypass removes excess water, resulting in a higher postoperative hematocrit level, decreased bleeding, fewer transfusion requirements, and improved pulmonary function. Modified ultrafiltration removes excess fluid and activates complement and cytokines, resulting in diminished neutrophil activation with less inflammatory mediated endothelial cell injury or capillary damage. Aggressive early postoperative ultrafiltration improves cardiac performance, improves pulmonary compliance and alveolar oxygen transport, and diminishes the risk of multiorgan injury.

Postoperative Care

Important principles in postoperative pediatric cardiac intensive care are constant observation, monitoring of the electrocardiogram, continuous measurement of central venous, left atrial, and arterial pressure, continuous monitoring of systemic oxygen saturation with a pulse oximeter, repeated measurement of arterial and mixed venous blood gases, monitoring of fluids, electrolytes, and urine output, and management of mechanical ventilation and respiratory therapy (Fig. 17-1).

The child's body temperature should be maintained and a nasogastric tube inserted to prevent gastric distention. Clinical changes occur very rapidly in small children and neonates; reaction times must be rapid and the treatment precise if optimal results are to be achieved. Postoperative care requires close communication between the surgeon, the pediatric cardiologist, the intensivists, and the critical care nurses.

Four key areas of postoperative management are: (1) hemodynamics, (2) fluids, electrolytes, and renal function, (3) arrhythmias, and (4) mechanical ventilation—respiratory problems.

Hemodynamics

Hemodynamic monitoring of the postoperative patient requires continuous measurement of preload (central venous and left atrial pressures), systemic arterial pressure, systemic oxygen saturation, mixed venous oxygen saturation, and urine output. Physical examination also is helpful in determining the adequacy of perfusion, which is reflected in the temperature of the extremities. Cool extremities reflect a modest reduction in cardiac output, whereas cold feet and legs often indicate a severe depression in cardiac output. The mixed venous oxygen saturation reflects the level of peripheral oxygen extraction, indirectly reflecting the cardiac output. A mixed venous oxygen saturation of less than 40 percent and partial pressure of oxygen less than 25 mmHg suggests a significantly depressed cardiac output. The cardiac output can be measured directly in selected patients using a thermistor and thermodilution techniques.

Cardiac preload and intravascular volume status should be assessed by monitoring of central venous pressure or left atrial pressure as indicated. These measurements reflect the loading conditions of the ventricles. Separate monitoring of various chambers often is necessary because the left-sided cardiac function and the right-sided cardiac function may respond differently after repair of complicated congenital lesions. Attempts should be made to optimize the cardiac filling pressures. If the preload is decreased and intracardiac pressures are low, blood transfusion is recommended if the patient's hematocrit level is less than 40 percent and fresh frozen plasma if the hematocrit level is greater than 40 percent, continuing transfusion until the filling pressures are optimized. If the intracardiac pressures are elevated and the cardiac output is depressed, this usually reflects a problem with cardiac contractility or cardiac tamponade.

A common cause of decreased preload and hemodynamic instability in the early postoperative period is bleeding. Often a coagulopathy exists after cardiac surgery in infants, frequently because of the combination of hypothermia, hemodilution, and platelet dysfunction. It is not uncommon for the prothrombin time to be elevated to 15 to 20 s immediately postoperatively, with abnormal clot formation. This demands immediate correction with fresh frozen plasma and platelets. If bleeding persists after clotting studies normalize, a surgical source must be suspected and consideration must be given to surgical reexploration.

Cardiac tamponade must be suspected whenever hemodynamics deteriorate in a postoperative patient. The classic signs of tamponade are a low systemic blood pressure, a pulsus paradoxus, a high central venous pressure, and a widened mediastinal shadow on the chest radiograph. In many patients the classic signs are not present, and tamponade should be suspected and ruled out whenever signs of a low cardiac output are present.

If decreased preload and tamponade are not present, low cardiac output is most likely a result of depressed myocardial contractility, which may occur in any patient after intracardiac repair. Common causes of depressed contractility are myocardial edema secondary to cardiopulmonary bypass and ischemia-reperfusion, poor myocardial protection, hyperkalemia, hypoxia, drug toxicity, and intrinsic cardiac disease. Mechanical intracardiac defects also must be ruled out. Once obvious correctable causes have been excluded, the patient with poor cardiac contractility should be started on inotropic support. The most commonly used inotropic agents are dopamine (5 to 20 mg/kg/min), dobutamine (5 to 20 mg/kg/min), epinephrine (0.05 to 0.5 mg/kg/min), and norepinephrine (0.05 to 0.5 mg/kg/min). Phosphodiesterase inhibitors such as amrinone and milrinone have also been used, but these agents probably work mostly through vasodilation and a reduction in afterload because the myocardial phosphodiesterase—cyclic AMP system may be poorly developed in neonates. Inotropic agents should always be given through a central venous line.

Fluids, Electrolytes, and Renal Function

Careful monitoring of fluid intake and output is essential in critically ill postoperative patients. Fluid and blood administration must be balanced with urine output, blood losses, and insensible losses. The intraoperative procedure often is the initial cause of volume overload, secondary to hemodilution during cardiopulmonary bypass. The combination of cardiopulmonary bypass and hypothermia also often induces some degree of renal dysfunction, which limits the patient's ability to clear fluids postoperatively. Most neonates or infants undergoing complex intracardiac repair or hypothermic circulatory arrest are started on low-dose dopamine (3 to 5 mg/kg/min) immediately postoperatively to enhance renal blood flow.

The maintenance fluids are usually given with D5/NS, restricting sodium and volume intake. In small neonates, D10/NS is frequently used to maintain adequate serum glucose. Total fluids are restricted over the first 48 h. Normal maintenance fluid requirements are calculated as 100 mL/kg/24 h for the first 10 kg, plus 50 mL/kg/24 h for the second 10 kg, plus 20 mL/kg/24 h for weight above 20 kg. After operation, children are given 50 to 75 percent of maintenance calculations. Potassium is seldom replaced in the early postoperative phase unless the serum potassium level is less than 3.0 mEq/L in the presence of good cardiac output and urine output. When necessary, potassium chloride is given in one to two doses of 0.1 mEq/kg over 30 min each, after which the serum potassium level is remeasured.

Urine output is a very good indicator of organ perfusion, as low cardiac output often results in an immediate drop in urine output in infants. Some degree of renal dysfunction often occurs secondary to cardiopulmonary bypass. Most patients are started on renal doses of dopamine immediately after operation. Patients with poorly perfused, cool extremities, a low mixed venous oxygen saturation, and a dropping urine output should be started on inotropic support. Diuretics (furosemide 0.2 to 2 mg/kg) also are given to increase the urine output. An hourly urine output of less than 0.5 mL/kg should be of great concern, because this often reflects low cardiac output syndrome, impending renal dysfunction, or both. Because the problems associated with volume overload, myocardial edema, and hyperkalemia are often fatal, aggressive therapy with inotropic agents and diuretics is critical. If the urine output remains below 0.5 mL/kg/h and the patient does not respond within 1 to 3 hours, early peritoneal dialysis is recommended.

Arrhythmias

Cardiac arrhythmias after congenital cardiac surgery are not uncommon. The diagnosis is made by the standard 12-lead electrocardiogram, or by an atrial electrocardiogram where the atrial pacing wire is connected to the chest lead. The ECG is assessed for heart rate, rhythm, the presence of P waves, atrioventricular (A-V) conduction (or dissociation), and QRS morphology. In some patients, a transient bolus of adenosine aids in treatment and diagnosis. All serious arrhythmias should be treated promptly in consultation with the pediatric cardiologist and intensivist, because most postoperative arrhythmias are associated with a drop in cardiac output with progressive hemodynamic compromise.

Postoperative arrhythmias may be classified as bradyarrhythmias—either sinus node dysfunction or third degree atrioventricular block; and as tachyarrhythmias—either primary atrial tachycardia, atrioventricular reentry tachycardia, His bundle or junctional ectopic tachycardia, ventricular tachycardia, or ventricular fibrillation.

The postoperative *bradycardias* have two primary causes. The first, *sinus node dysfunction*, often results from injury to the sinoatrial (S-A) node. Patients with S-A node dysfunction usually develop ectopic or absent atrial activity with junctional or ventricular escape rhythms. This rhythm often can be overridden and treated by atrial pacing. Postoperative bradycardia also may occur secondary to *third-degree heart block*, which may develop secondary to surgical trauma or intrinsic disease. Patients with third-degree heart block and A-V dissociation require A-V sequential pacing. These patients should not be discharged from the hospital until the heart block resolves or a permanent pacemaker is placed.

Atrial tachycardia may arise from an *ectopic atrial focus* (with an abnormal P wave) or from *atrial flutter (atrial reentry tachycardia)*. Intravenous adenosine (100 to 300 mg/kg) may help establish the diagnosis and provide initial treatment. These arrhythmias usually are treated with drugs to slow A-V conduction, such as digoxin or verapamil, or by Class I or Class II antiarrhythmic agents.

Atrioventricular reentry tachycardia usually involves accessory pathways as seen in Wolf-Parkinson-White syndrome. A-V reentry tachycardia may require cardioversion and should be treated with Class I or Class II antiarrhythmic agents.

An increasingly recognized tachyarrhythmia after congenital heart surgery is *His bundle automatic tachycardia* or *junctional ectopic tachycardia (JET)*. This arrhythmia is characterized by a rapid heart rate (180 to 220) and A-V dissociation, with a QRS morphology that is similar to that noted during sinus rhythm. While JET frequently lasts for only 72 to 96 h, it is unfortunately associated with a high mortality rate that is a consequence of progressive cardiac dysfunction unless it is promptly treated and converted. Treatment involves sedation to decrease endogenous catecholamines, minimizing the use of exogenous catecholamines, neuromuscular paralysis, systemic cooling to 32 to 35°C and intravenous antiarrhythmia therapy with amiodarone. Amiodarone is a Class III agent that slows depolarization and repolarization. The loading dose is 5 mg/kg over 1 h, with a maintenance dose of 5 to 7 mg/kg/h.

Ventricular tachycardia or *ventricular fibrillation* may appear without warning but can be corrected if therapy can be started within 1 to 3 min. Immediate cardiopulmonary resuscitation (CPR) with closed-chest massage should be initiated. These patients should be treated with electric cardioversion (2 watt-sec/kg) and with intravenous Class I (lidocaine, procainamide) or Class III (bretylum, amiodarone) agents. Electrolyte abnormalities should always be ruled out by checking for potassium, magnesium, phosphorous, and other abnormalities.

Mechanical Ventilation—Respiratory Problems

Excellent respiratory and ventilator management is essential in the postoperative care of patients after congenital heart surgery. Many of these patients present with increased pulmonary blood flow preoperatively, congestive heart failure, and pulmonary edema. Respiratory management may be further complicated by the reactive pulmonary vasculature and reactive small airways found in neonates and infants. The secondary effects of cardiopulmonary bypass result in pulmonary capillary leakage with decreased lung compliance. While early extubation is recommended frequently in patients at low risk, most neonates and infants with complex lesions are ventilated for at least 24 h postoperatively.

The child usually is intubated with a nasotracheal tube, which should be properly secured. Because the tracheobronchial passages and the endotracheal tube are small, secretions are difficult to remove and dislodgment can occur easily. Meticulous suctioning is required. One of the most common causes of cardiac arrest or bradycardia postoperatively is acute hypoxia and respiratory acidosis from a plugged or dislodged endotracheal tube. The critical care team should be acutely aware of this possibility, and if the ventilated child develops acute hypoxia or bradycardia the patient should be disconnected from the ventilator, attached to a breathing bag with 100% oxygen, and suctioned. If breath sounds are not subsequently heard, strong consideration should be given to changing the endotracheal tube. Other mechanical considerations such as atelectasis or tension pneumothorax must be ruled out.

Mechanical ventilation is performed by delivering a tidal volume of approximately 10 mL/kg. Barotrauma is of great concern in children with immature or noncompliant lungs, and care is taken not to exceed a peak inspiratory pressure of 30 to 35 mmHg, because this can result in overdistention of the alveoli and cause pulmonary injury. Conversely, children in the first year of life are dependent on the distending ventilation pressure to keep the alveoli open. Lung compliance is poor postoperatively, and there is a strong tendency toward atelectasis. This may be prevented by positive end-expiratory pressure (PEEP), usually at 3 to 6 mmHg. Other than tidal volume and inspiratory pressure, the respiratory rate and inspired oxygen concentration are variables that can be manipulated.

Serial measurement of arterial blood-gas tensions is essential to assess oxygenation and adequacy of ventilation. Continuous monitoring of oxygen saturation may also be used,

along with monitoring of end tidal carbon dioxide tension. The desired arterial oxygen tension varies with the cardiac physiology and the degree of residual shunting. The appropriate level for a particular patient should be determined, and prolonged high levels of inspired oxygen should be avoided, because this results in oxygen toxicity with damage to the type II pneumocytes. Elevated arterial P_{CO_2} exceeding 40 to 45 mmHg occur from hypoventilation, resulting in acidosis and pulmonary vasoconstriction. In some patients this is desirable, but for most patients the tidal volume and respiratory rate should be adjusted to obtain a normal Pa_{CO_2} .

In patients with incompletely corrected physiology and continued bidirectional shunting, pulmonary and systemic blood flows are determined by the relative resistances of the pulmonary and systemic vascular beds. The extreme example of this is in the management of the patient with hypoplastic left heart syndrome who has undergone a stage 1 Norwood operation (outflow correction by conversion to single-ventricle physiology, with a central-systemic-to-pulmonary shunt for pulmonary blood flow—see section below). If the systemic oxygen saturation is too high and the Pa_{CO_2} is low, pulmonary blood flow is increased and the lungs become flooded at the expense of a decreased systemic cardiac output. Ideally, these patients should have balanced pulmonary and systemic flows, which is best achieved with a systemic oxygen saturation of 75 to 85 percent ($Pa_{O_2} = 40$ mmHg) and a Pa_{CO_2} of approximately 40 to 45 mmHg. Extra in-line carbon dioxide may be added to the ventilator circuit to achieve this goal without hypoventilating the patient. The systemic and mixed venous oxygen saturations are sequentially monitored to evaluate the pulmonary (Q_p) versus the systemic (Q_s) blood flows.

Pulmonary hypertensive crisis is a severe complication that is sometimes seen postoperatively in patients with reactive pulmonary vascular disease. This typically results in a suprasystemic pulmonary artery pressure, with a low systemic arterial blood pressure. While the central venous pressure and pulmonary arterial pressure are elevated, the left atrial pressure remains low because blood flow through the lungs is diminished. Patients at risk for pulmonary hypertensive crisis are those with large left-to-right shunts, such as patients with atrioventricular septal defect, transposition of the great vessels with ventricular septal defect, truncus arteriosus, total anomalous pulmonary venous return, or a large ventricular septal defect. These patients usually have preoperative pulmonary hypertension and an increased pulmonary vascular resistance secondary to medial hypertrophy in the pulmonary arterioles. The best treatment is prevention. Care should be taken to avoid hypoventilation or acidosis, maintaining a Pa_{O_2} above 85 to 90 mmHg and a Pa_{CO_2} of 34 to 38 mmHg, with a slight respiratory alkalosis. Hypoxia and acidosis from any cause are potent pulmonary vasoconstrictors. Patients with pulmonary hypertension and a high pulmonary vascular resistance usually are paralyzed and sedated with fentanyl for 24 to 48 h to minimize endogenous catecholamine production. Careful suctioning is used, because stimulation of the airway or hypoxia during suctioning can initiate a crisis. If possible, exogenous catecholamines and alpha-adrenergic agonists are avoided. Medications used to prevent or treat severe pulmonary hypertension are isoproterenol, nitroglycerine, nitroprusside, tolazoline, prostacyclin, amrinone or milrinone, and inhaled nitric oxide. Inhaled nitric oxide is a potent pulmonary vasodilatory that has been found to be highly efficacious in many patients.

OBSTRUCTIVE LEFT-SIDED LESIONS

Coarctation of the Aorta

Coarctation is a common congenital malformation, occurring in 10 to 15 percent of patients with congenital heart disease. It is more common in males (3:1 ratio). Coarctation of the aorta often represents a spectrum of disease, from isolated obstruction adjacent to the ligamentum arteriosus to diffuse hypoplasia extending proximally into the aortic arch. Classically, preductal or “infantile type” coarctation represents a diffuse narrowing of the aorta between the subclavian artery and the ductus arteriosus, usually with ductus-dependent blood flow distally. These children present with acute heart failure as newborns. Postductal or “adult type” coarctation involves a more localized narrowing at the site of insertion of the ligamentum arteriosus. Patients with localized coarctation are often asymptomatic, presenting with hypertension later in childhood. The extent and severity of coarctation varies widely, from diffuse aortic arch hypoplasia to a mild isolated aortic stenosis.

The ligamentum arteriosus is attached to the medial surface of the aorta near the site of coarctation in older patients. The stenotic area may have two or three component parts. The most frequent is a localized shelf, consisting of an infolding of the aortic media into the lumen. This is most visible on the aortic wall opposite the ligamentum arteriosum. In the lumen, a thickened ridge of intima may be present and may increase the severity of the stenosis.

Distal to the coarctation, the aorta usually is dilated. In adults, a true aneurysm forms in a small proportion of patients. Large, dilated intercostal arteries entering the distal aorta, providing collateral circulation around the site of obstruction, are a striking feature. In older patients, these large arteries produce “notching” of the ribs that is visible on the chest radiograph. Rarely, they may become aneurysmal and rupture.

Patients with infantile coarctation present early in life. In these patients a varying degree of “tubular hypoplasia” is common, consisting of a narrowing of the aorta between the coarctation and the left subclavian artery, often extending proximally to involve the distal aortic arch. The condition usually is fatal unless treated and is associated with other cardiac defects, such as ventricular septal defect, bicuspid aortic valve, and mitral valve anomalies in 75 percent of the cases. In this condition, a large patent ductus perfuses the distal aorta with blood from the pulmonary artery. The coarctation is located proximal to this. The association of coarctation of the aorta, subaortic stenosis, parachute mitral valve, and supraaortic left atrial ring is known as Shone's complex.

Pathophysiology and Clinical Manifestations

Neonates usually present with severe congestive heart failure, which is exacerbated by the presence of a ventricular septal defect or by an additional valvular lesion. If the coarctation is severe, closure of the ductus arteriosus precipitates extreme acidosis and renal shutdown as well as pulmonary congestion. These patients must be vigorously resuscitated, often requiring intubation, prostaglandin infusion, intravenous dopamine, intravenous furosemide, and correction of acidosis before urgent operation.

After the first year of life, congestive heart failure rarely occurs before the age of twenty. Hypertension, however, becomes a significant concern. Children in their early teens often have significant hypertension with changes in the aortic wall, including aneurysm formation. Without treatment the average life expectancy is only 30 to 40 years. The four most common causes of death in patients who do not undergo surgical treatment are rupture of the aorta, cardiac failure, rupture of intracranial aneurysms, and bacterial endocarditis.

The diagnosis often is made by a routine school physical examination uncovering hypertension. Headache, epistaxis, and leg fatigue are the most frequent symptoms. Claudication in the lower extremities is uncommon. Before surgery these patients should be treated with beta-adrenergic blockers to lessen ventricular strain, lower the hypertension, and minimize the risk of postoperative rebound hypertension.

The classic combination of hypertension in the upper extremities with absent or decreased pulses in the lower extremities of a child immediately suggests coarctation. If weak femoral pulsations are present, direct measurement of the blood pressure in the upper and lower extremities may be necessary to confirm the diagnosis. Prominent pulsations from collateral circulation may be visible in the neck and over the muscles of the shoulder girdle. A systolic murmur usually is audible over the left hemithorax.

In neonatal coarctation the diagnosis is accurately established by echocardiography, and emergency repair usually is done on the basis of this test alone. In older patients the chest radiograph may help to establish the diagnosis by demonstrating bilateral notching of the ribs posteriorly. Notching is unusual in patients under 6 years of age but is almost always present by age fourteen. The electrocardiogram characteristically shows signs of left ventricular hypertrophy and often left ventricular strain. In most patients the diagnosis can be made accurately from the clinical findings in combination with the echocardiogram. MRI or enhanced magnetic resonance angiography can establish the diagnosis with certainty and outline the anatomy preoperatively.

Operative Indications

Neonates and infants are treated urgently, at the time of presentation. Usually they are stabilized for 24 to 48 h in the intensive care unit to minimize congestive heart failure, correct acidosis, and improve renal perfusion. Concomitant defects may be treated at the time of coarctation repair or staged for treatment at a later time, depending on the severity. In older children the ideal age for operation is between 3 and 4 years. Children with mild to moderate coarctation are treated whenever proximal hypertension or significant left ventricular hypertrophy begins to develop. Although balloon dilation has been used successfully to treat recurrent coarctation, this technique is less frequently used for primary coarctation repair, and operative correction usually is the treatment of choice.

Operative Technique

A left posterolateral thoracotomy in the fourth intercostal space is used. The coarctation usually is readily seen, with the typical medial indentation at the site of insertion of the ligamentum arteriosum and large, tortuous intercostal arteries entering the distal aorta. The mediastinal pleura is incised, after which the vagus nerve is retracted medially, noting the course of the recurrent laryngeal nerve encircling the ligamentum arteriosus. The aortic arch proximal to the left subclavian artery, the left subclavian artery, the ligamentum arteriosum, and the distal aorta are serially mobilized. The intercostal arteries should be isolated and preserved, but they may be divided if necessary.

Once the vessels have been adequately mobilized, the proximal aorta, the left subclavian artery, and the distal aorta are occluded with vascular clamps, after which the coarctation is repaired. Repair is performed with any one of three techniques: (1) subclavian flap arterioplasty (Fig. 17-2); (2) resection and end-to-end anastomosis using absorbable vascular sutures to allow for growth (Fig. 17-3); or (3) wide resection with beveled hemiarch anastomosis (Fig. 17-4). The technique used depends on the particular anatomy and the length of coarctation; the beveled hemiarch technique is used for patients with long tubular coarctation and diffuse distal arch hypoplasia.

Once the aorta is clamped, the distal aortic pressure may be measured to determine the adequacy of flow through collateral channels. This is less important in neonates but is critical in older children with moderate coarctation. A distal aortic pressure of more than 50 to 55 mmHg suggests adequate collateral flow. In this situation, the length of the cross-clamp time becomes less critical because the collaterals provide adequate perfusion of the distal spinal cord. If the distal aortic pressure is less than 45 to 50 mmHg, the child is at increased risk for spinal cord ischemia if the cross-clamp time exceeds 20 min. In these patients the operation must be planned and executed in an expedient manner or some form of distal shunt must be used.

The anastomosis usually is done with continuous absorbable monofilament suture. Some surgeons have advocated placing interrupted sutures in the anterior wall of the anastomosis to avoid a “purse-string” effect and to allow for further growth, but we have found this unnecessary in most cases. After completion of the anastomosis and removal of vascular clamps, the blood pressure should be measured proximal and distal to the anastomosis to confirm that no significant gradient remains. If repair is done for neonatal coarctation in association with ventricular septal defect, pulmonary artery pressure is measured after repair of the coarctation. If the pulmonary artery pressure remains elevated, immediate pulmonary artery banding is done to restrict pulmonary blood flow or, alternatively, formal repair of the ventricular septal defect is performed in 7 to 10 days.

In adults, extensive degenerative changes in the aorta, calcification, and fibrosis make insertion of a prosthetic graft necessary in most patients, because direct anastomosis cannot be done. In such instances the coarctation may be excised and an end-to-end interposition graft or an end-to-side graft from the distal arch and subclavian artery to the aorta beyond the site of coarctation, bypassing the coarctation site, may be used.

Results

Repair of isolated coarctation has an operative mortality of 1 percent or less, approaching zero in older children. Repair of neonatal coarctation in children with associated cardiac

lesions is more difficult, with a mortality of 10 to 15 percent, depending on the severity of the associated conditions. Complications include paraplegia (0 to 0.5 percent), renal failure, bleeding, paradoxical postoperative hypertension with intestinal ischemia, chylothorax, and late reoperation for recurrent coarctation.

Paradoxical hypertension typically occurs in the first 48 to 72 h after operation, usually in older patients with severe, long-standing coarctation. These patients almost always have had severe hypertension preoperatively. The syndrome is related to an increase in arterial pressure in visceral arteries, previously functioning with a lower mean pressure. These patients may develop severe abdominal pain and persistent, severe hypertension postoperatively. In extreme cases intestinal necrosis can occur. This risk of this complication is lessened by starting beta-adrenergic blockers preoperatively and continuing beta blockers and sodium nitroprusside postoperatively to tightly control hypertension, which usually eliminates this complication.

Some residual, persistent hypertension is common in patients operated on after 5 years of age and increases with age. This is related to an up-regulation of the renin-angiotensin system. Residual hypertension occurs much less frequently in patients operated on before 3 to 4 years of age.

Regardless of the technique used, recurrent coarctation occurs in a small number of patients within 10 to 15 years. The incidence ranges from 2 to 15 percent, depending on the patient's age and the severity of the coarctation at the time of initial repair. Balloon dilation of the recurring coarctation is the initial treatment of choice for most patients, although reoperation is feasible.

Interrupted Aortic Arch

Interrupted aortic arch (IAA) is a rare defect. Neonates with this condition present with severe congestive heart failure and acidosis, with hypoperfusion of the lower half of the body. These symptoms begin 2 to 3 days after birth, when the patent ductus arteriosus begins to close. Without surgery death usually occurs within 7 to 10 days. Approximately 30 percent of patients with Type B IAA have DiGeorge's syndrome, manifested by an absence of thymic tissue, hypocalcemia, and immunologic abnormalities.

Pathologic Anatomy and Physiology

IAA is classified by the anatomic site of aortic interruption. In *Type A IAA*, which occurs in 40 percent of the cases, the interruption is distal to the left subclavian artery, similar in location to that of patients with infantile type coarctation. It is sometimes difficult to differentiate between severe infantile coarctation and Type A IAA, because they are physiologically similar. *Type B IAA*, the most common form (55 percent), results in total interruption of the arch between the left carotid and left subclavian arteries. *Type C IAA* accounts for only 5 percent of the cases, with the interruption occurring proximally between the innominate artery and the left carotid artery.

The majority of patients with IAA have a large *ventricular septal defect (VSD)*. There also is an association between IAA and other left-sided obstructive lesions. These patients often exhibit varying degrees of hypoplasia of the *left ventricular outflow tract (LVOT)* and the ascending aorta. The aortic valve is bicuspid in 40 to 50 percent of patients, the aortic annulus may be moderately to severely hypoplastic, and a significant number of patients with Type B IAA have subaortic obstruction.

Children with IAA are totally dependent on ductal flow for perfusion of the lower half of the body. As long as the ductus arteriosus is open, the condition frequently is not apparent immediately after birth. As the patent ductus begins to close, however, the child develops poor perfusion of the lower body with rapidly progressive metabolic acidosis and renal insufficiency. Because of the impedance to forward blood flow produced by the interrupted aorta, severe pulmonary congestion and heart failure also rapidly develop. The pulmonary congestion is worsened by left-to-right shunting across the ventricular septal defect.

Diagnosis

Prompt diagnosis and treatment are essential; these children rapidly become acidotic and die. It is estimated that approximately 10 percent of the children with IAA die before operation. The diagnosis is almost always made with echocardiography. MRI scanning should be performed to determine the site of arch interruption and to assess the remainder of the ascending aorta and the LVOT. Cardiac catheterization rarely is necessary.

Treatment

Once the diagnosis of IAA is made an immediate infusion of prostaglandin E₁ is begun to maintain ductal patency. Acidosis should be corrected and inotropic agents are often begun to lessen the degree of heart failure and enhance renal perfusion. Intubation and mechanical ventilation frequently are required as well. Once the acidosis is corrected and the urine output improves, urgent operation is performed.

Type A lesions are corrected through the left side of the chest with an incision in the fourth intercostal space, similar to the repair for aortic coarctation. The proximal aortic arch, left subclavian artery, and distal aorta are mobilized widely. Resection and beveled hemiarch repair are performed as for neonatal coarctation with tubular arch hypoplasia. If a ventricular septal defect is present, placement of a pulmonary artery band may be considered, or the child is allowed to recover and an early complete repair is performed. A complete repair through a midline approach may be considered in some patients if the VSD is large.

Most children with IAA Types B and C should undergo early complete repair through a midline sternotomy with deep hypothermia and circulatory arrest. The aorta is mobilized, the coarcted segment is resected, and primary end-to-end anastomosis usually can be performed. The associated ventricular septal defect is repaired through a right atriotomy incision, and other cardiac defects are corrected at this time. When severe LVOT obstruction is present in association with IAA, the subvalvular obstruction may be corrected with septal myotomy and myectomy. Augmentation of the ascending aorta and arch also may be considered in patients with multiple levels of obstruction.

A small proportion of patients have such severe associated LVOT and subvalvular obstruction that they are considered to be within the spectrum of hypoplastic left heart syndrome. This group of patients generally has an aortic annulus less than 4 mm in diameter with severe subvalvular obstruction. In these patients consideration should be given to performing a conversion to a single-ventricle type of physiology and performing a stage 1 Norwood procedure.

Results

The operative mortality for Type A IAA is 5 to 10 percent, depending on the severity of the associated cardiac pathology. Repair of Types B and C IAA with VSD has an operative mortality of 10 to 25 percent. Late survival rate is approximately 60 to 80 percent at 5 years. Reoperation for recurrent obstruction at the repair site may be necessary, and patients with subaortic obstruction may develop progressive LVOT obstruction. Recurrent stenosis at the repair site may be treated with balloon dilation, whereas progressive LVOT obstruction requires reoperation.

Jonas and associates reported the results of a multi-institutional study of the repair of 183 patients with IAA and VSD. Survival was 73 percent at 1 month and 63 percent at 4 years. The risk of death was increased by low birth weight, younger age, Type B anatomy, smaller VSD, and subaortic obstruction. Some reintervention was required for a coexisting obstructive lesion in 23 percent of the patients within 3 years. In patients with multiple levels of left ventricular outflow obstruction, augmentation of the ascending aorta and arch during initial surgery had a positive effect on survival.

Aortic Stenosis (Valvular/Subvalvular/Supravalvular)

Categories

Congenital Aortic Stenosis

Congenital aortic stenosis is a relatively common abnormality, representing 8 to 10 percent of all patients with congenital heart disease. The stenosis may be discrete or it may encompass diffuse parts of the left ventricular outflow tract. Patients with critical neonatal aortic stenosis may have diffuse endocardial fibroelastosis within the left ventricle, which may become true hypoplastic left heart syndrome if severe. Aortic stenosis frequently is associated with coarctation of the aorta, pulmonary stenosis, mitral valve abnormalities, patent ductus arteriosus, and ventricular septal defect.

Aortic stenosis is three to four times more frequent in males than in females. No causative factors are known for valvular stenosis. The variant of supravalvular stenosis appears caused by a genetic linkage, resulting in abnormal elastic tissue. Supravalvular stenosis is known to be associated with peripheral pulmonary stenosis and Williams syndrome, which is characterized by abnormal facies, mental retardation, and hypercalcemia. Subaortic obstruction may be a result of genetically linked hypertrophic cardiomyopathy.

Congenital aortic insufficiency is rare. When found, it is usually secondary to other abnormalities, such as ventricular septal defect, Marfan syndrome or another connective tissue disease, congenital stenosis with secondary insufficiency, or rheumatic disease.

Valvular Stenosis

Approximately 75 percent of patients with congenital valvular stenosis have a bicuspid aortic valve with varying degrees of annular hypoplasia. A bicuspid valve is a common anomaly occurring in nearly 2 percent of the population, usually without significant stenosis early in life. A common anatomic finding is fusion of the right and left cusps, with the undeveloped commissure represented by a median raphe that may or may not extend to the ventricular wall. Thickening of the valve cusp from abnormal tissue is common and may contribute to the stenosis. Mild poststenotic dilatation of the ascending aorta is common.

In infants with severe valvular stenosis, more severe deformities are common, such as a single-cusped valve, a small annulus with annular hypoplasia, and diffuse ventricular fibroelastosis. At the severe extreme, the left ventricle may be so underdeveloped as to become nonsalvageable, and the patient is considered to have hypoplastic left heart syndrome.

Subvalvular stenosis is rare. The pathology ranges from a discrete fibrous ring with localized obstruction to diffuse fibromuscular obstruction. Gradations exist between these two extremes.

Discrete ringlike stenosis is present in about one-half of patients with subvalvular obstruction. In these patients the proximal muscular outflow tract may be secondarily narrowed from muscular hypertrophy. The stenotic ring usually is connected to the base of the aortic cusp with a small raphe of fibrous tissue. Two other anatomic relationships also are of importance. Beneath the noncoronary cusp the stenotic ring is attached to the ventricular septum, where the conduction bundle may be injured if appropriate landmarks are not observed. Beneath the left coronary cusp, the ring is often attached to the base of the anterior leaflet of the mitral valve, which must be protected during excision of the ring.

Diffuse fibromuscular subvalvular stenosis or *tunnel-like subaortic obstruction* results from diffuse fibromuscular narrowing of the subvalvular left ventricular outflow tract. The fibromuscular obstruction usually is concentric and severe, encompassing a long "tunnel" of the outflow tract. Symptoms usually develop early in life and are severe. The obstructive

gradient is fixed and not dynamic, which helps in differentiating it from idiopathic hypertrophic subaortic stenosis.

Idiopathic Hypertrophic Subaortic Stenosis (IHSS) is an inherited hypertrophic cardiomyopathy that results in asymmetric septal hypertrophy, systolic anterior motion (SAM) of the anterior leaflet of the mitral valve, and dynamic left ventricular outflow tract obstruction. In patients with IHSS, symptoms gradually increase with age as the septal hypertrophy increases. The symptoms are angina, dyspnea, and syncope. A systolic murmur of medium intensity near the apex, but not prominent at the base of the heart, may be the first sign of disease. With progressive disease, atrial fibrillation, systemic emboli, and sudden death are the most significant events. Sudden death is distressingly common, presumably from an arrhythmia.

Supravalvular Stenosis

There is considerable variation in the anatomic type of supravalvular obstruction. Peterson and colleagues, reviewing 68 cases, found three types: *hourglass* (45 cases), *diffuse hypoplasia* (14 cases), and *membranous* (9 cases). Associated abnormalities are frequent, including a close association with Williams syndrome. Peripheral pulmonary stenosis should always be ruled out in patients with supravalvular aortic stenosis. In addition to peripheral pulmonary stenosis, focal stenosis of the aortic arch also may be present. Approximately 30 percent of the patients have associated involvement of the aortic valve cusps, usually because of distortion causing aortic regurgitation. Coronary abnormalities are found in a significant number of the patients.

Pathophysiology

The physiologic abnormality is directly related to the severity of the obstruction. At one extreme is the neonate with critical aortic stenosis. These babies present with severe heart failure and metabolic acidosis, often requiring intubation, inotropic support, and prostaglandin infusion to maintain ductal patency. Intensive therapy must be initiated before surgery to “unload” the heart, correct acidosis, and improve visceral organ perfusion. After stabilizing the patient, urgent intervention is indicated with balloon angioplasty or operative correction.

Milder forms of congenital aortic stenosis often have little immediate physiologic significance. These patients may remain asymptomatic for many years, slowly developing the classic findings of left ventricular hypertrophy and cardiomegaly. Progressive stenosis can lead ultimately to the development of significant concentric ventricular hypertrophy, with decreased exercise capacity, chest pain, arrhythmias, or congestive heart failure. A mean gradient of less than 50 mmHg usually does not produce enough disability to require operation, but correction should be considered in asymptomatic patients if the gradient is more than 50 to 60 mmHg and the cross-sectional area is less than 0.5 cm^2 . Another indication for operation is deteriorating left ventricular systolic function according to echocardiographic or radionuclide studies. Moderate levels of stenosis of uncertain significance can be further assessed by exercise testing. A finding of decreased exercise capacity, an abnormal drop in the ejection fraction in response to exercise, arrhythmias, or pulmonary congestion on exercise testing usually is an indication for operation. The goal is to initiate intervention on the basis of deteriorating but reversible changes in physiology—before the onset of irreversible cardiac damage. Operation is indicated in almost every patient once symptoms develop. In patients with subvalvular stenosis, operation is indicated once the gradient exceeds 40 to 50 mmHg or with the first sign of aortic valve involvement, before the development of significant aortic insufficiency, in an attempt to preserve the aortic valve.

Clinical Manifestations

Neonates with severe aortic stenosis present with congestive heart failure, acidosis, and low-output syndrome in the first days of life. Many older children with significant stenosis are asymptomatic, emphasizing the importance of echocardiography or catheterization to measure the severity of the abnormality. The most common symptoms are fatigue, dyspnea, angina, arrhythmias, and syncope, found in 30 to 50 percent of patients. Usually these are found in patients with a gradient of more than 50 to 60 mmHg and significant left ventricular hypertrophy.

The three most frequent physical findings are a systolic ejection murmur, a forceful left ventricular impulse, and a narrow pulse pressure. The systolic murmur is a harsh, ejection-type murmur, heard best in the second right interspace, widely transmitted to the neck and arms. A palpable thrill may be present. With long-standing disease and left ventricular hypertrophy the ventricular impulse is forceful and heaving. The pulse pressure often is decreased when stenosis is severe, although it may be normal. A diastolic murmur may indicate concomitant aortic insufficiency.

The electrocardiogram, indicating the degree of left ventricular hypertrophy, provides a moderately sensitive noninvasive guide to the severity of aortic stenosis, but it has distinct limitations. The usual abnormalities are signs of left ventricular hypertrophy and subsequent depression of the ST segment and inversion of T waves. With a gradient of more than 50 mmHg, a left ventricular strain pattern may be seen. Some patients may have severe obstruction with few ECG abnormalities. The chest radiograph may show signs of pulmonary congestion and cardiomegaly, or it may be normal in patients with more moderate stenosis.

The echocardiogram is helpful in establishing the diagnosis and should be performed immediately once the diagnosis is suspected. It is accurate in determining the transvalvular gradient and the annular size and in assessing the subvalvular left ventricular outflow tract. In patients with supravalvular stenosis, an MRI scan should be done to further delineate the anatomy and to assess the aortic arch and peripheral pulmonary arteries. If the diagnosis is suspected or the gradient is of uncertain significance, exercise testing and cardiac catheterization should be considered.

Treatment

Valvular Aortic Stenosis

Neonatal aortic stenosis requires urgent intervention. Balloon valvuloplasty and surgical valvotomy using cardiopulmonary bypass have been successful. Initial therapy depends on several factors, including the degree of valvular degeneration, the size of the aortic annulus, and the presence of associated pathology. Initial balloon valvuloplasty has been most successful in children with well-formed bicuspid valves and an aortic annulus of adequate size. When feasible this approach obviates taking the critically ill neonate to the operating room. In neonates with more primitive valvular anatomy, such as those with an extremely thickened bicuspid valve or a single-cusped valve, and in patients with a small, nearly hypoplastic annulus, surgical therapy yields the best initial results. In either case, initial valvuloplasty should be considered palliative; further surgical correction is almost always required later in life.

Surgical valvotomy is performed with the patient on cardiopulmonary bypass and cardioplegic arrest. The ascending aorta is incised with a curved incision extending down into the noncoronary sinus. Calibrated Hegar dilators are useful for measuring the diameter of the stenotic orifice before and after commissurotomy. Nomograms based on the child's body surface area are used to estimate the appropriate annular size. Cautious valvotomy is then performed, cutting the fused stenotic area up to the commissure (Fig. 17-5). Overcorrection can result in tearing the valve and producing aortic insufficiency. The annulus usually grows as increased antegrade flow is established.

With valvular stenosis, the fused commissures are carefully incised with a small knife blade, carefully dividing the fused commissures exactly along the center of the fibrous raphe in order to leave a thick margin on each of the two cusps that are separated. The incisions may be carried to the aortic wall or terminated 1 to 2 mm from the wall, depending on the anatomy. Commissural incisions should be limited to where the commissures are well formed. With the classic bicuspid valve, the commissure between the right and left cusps is underdeveloped. Usually no incision at all is made in this area, leaving the valve as a bicuspid valve. Primitive, thickened, hypoplastic leaflet tissue is partially excised to decrease the thickness of the leaflets and improve leaflet mobility. In older children with isolated stenosis from a bicuspid valve, balloon valvuloplasty often is the treatment of choice.

Valve replacement is reserved for children with significant annular hypoplasia or those with recurrent stenosis. When significant annular hypoplasia is present, a more extensive annular enlarging—valve replacement procedure often is necessary. Also, progressive aortic insufficiency or mixed recurrent stenosis with progressive insufficiency may develop in children who have previously undergone correction of valvular or subvalvular stenosis, necessitating reoperation for valve replacement.

Most children who require valve replacement are now treated with the Ross procedure (pulmonary autotransplant). When significant annular hypoplasia is present, extended aortic root replacement using a cryopreserved human homograft or a combination of Ross procedure and root enlargement is used. The use of prosthetic valve replacement is avoided whenever possible in children, since xenografts (bioprostheses) have a high early failure rate from progressive calcification, and mechanical prostheses necessitate long-term anticoagulation therapy.

The operative risk for repair of critical aortic stenosis in neonates is significant, with mortality ranging from 10 to 30 percent, depending on the size of the aortic annulus and the degree of left ventricular hypoplasia. For older children, there is little operative risk in repair of valvular aortic stenosis, with mortality less than 1 percent. Late reoperation often is required for patients undergoing correction early in life, but it may be postponed for many years if the initial procedure is successful. Valve replacement often is required as the secondary procedure in 10 to 15 years. The operative mortality is approximately 1 percent for the Ross procedure and other valve replacement operations not requiring extensive annular enlargement.

Hsieh and associates reported long-term results in 59 patients with a mean follow-up of 18 years. Of the 13 patients who died, sudden death occurred in seven, at least four of whom were known to have significant residual disease. Actuarial analysis indicated that the probability of reoperation increased from 2 percent at 5 years to 44 percent at 22 years. Dobell et al. reported more discouraging results; one-third of the group required a repeat operation within 10 years.

Elkins and associates reviewed 301 patients treated with balloon or surgical valvuloplasty. A subsequent valve replacement was required in 160 patients, whose progress was then followed to evaluate the efficacy of valve replacement. Survival was significantly better after the Ross operation than after other forms of valve replacement. Similarly, the risk of reoperation was lower after the Ross operation (87 percent freedom from reoperation at 9 years) than after other forms of valve replacement (55 percent freedom from reoperation at 9 years). The Ross operation offers significant advantages over other forms of valve replacement in children, with better rates of survival and freedom from reoperation and a better quality of life.

All patients undergoing treatment for congenital aortic stenosis should be seen at yearly intervals indefinitely, with echocardiograms performed to assess valve function and to detect any growth of the aortic annulus. Exercise testing may be indicated before clearing patients for vigorous physical exercise. The long-term prognosis varies, with many patients going over 20 years without subsequent problems. Most reports indicate that at least 30 to 50 percent of the patients require a subsequent operative procedure within 10 to 20 years. Once valve replacement is required, the late results after the Ross procedure are exceedingly good, although these patients must also be observed in long-term follow-up, as late operation may subsequently be necessary.

Subvalvular Stenosis

For treatment of patients with a *discrete subvalvular ring*, the valve cusps can be carefully retracted and the fibrotic ring excised (Fig. 17-6). Excellent visualization is required to prevent injury to the base of the aortic valve, the mitral valve, or the conduction bundle in the ventricular septum. The ring may consist of thin, fibrous tissue, which is easily removed, or it may be a thick, fibrotic structure. The fibrous ring often involves the base of the left coronary cusp of the aortic valve and the anterior leaflet of the mitral valve and

must be removed carefully from these areas. Usually the fibrous ring involves approximately 270 degrees of the circumference of the left ventricular outflow tract. Complete excision is required.

In many patients with a known fibrous ring, more diffuse subvalvular obstruction also is present, and failure to address this finding results in an increased incidence of late recurrence and restenosis. The surgeon should carefully look for fibromuscular obstruction during surgery and, if any is found, a block of muscle from the septum should be resected, similar to the operation for *IHSS*. Subvalvular obstruction can recur after initial operative correction, particularly in patients who have diffuse fibromuscular obstruction. The incidence of late operation is lessened by the more aggressive use of septal myotomy and myectomy during the initial operative correction of subvalvular obstruction.

Tunnel-like or *diffuse subvalvular obstruction* requires extensive resection of fibromuscular tissue from the left ventricular outflow tract. The operation is similar to the myotomy and myectomy performed for *IHSS*. This is adequate in most cases, although patients with severe *LVOT* obstruction may have a combination of annular hypoplasia and subvalvular obstruction and require aortoventriculoplasty. Konno described the initial aortoventriculoplasty procedure, using Dacron patch enlargement of the LVOT and aortic annulus and aortic valve replacement with a mechanical prosthesis. Patients who require aortoventriculoplasty are more often treated with extended root replacement using a homograft or with the combination of the Ross procedure and patch enlargement of the outflow (Fig. [17-7](#)). These procedures obviate the need for anticoagulation therapy, and the Ross procedure also has the advantage of growth potential.

IHSS

Most patients with IHSS are treated medically initially, with operation reserved for those with symptomatic, severe obstruction that does not improve with medical therapy. Beta-adrenergic blockers or calcium channel blockers usually are used. Surgical myotomy and myectomy is indicated in symptomatic patients with an outflow gradient of 50 mmHg or greater despite medications.

Using a transaortic approach, a rectangular block of ventricular muscle is excised from the septum, extending from just below the aortic valve, down the septum several centimeters, stopping at the level of the bottom of the anterior leaflet of the mitral valve. The myectomy may be 0.5 to 1.5 cm wide and should stay to the left of the right coronary ostium to avoid penetrating the conduction bundle. Upon completing the procedure, relief of the gradient should be confirmed by measuring left ventricular and aortic pressures.

Supravalvular Stenosis

With the hourglass type of stenosis, widening the stenotic area by adding a patch of Dacron or pericardium produces excellent correction. Before the patch is placed, the fibrous ridge above the sinotubular junction should be excised as completely as possible. Usually a bilobed patch is placed with extension into the right and the noncoronary sinuses of Valsalva (Fig. [17-8](#)). This opens the sinotubular junction and provides effective relief of obstruction. An alternative method is to excise totally the supravalvular ridge of stenosis and perform an end-to-end anastomosis between the distal aorta and the aortic root, advancing small "tongues" of the distal aorta into the noncoronary and right coronary sinuses of Valsalva for enlargement. The incidence of reoperation is low after correction of supravalvular stenosis.

Congenital Mitral Valve Disease

Congenital abnormalities of the mitral valve are rare, accounting for less than 1 percent of all cases of congenital heart disease. Rheumatic heart disease, endocarditis, and cardiomyopathy can produce mitral valve pathology during childhood. Severe mitral insufficiency of ischemic origin usually is seen in children only in association with an aberrant origin of the left coronary artery.

Pathology

Four general types of congenital pathologic mitral valve abnormalities were described by Ruckman and Van Praagh: (1) Typical congenital mitral stenosis, with varying degrees of obliteration and fusion of the chordae tendineae and subvalvular apparatus and mild-to-moderate deficiency of leaflet tissue, is the most common form (50 percent) of congenital mitral valve disease. Mitral insufficiency may be present concomitantly because of annular dilation, leaflet prolapse, abnormal clefts, leaflet tissue deficiency, and subvalvular restriction. (2) True "parachute mitral valve" is relatively uncommon. The term "parachute mitral valve" refers to the insertion of all chordae tendineae into a single, shortened papillary muscle. This results in restricted leaflet mobility with valvular obstruction. More commonly the pathology is somewhere along a continuum between typical congenital mitral stenosis, which results from fusion or obliteration of "fanlike" chordae, and "parachute mitral valve" as a result of true single papillary muscle. (3) A more severe form of congenital mitral stenosis develops when the mitral annulus is significantly hypoplastic. Mitral stenosis with annular hypoplasia may be part of diffuse left ventricular outflow tract obstruction. Hypoplastic left heart syndrome represents the most extreme form of this condition. Some degree of annular hypoplasia is present in approximately 40 percent of patients with congenital mitral stenosis. (4) Supraannular mitral stenosis is a relatively rare condition resulting from a supraannular ring of connective tissue in the left atrium, producing physiologic stenosis.

Associated cardiac malformations occur in 75 percent of patients with congenital mitral obstruction. These include ventricular septal defect (30 percent), valvular aortic stenosis (29 percent), aortic atresia and hypoplastic left heart syndrome (29 percent), less severe forms of subvalvular *LVOT* obstruction (30 to 60 percent), and coarctation of the aorta (27 percent). Abnormal left ventricular muscle with endocardial fibroelastosis occurs in most patients with mitral stenosis and diffuse LVOT obstruction and in nearly 50 percent of all patients with congenital mitral stenosis. The combination of supraannular mitral ring, parachute mitral valve, left ventricular outflow obstruction, and aortic coarctation is called Shone's complex.

Clinical Manifestations

Symptoms of pulmonary venous congestion often appear in infancy and include dyspnea, orthopnea, and pulmonary edema. If the condition is untreated approximately one-half of the patients die within 6 months after the appearance of symptoms. Those with less severe obstruction, better left ventricular development, and fewer associated lesions may not develop symptoms until 2 to 4 years of age and rarely remain asymptomatic until 10 to 12 years of age.

The chest radiograph and electrocardiogram often demonstrate an enlarged left atrium, pulmonary congestion, and P mitrale of stenotic lesions. With mitral insufficiency, cardiomegaly and pulmonary congestion are often present. The echocardiogram is the primary diagnostic tool, with transesophageal echocardiography used as necessary. With transesophageal echocardiography lesions in the left atrium, the valve, and the subvalvular apparatus can be readily identified and the degree of stenosis and insufficiency accurately assessed. Cardiac catheterization may be recommended before operative repair in some patients.

Treatment

Operation should be timed to avoid significant deterioration in left ventricular function. Because of the possibility that repair may not be feasible and valve replacement may be required, the anatomy should be carefully analyzed echocardiographically before surgery. If valve repair is not feasible, the patient may be managed medically until later in the clinical course. If valve repair is feasible, operation should be recommended at the first sign of deteriorating ventricular function. While operation is clearly indicated, once congestive heart failure or significant symptoms develop, a more optimal time for intervention would be before the development of symptomatic left ventricular dysfunction, such as the first echocardiographic sign of diminishing systolic function. If valve repair is accomplished at this time, the long-term functional results are excellent.

Results

Coles reported operative experiences with reparative procedures in 48 patients, with an operative mortality of only 2.9 percent. This study suggests improved late results when valve repair was possible compared with a similar group of patients undergoing mitral valve replacement. Kodoba reported a 5-year survival rate of only 43 percent after mitral valve replacement in the first year of life, and a 3-year freedom-from-reoperation rate of only 45 percent. The most important factors affecting survival are the severity of associated defects and the adequacy of left ventricular function. After operation late trends suggest improved results when mitral valve repair is feasible, and this is preferred over valve replacement whenever possible. Our own experience with more than 70 cases of congenital mitral valve procedures over the past 15 years suggests that valve repair should be feasible in more than 90 percent of patients, with an operative mortality of approximately 1 percent. The long-term results after valve repair are excellent.

Cor Triatriatum

Pathology

This abnormality may be viewed as a variant of total anomalous pulmonary venous drainage, except that the unreabsorbed common pulmonary venous sinus empties into the left atrium through a restricted aperture rather than through a vertical vein to the right side of the heart. The common venous chamber is superior and posterior to the left atrium, with a diaphragm separating this chamber from the true left atrium, where the left atrial appendage enters. A small opening in the thick muscular diaphragm is the only communication between the upper pulmonary venous chamber and the lower true atrial chamber. This severely obstructs pulmonary venous return and produces supraannular mitral obstruction, with left-to-right shunting across any defect in the atrial septum. An atrial septal defect is present in about 70 percent of cases, generally communicating with the common upper pulmonary venous chamber, resulting in a left-to-right shunt.

Clinical Manifestations

Cor triatriatum produces severe pulmonary congestion with pulmonary artery hypertension, identical to the pathophysiology of mitral stenosis. Congestive heart failure is usually quite severe, and the patients' symptoms are pronounced. Gradients as high as 20 mmHg have been recorded between the venous chamber and the lower left atrial chamber. The mortality is high when pulmonary venous obstruction is present, and if the anomaly is not corrected operatively 70 to 75 percent of these infants die in the first year of life.

The chest radiograph shows pulmonary congestion with right ventricular enlargement. Right ventricular hypertrophy is evident on the electrocardiogram, varying with the degree of pulmonary hypertension. Standard or transesophageal echocardiography usually is diagnostic, outlining the abnormal chambers. MRI is helpful in establishing the diagnosis in some cases. Cardiac catheterization is often unnecessary, although it permits measurement of pulmonary artery pressure and precise delineation of other, associated anomalies; catheterization may be used if the diagnosis is uncertain. The differential diagnosis includes total anomalous pulmonary venous return, congenital pulmonary vein stenosis, and mitral stenosis. Occasionally cor triatriatum is encountered unexpectedly in a patient with an atrial septal defect and an inordinate degree of left-to-right shunting.

Treatment

The need for early operation varies, depending on the severity of pulmonary venous obstruction. Operation should be performed promptly in patients with severe obstruction because of the rapid development of pulmonary hypertension. Less severely obstructed patients with significant left-to-right shunting may be operated on later in childhood, as is the case for correction of isolated atrial septal defect.

During infancy hypothermic circulatory arrest may be used, although standard perfusion techniques are used in older patients. The defect is approached through the right atrium, enlarging the atrial septal defect and excising the left atrial membrane to create a common, unobstructed left atrial chamber. This eliminates all obstruction to pulmonary venous

drainage and allows unrestricted flow through the normal mitral valve. The atrial septal defect is closed with a patch of pericardium. The operative risk is low, with a mortality of less than 1 percent, and late results are excellent, with surviving patients exhibiting normal physiology.

INCREASED PULMONARY BLOOD FLOW (LEFT-TO- RIGHT SHUNTS)

Patent Ductus Arteriosus

Patent ductus arteriosus is one of the most common forms of congenital heart disease, constituting about 10 percent of all cases of congenital heart disease. The increased incidence of patent ductus in premature infants is widely recognized, varying inversely with the birth weight and gestational age, ranging in frequency from of 25 to 100 percent. The presence of a patent ductus arteriosus represents a normal physiologic state in severely premature infants. In older, full-term infants, the incidence of patent ductus is much less common, representing a true pathologic event. Patent ductus arteriosus is two to three times more common in females than in males.

The ductus arteriosus, which develops as an embryologic remnant of the sixth left aortic arch, is an important normal fetal pathway connecting the pulmonary artery at its bifurcation to the aorta just beyond the origin of the left subclavian artery. Through this channel in embryonic life, blood bypasses the collapsed lungs, flowing directly from the pulmonary artery into the aorta. With the expansion of the lungs at birth, the ductus normally closes within a few days, becoming the fibrotic ligamentum arteriosum.

The physiologic stimuli responsible for closure of the ductus have been studied in detail. Changes in the oxygen tension of the arterial blood exert a profound stimulus on the closure. An important mechanism of closure lies the distinctive histologic structure of the wall of the ductus, which is different from that of the pulmonary artery or the aorta. As the ductus closes, the wall of the ductus contracts, the internal elastic membrane fragments, and smooth muscle projects into the lumen as progressive fibrosis obliterates the patent channel. Naturally occurring prostaglandins oppose closure of the ductus. In full-term infants, the ductal tissue is more responsive to oxygen, leading to ductal closure, whereas in premature infants the prostaglandin effect is more prominent, resulting in increased ductal patency.

Closure of a patent ductus can be significantly hastened by the administration of indomethacin, which blocks the synthesis of the prostaglandins that normally oppose contraction of ductal smooth muscle. In contrast, ductal patency can be maintained when necessary by an intravenous infusion of prostaglandin E₁.

Pathology and Pathophysiology

The diameter of a ductus typically is 5 to 7 mm, though it ranges from as little as 2 to 3 mm to more than 10 mm. The length of the ductus ranges from 5 to 10 mm. Associated anomalies occur in approximately 15 percent of cases; the most common are ventricular septal defect and coarctation of the aorta, although a patent ductus may occur in association with many other congenital cardiac defects.

Depending on the diameter of the ductus, a varying amount of blood is shunted from the aorta to the pulmonary artery, constituting a left-to- right shunt. In a large ductus, the Q_p:Q_sratio may be 3:1 or greater. The severity of symptoms is directly proportional to the size of the shunt.

In infancy the high pulmonary vascular resistance of fetal life subsides gradually in the first month of life. In some infants with patent ductus, the increased pulmonary blood flow causes the pulmonary vascular resistance to remain elevated, resulting in pulmonary hypertension. The pulmonary resistance usually decreases immediately to normal after closure of the patent ductus, but only a partial regression may occur if the pulmonary vascular resistance has been elevated for a long time. In some patients the pulmonary vascular resistance may become fixed by as early as 5 to 6 years of age, resulting in right-to-left shunting and cyanosis. Patients with patent ductus arteriosus have an increased susceptibility to bacterial endocarditis.

Clinical Manifestations

In premature infants a large patent ductus may cause serious heart failure, whereas most full-term infants and older children are asymptomatic. When symptoms are present, the most common are palpitations, dyspnea, and decreased exercise tolerance. Symptoms of congestive heart failure may develop in adults. Approximately 40 percent of patients with a large patent ductus die before the age of 45 years if untreated.

The hallmark of a patent ductus arteriosus is the continuous “machinery” murmur, one of the most distinctive signs in clinical medicine. A wide pulse pressure usually is found with a large ductus, produced by a decrease in diastolic pressure. In the extremely large ductus, the diastolic pressure may approach very low levels and be associated with peripheral vascular findings similar to those of severe aortic insufficiency. Signs of pulmonary congestion may be present.

The diagnosis may be made in premature infants from the widened pulse pressure detected through an umbilical arterial catheter and confirmed by echocardiography. The chest radiograph usually shows increased pulmonary blood flow. In older children the diagnosis is made from the characteristic murmur and by echocardiography. Catheterization usually is used only in the treatment of children with patent ductus arteriosus and is not necessary for diagnostic purposes. In adult patients diagnostic catheterization is performed to measure the pulmonary vascular resistance and to assess ductal length and any calcification, which may make repair difficult.

Treatment

Ductal closure can be achieved in most premature infants with indomethacin therapy, producing ductal closure in approximately 90 percent of patients with two or three courses of therapy. Operation is indicated in premature infants with severe respiratory insufficiency who do not respond to indomethacin therapy. In full-term infants who do not have congestive heart failure, ductal closure should be performed at some time between 6 months and 2 years of age. The intraluminal insertion of a specially designed coil in the cardiac catheterization laboratory results in successful occlusion of the patent ductus the in vast majority of older children. Surgical division is recommended in children who have a ductus of large diameter or of extremely short length, making coil occlusion more risky or unfeasible. The mortality of surgical ductal closure approaches zero.

Mikhail and colleagues reported on experiences with operative closure through a small posterolateral thoracotomy in 306 infants with an average age of 11 days, without any deaths. Some centers recently have used thoroscopic approaches for ductal closure with excellent results, although additional clinical benefit over standard techniques is hard to document. Coil occlusion in older children also carries a low operative risk, with a mortality close to zero, and achieves excellent intermediate-term results.

Operative Technique

For operative closure, the patent ductus is exposed through a short, posterolateral incision in the fourth intercostal space. In premature infants the patent ductus is double ligated with a heavy silk or doubly occluded with metallic clips; operating time usually is less than 30 min and the procedure is extremely safe. In older children the preferred technique is complete surgical division. A partial-occlusion clamp is placed on the aorta adjacent to the ductus and an angled vascular clamp is placed on the pulmonary-artery side of the ductus. The ductus is divided sharply and each side is oversewn with a continuous double layer of monofilament suture. Care is taken to ensure that the suture line is flush with the aorta to avoid late aneurysm formation because of an unobliterated ductus diverticulum.

Aortopulmonary Window

Aortopulmonary window is a rare abnormality. At the Toronto Children's Hospital, only 23 of 15,000 patients with congenital heart disease who were seen over a period of 20 years had an aortopulmonary window.

Pathology and Pathophysiology

Embryologically, the defect results from incomplete development of the spiral septum dividing the primitive truncus arteriosus into the aorta and pulmonary artery. Persistent truncus arteriosus is a more severe malformation of similar cause. The opening, or “window,” between the aorta and the pulmonary artery may vary in diameter from 5 to 30 mm. Usually it is located proximally, near the ostium of the coronary arteries. At least 30 percent of patients have a severe additional cardiac malformation.

The large left-to-right shunt is similar to that of a large patent ductus arteriosus or ventricular septal defect. The clinical course is rapidly progressive because of the tremendous amount of shunting, with early development of severe congestive heart failure. Increased pulmonary vascular resistance occurs quickly, by 6 months of age.

Clinical Manifestations

The clinical findings may be identical to those of a large patent ductus arteriosus, with a continuous murmur and wide pulse pressure. Often, however, only a systolic murmur is present because of the severe pulmonary hypertension. The differential diagnosis includes large patent ductus, ventricular septal defect, and truncus arteriosus.

The diagnosis is readily made by echocardiography and can be confirmed by MRI if necessary. Cardiac catheterization usually is unnecessary unless the child is older and a fixed pulmonary vascular resistance is suspected.

Treatment

Operation should be performed as soon as the diagnosis has been established because of the rapidity of development of irreversible pulmonary vascular disease. A transaortic approach usually is used, and large defects are closed with a prosthetic patch. The pulmonary artery is clamped separately. Care is taken to avoid injury to the coronary arteries and the pulmonary valve. In patients operated on in infancy or before the development of severe pulmonary vascular disease, the results have been excellent. The operative risk is proportional to the increase in pulmonary vascular resistance, and the overall operative mortality is less than 5 percent.

Ventricular Septal Defects

Ventricular septal defect (VSD) is a common form of congenital heart disease, constituting 20 to 30 percent of congenital defects. There are no known etiologic factors. Associated anomalies are common. These include patent ductus arteriosus, coarctation of the aorta, atrial septal defect, right ventricular outflow tract obstruction, tetralogy of Fallot, double-outlet right ventricle, transposition of the great arteries, truncus arteriosus, and aortic insufficiency from prolapse of an aortic valve cusp into the ventricular septal defect.

Pathology and Pathophysiology

Ventricular septal defects have been classified according to the position in the ventricular septum: (1) perimembranous, (2) posterior inlet or atrioventricular canal type, (3) outlet or supracristal, and (4)muscular (Fig. 17-9).

Perimembranous VSDs (Fig. 17-10) are the most common in patients requiring surgery, accounting for 80 percent. These defects involve the membranous septum and include the malalignment type of defects seen in tetralogy of Fallot. The bundle of His is located along the posterior, rightward rim of the septum, where it bifurcates into left and right conduction bundles. The defect may extend superiorly into the outlet septum next to the aortic valve annulus, which often is visible through the upper part of the defect. Operative

closure with a Dacron patch frequently is possible by working via the right atrium through the tricuspid valve (Fig. [17-11](#)). In some cases in which the defect is high, a transverse right ventriculotomy incision may be used for exposure. The base of the tricuspid valve leaflet may be temporarily detached for better exposure of the upper part of the defect. Posteriorly, the sutures often are woven into the base of the tricuspid valve leaflet to avoid the conduction tissue along the crest of the septum.

A rare perimembranous defect produces shunting from the left ventricle to the right atrium, either directly or through defective tricuspid tissue along the base of the annulus. The resulting shunt usually is large because of the great difference in pressure between the left ventricle and the right atrium.

Inlet or atrioventricular canal type defects are perimembranous defects that extend posteriorly, beneath the conal papillary muscle and the tricuspid valve, involving the inlet septum. The conduction tissue runs adjacent to the rim of the septum, similar to perimembranous defects, and care must be taken to avoid heart block during repair.

Outlet or supracristal defects are in the infundibular septum, adjacent to the pulmonary and aortic valves. Consequently, aortic insufficiency is a common feature because of deficient support in the aortic annulus combined with a Venturi effect from the left-to-right shunt. These defects are safely away from the conduction bundle, so heart block is not a risk, but concomitant repair of the aortic valve frequently is necessary.

Muscular *VSDs* are the most common, although many close spontaneously and do not require surgery. Closure usually occurs before 2 to 3 years of age. Muscular defects are located inferiorly, anywhere in the muscular septum, and are often multiple. They are safely away from conduction tissue. The rare “Swiss cheese” type of muscular VSD consists of multiple communications into the right ventricle, making visualization and closure difficult.

VSDs vary from as small as 3 to 4 mm to larger than 3 cm in size. The defect may be classified as restrictive or nonrestrictive, depending on whether the right ventricular pressure is elevated to systemic levels or not. In general the nonrestrictive defect is equal in diameter to the aortic annulus. In patients with a large, nonrestrictive VSD the right ventricular pressure is equal to systemic pressure and the left-to-right shunt ($Q_p:Q_s$) may be 4:1 or greater, producing pulmonary congestion and heart failure. In large defects the degree of shunting is dictated by the relative levels of pulmonary and systemic vascular resistance. With a long-standing defect, the pulmonary resistance may increase significantly, leading to irreversible pulmonary vascular changes. When an irreversible increase in pulmonary vascular resistance develops, a right-to-left shunt may develop, leading to cyanosis. This pathologic condition is referred to as Eisenmenger’s syndrome.

Small restrictive septal defects ($Q_p:Q_s < 1.5:1$), which produce little or no increase in the right ventricular pressure, have few immediate physiologic consequences. The long-term risk of bacterial endocarditis is increased, apparently because of endocardial damage from the jet of blood through the defect. Some cardiologists recommend closure of small defects to lower the lifelong risk of endocarditis, but this is controversial and not routinely performed.

Clinical Manifestations

Patients with small defects usually are asymptomatic even though a loud murmur and thrill may be present. With large defects, severe heart failure, dyspnea, and pulmonary congestion are common. These patients may have frequent respiratory symptoms and pneumonia or may show a lag in growth and development. Severe cardiac failure usually occurs within the first few months of life or much later in adulthood. Patients with increased pulmonary vascular resistance may be deceptively asymptomatic for several years, until cyanosis and hemoptysis develop.

The chest radiograph may be normal or may show cardiomegaly with pulmonary congestion. The electrocardiogram usually shows signs of left ventricular or biventricular hypertrophy. The echocardiogram is almost always diagnostic, demonstrating the location and size of the defect and any associated cardiac anomalies. The echocardiogram can be used to estimate the magnitude of left-to-right shunting and the pulmonary artery pressure. More precise information can be obtained by cardiac catheterization, but this usually is not necessary unless the pulmonary pressure is near the systemic pressure, requiring an accurate assessment of pulmonary vascular resistance.

Treatment

Small defects should simply be observed, since 60 to 70 percent will close in early life. More than one-half of small muscular defects close before 3 years of age and about 90 percent by 8 years.

The treatment of large defects depends on the presence of cardiac failure or increasing pulmonary vascular resistance. Severe cardiac failure in infancy may be fatal, and prompt operation is performed in the first few weeks or months of life. Even without severe heart failure, children with large left-to-right shunts are operated on electively between 3 and 6 months of age, since irreversible changes in the pulmonary vascular bed may develop early, even during the first year of life. When pulmonary artery pressure is already at systemic levels and the pulmonary vascular resistance is increased, the operative risk is higher, but long-term benefit can be obtained if the patient still has a reactive pulmonary vascular bed with left-to-right shunting. The criteria for inoperability vary significantly but generally include a nonreactive, fixed pulmonary vascular resistance of greater than 10 Woods units. When operation is performed at less than 6 to 9 months of age, reversibility usually is noted.

Operative Technique

Operation is performed through a median sternotomy with extracorporeal circulation. If a patent ductus arteriosus is present, it must be closed at the beginning of operation. The *VSD* usually is closed through a right atrial approach and occasionally through a short transverse ventriculotomy. The transatrial approach is preferable because it minimizes the risk of ventricular dysfunction and arrhythmias. A prosthetic patch is routinely used (see Fig. [17-11](#)). The critical part of the operation is to avoid heart block by identifying key anatomic guides at the posterosuperior margin of the defect. With a still, dry field, the fibrous trigone located at the bottom of the noncoronary sinus can be identified on inspection through the ventricular septal defect. The conduction bundle passes through this trigone and then along the area where the membranous septum joins the muscular septum posteriorly (see Fig. [17-10](#)). Placing sutures to the right of an imaginary line projected between the fibrous trigone and the papillary muscle of the conus usually avoids injury to the conduction bundle.

With today’s techniques, the risk of heart block is very small. Outlet (infundibular) defects and muscular defects can be readily repaired with a prosthetic patch because there is no danger of injury to the conduction bundle. After cardiopulmonary bypass has been established, residual shunts may be detected by measuring the oxygen content of blood samples drawn simultaneously from the right atrium and the pulmonary artery. Intraoperative transesophageal echocardiography also may be used to confirm complete closure of the defect.

A small proportion of patients with *VSDs*, usually those with outlet defects, develop severe aortic insufficiency from prolapse of an aortic valve cusp into the underlying defect. The insufficiency often is progressive as the aortic cusp herniates to a greater degree, virtually tamponading the underlying septal defect. Surgical correction often can be done by aortic valvuloplasty.

Results

The operative mortality in *VSD* repair is less than 2 to 3 percent, depending on the size and the age of the patient and the pulmonary vascular resistance. The risk of perioperative heart block is less than 2 percent. Residual defects may develop around the repair in a small percentage of patients but are usually of no hemodynamic consequence. Late results are excellent; most patients have normal ventricular function and exercise capacity after repair.

Atrial Septal Defects

A variety of malformations involve the atrial septum or the pulmonary veins and result in a left-to-right shunt of blood from the systemic to the pulmonary circulation. These include ostium secundum defects, sinus venosus defects with partial anomalous pulmonary venous return, and ostium primum defects (incomplete atrioventricular septal defects). The physiologic abnormality is identical with secundum defects and with sinus venosus defects, consisting simply of a left-to-right shunt. Atrial septal defects are among the most common cardiac malformations, representing 10 to 15 percent of all cases of congenital heart disease. They are more than twice as frequent in females than in males. Embryologically, the secundum defects result from failure of the septum secundum to develop completely.

Pathology and Pathophysiology

Atrial septal defects (ASDs) vary widely in size and location. The majority of *ASDs* are ostium secundum defects (Fig. [17-12](#)), located in the middle part of the atrial septum in the area of the ostium secundum. *ASDs* may range from openings as small as 1 cm in diameter to the virtual absence of the atrial septum with a common atrium. Most are 2 to 3 cm in diameter. A patent foramen ovale should not be considered an atrial septal defect, for it is a normal opening in 15 to 25 percent of adult hearts. Because of its slit-like construction, a normal foramen ovale allows shunting of blood only from right to left. A “high” subcaval defect near the orifice of the superior vena cava is commonly referred to as a sinus venosus defect (Fig. [17-13](#)), and it is usually associated with anomalous entry of one or more right pulmonary veins into the superior vena cava. This most common form involves drainage of the upper and middle lobe veins, which enter the superior vena cava below the entry site of the azygos vein. More unusual defects include common atrium, different forms of “unroofing” of the coronary sinus, and low ostium secundum defects that extend toward the inferior vena cava. Right pulmonary veins, which enter the right atrium directly, may be found with a common atrium or with a large posterior ostium secundum defect. Part of the septum may be fenestrated, but true multiple defects are rare.

An unusual variant of partial anomalous pulmonary veins entering the inferior vena cava has been described as a “scimitar” syndrome, emphasizing a characteristic radiologic appearance resulting from the shadow of the anomalous vein, which is parallel to the right border of the heart. The malformation is associated with hypoplasia of the right lung and anomalous origin of the pulmonary arteries from the aorta. A left-to-right shunt is present.

A rare variant of atrial septal defect is an ostium secundum defect combined with mitral stenosis, known as Lutembacher’s syndrome. The mitral stenosis retards the flow of blood from the left atrium to the left ventricle and produces an enormous left-to-right shunt through the septal defect, with massive dilatation of the pulmonary arteries. Some mitral valve prolapse occurs in 10 to 20 percent of patients with atrial septal defects, because of underfilling of the left ventricle. This usually resolves simply by repairing the atrial septal defect, with less than 5 percent having significant mitral insufficiency that must be corrected at operation.

An atrial septal defect results in a left-to-right shunting because of compliance and resistance characteristics between the left and right sides of the cardiac circulation. The thick-walled left ventricle is less compliant than the right ventricle, and the systemic vascular resistance is higher than the pulmonary resistance. The shunt is left-to-right despite the absence of a pressure difference across the defect. The size of the septal defect exerts influence only if it is small and restrictive. During infancy the left-to-right shunt remains small until the pulmonary vascular resistance drops at 1 to 3 months of age and the right ventricle becomes more compliant, increasing the shunt. Most older children with defects of significant size have shunts of 3:1 or greater.

Pulmonary vascular changes do not develop early in life, in contrast to patients with ventricular septal defects, and pulmonary hypertension infrequently develops, occurring in less than 5 percent of children with atrial septal defects. Increased pulmonary vascular resistance may occur during the fourth or fifth decade, however, if the defect is left untreated.

Cardiac failure occurs very late, usually in the sixth decade, after the onset of pulmonary hypertension and atrial fibrillation. Without treatment, life expectancy is decreased by 15 to 20 years.

Clinical Manifestations

Symptoms are uncommon in the first few years of life because the shunt is small until the right ventricular hypertrophy of infancy has subsided. Frequently children with large shunts are physically active and asymptomatic. The most frequent symptoms are fatigue, palpitations, and exertional dyspnea. In adults, signs of congestive heart failure or arrhythmias gradually appear, often with the first pregnancy or later in life.

A soft systolic murmur usually is audible in the second or third left intercostal space. In the first few years of life this murmur may be faint or considered a functional murmur, but it increases after 2 years of age. The murmur arises from increased flow through the right ventricular outflow tract. The second pulmonic sound is characteristically widely split and “fixed.”

The chest radiograph may show mild to moderate cardiac enlargement, principally the result of a large right ventricle. The right atrium and pulmonary artery are also prominent, with increased vascularity in the lung fields. The electrocardiogram usually is characteristic with a right-axis deviation. The echocardiogram usually is diagnostic, and cardiac catheterization is seldom necessary.

Treatment

Because most children with atrial septal defects are asymptomatic, operation is frequently recommended on the basis of a large echocardiographic defect with significant left-to-right shunting. Most defects 1 to 2 cm in size or larger should be closed at 2 to 4 years of age. The only contraindication to operation is increased pulmonary vascular resistance and Eisenmenger’s syndrome, which occurs much later in life.

Operative Technique

The operation is performed with the patient on extracorporeal perfusion (cardiopulmonary bypass) through a standard sternotomy incision or through a less invasive right minithoracotomy incision. Complete repair with excellent long-term results is achieved with both approaches, and the surgical team should use the approach that they are most familiar with; the overall operative mortality should approach zero in patients undergoing atrial septal defect repair.

Once operative exposure is obtained and the patient is placed on cardiopulmonary bypass, the heart is electrically fibrillated or arrested with cardioplegia, so that the defect can be repaired precisely. The right atrium is opened (Fig. 17-14), and the defect is closed with continuous suture or with a small pericardial patch. Most ostium secundum defects in children can be closed primarily. Large ostium secundum defects with a near common atrial chamber may require patch closure with pericardium (Fig. 17-15). Large defects with partial anomalous venous drainage into the right atrium are corrected by placement of a pericardial patch in such a way as to recreate the atrial septum, redirecting the anomalous veins into the newly created left atrial chamber.

Sinus venosus defects also are closed by rerouting the anomalous pulmonary venous blood from the right upper and middle lobe veins across the high sinus venosus defect, using an intracardiac pericardial baffle. This simultaneously corrects the partial anomalous venous drainage and closes the septal defect. Care must be taken to avoid obstructing drainage of the anomalous veins or the superior vena cava. Native atrial tissue often is used to enlarge the caval-atrial junction and prevent obstruction of the superior vena cava after sinus venosus repair, using an inverted Y-to-V advancement flap of right atrial appendage onto superior vena cava.

Several centers have performed closure of secundum defects in the catheterization laboratory, using either “clamshell” or “angel-wing” devices. Early reports have been encouraging in properly selected patients, although some problems with device fracture or migration have occurred in a small number of patients. The long-term risks of clot formation and endocarditis also remain uncertain. Device closure of atrial septal defects is an exciting new technical development that may be feasible in a significant number of patients with ostium secundum–type defects.

Results

Operative mortality for surgical treatment of uncomplicated atrial septal defect approaches zero. In our experience at the New York University Medical Center, no deaths have occurred in children undergoing repair of secundum or sinus venosus defects over the past 15 years, which supports the policy of routine closure of virtually all ASDs. Long-term survival is primarily related to age and pulmonary vascular resistance. Murphy and associates found late survival rates to be equal to those of the normal population in patients operated on early in life before the development of atrial fibrillation, heart failure, and pulmonary hypertension. The 30-year survival rate was 97 percent for patients whose defect was repaired early in life but only 40 percent for those whose repair was made after 40 years of age.

Outcomes data support a policy of routine closure of ASDs, even in older adult patients, as long as the patient does not have a fixed increased pulmonary vascular resistance. The results reported by Fiore and associates for surgical repair in adults described survival rates that were significantly higher than in nonsurgically treated patients. If the pulmonary vascular resistance is significantly elevated, the operative risk is increased and long-term benefit is less compared with early repair. Early operation during childhood is indicated whenever feasible.

Incomplete Atrioventricular Septal Defects

The terms *incomplete atrioventricular septal defect*, *incomplete atrioventricular canal defect*, and *ostium primum atrial septal defect* are used interchangeably. These defects are relatively uncommon, accounting for 4 to 5 percent ASDs. Associated abnormalities include unroofed coronary sinus, patent ductus arteriosus, persistent left superior vena cava, coarctation of the aorta, and left ventricular outflow tract obstruction. Approximately 20 percent of patients with incomplete atrioventricular septal defect have Down syndrome. Except for this unusual association, no etiologic factors are known.

Pathology and Pathophysiology

The two significant anatomic defects are a cleft in the anterior leaflet of the mitral valve and a low, crescent-shaped defect in the lower atrial septum (Fig. 17-16). The cleft in the anterior leaflet of the mitral valve may be partial, extending for a short distance from the ventricular septum, or complete, separating the entire anterior leaflet into halves. Chordae tendineae usually are attached to the margins of the cleft, constituting a “trileaflet valve,” with little or no mitral insufficiency. In other patients significant mitral insufficiency occurs. As described by Perloff, failure of the endocardial cushions to fuse produces a configuration in which the atrioventricular valves are in an abnormally low position and the aortic valve is in an abnormally high anterior position, resulting in the characteristic “gooseneck” deformity seen on the left ventricular angiogram. In extreme cases this may lead to left ventricular outflow tract obstruction. The endocardial cushion defect in the septum results in inferior displacement of the conduction system, which produces a characteristic left-axis deviation on the electrocardiogram.

The physiologic abnormalities are a left-to-right shunt combined with mitral insufficiency. When mitral insufficiency is minimal, the physiologic abnormality is identical to that of a large atrial septal defect of the ostium secundum type. When mitral insufficiency is moderate or severe, left ventricular failure and pulmonary hypertension appear early in life and produce a much more severe impairment of cardiac function than is seen in ostium secundum–type septal defects. An increase in pulmonary vascular resistance with pulmonary hypertension may develop but is more frequent with complete atrioventricular septal defects.

Clinical Manifestations

When mitral insufficiency is minimal, the clinical picture is similar to that of ostium secundum atrial septal defect. With significant mitral insufficiency, cardiac failure with pulmonary congestion and dyspnea may be fatal in the first year of life unless surgically corrected.

The chest radiograph usually shows a moderate cardiac enlargement, involving the right and left ventricles. Increased pulmonary vascularity is common. The electrocardiogram is useful in typically showing a left-axis deviation with counterclockwise rotation, compared with right-axis deviation in patients with ostium secundum defects. The echocardiogram shows classic abnormalities and demonstrates any valvular insufficiency. The echocardiogram is sufficient to confirm the diagnosis, and cardiac catheterization is performed only if significant pulmonary hypertension is present and the degree of reversibility is in question.

Treatment

In most patients, operative correction of the defect should be performed between the ages of 1 and 4 years. When pulmonary hypertension and cardiac failure or significant valvular insufficiency are present, operation may be necessary in infancy. Rarely, an adult is seen in the fourth or fifth decade without symptoms of heart failure and an unsuspected incomplete atrioventricular septal defect. These patients are those in whom mitral insufficiency has been minimal, with a clinical course similar to an ostium secundum–type of ASD. In most patients the combination of a left-to-right shunt and mitral insufficiency results in progressive cardiac enlargement and pulmonary congestion during childhood.

Operative Technique

Operation is performed through a median sternotomy or a small right anterior thoracotomy incision, with the patient on extracorporeal circulation. The operative objectives are correction of the mitral insufficiency and closure of the atrial septal defect, while taking care to avoid heart block from injury to the conduction bundle along the posterior margin of the defect.

The right atrium is widely opened, and the crescent-shaped septal defect is examined. The cleft in the anterior leaflet of the mitral valve is inspected carefully, as is the underlying ventricular septum, ruling out an unsuspected complete atrioventricular defect.

The authors prefer to close the cleft in the anterior mitral valve leaflet with three or four interrupted figure-of-eight sutures (Fig. 17-17). Although some surgeons do not close the cleft, routine closure lowers the risk of late postoperative valvular insufficiency. After repair of the cleft in the mitral leaflet, the atrial septal defect is repaired, usually with a patch of pericardium. Along the posterior rim of the defect, near the apex of the triangle of Koch, the penetrating conduction bundle is very superficial. To avoid heart block, the sutures are inserted superficially and leftward along the annulus of the mitral valve, or well rightward of the coronary sinus, redirecting coronary sinus flow into the left atrium. Both patch techniques are successful in minimizing the risk of heart block. Repair of the tricuspid valve usually is not necessary.

Results

The operative mortality is 1 to 2 percent for the group of patients without additional risk factors. Factors that increase the operative risk are hypertension, mitral insufficiency, and left ventricular outflow tract obstruction. If repair with adequate correction of valvular insufficiency is accomplished before the development of severe pulmonary hypertension, the recovery usually is uneventful, similar to that for ostium secundum ASD. The risk of heart block is approximately 1 to 2 percent. Late complications include recurrent mitral

insufficiency, which occurs in less than 10 percent of patients, with less than 5 percent of patients requiring subsequent reoperation.

The functional results and late survival rates are excellent in the majority of patients. King and associates reported long-term results in 199 patients, the majority of whom had maintained an excellent result after operation. Late survival was 96 percent at 20 years, which matched the general population.

Complete Atrioventricular Septal Defects

Pathology and Pathophysiology

Complete atrioventricular septal defect also is referred to as *complete atrioventricular canal defect* or *complete endocardial cushion defect*. The malformation results from failure of fusion of the endocardial cushions in the central portion of the heart, causing a large defect involving the atrial and ventricular septum (Fig. [17-18](#)). The central portion of the annulus between the mitral and tricuspid valves also fails to form, creating a single, six-leaflet atrioventricular valve. Down syndrome is present in approximately 80 percent of patients with complete atrioventricular septal defect.

The variations in valvular deformity in patients with complete atrioventricular septal defect was described by Rastelli in 1966. The Rastelli classification divides the deformity into three groups, types A, B, and C, on the basis of the presence of clefts or septal attachments in the bridging superior common leaflet. Since the posterior leaflets also can have varying pathology, it is more practical to visualize the common atrioventricular valve as a six-leaflet structure, overlying a large septal defect that involves the ventricular and the atrial septum. The bridging and chordal attachments of the various leaflets are described separately. When all components are present but the VSD is restrictive, the term *intermediate or transitional atrioventricular septal defect* is used. When the single atrioventricular valve overrides one ventricle by more than 50 percent, with underdevelopment of the other ventricle, the lesion is termed *unbalanced*. When the defect is severely unbalanced, a biventricular repair may not be feasible, and the patient is treated as having single-ventricle physiology. The physiologic defect is a large left-to-right shunt at the atrial and ventricular levels, resulting in pulmonary hypertension and cardiac failure in infancy. The severity of the symptoms depends on the extent of insufficiency of the atrioventricular valve and the size of the VSD component. When the VSD is large or when atrioventricular valvular insufficiency is severe, the clinical course is a malignant one, with heart failure, pulmonary hypertension, and death within 6 months without operative correction. More than one-half of the children with complete atrioventricular septal defect die by 1 to 2 years of age without treatment.

The diagnosis is established principally by echocardiography. Cardiac catheterization should also be done for evaluation of patients with severe pulmonary hypertension and elevated pulmonary vascular resistance, particularly if the child is more than 6 months of age or if other associated lesions are suspected. The catheterization shows a typical “gooseneck” deformity in the left ventricular outflow tract.

Treatment

The use of pulmonary artery banding to diminish pulmonary blood flow in patients with complete atrioventricular septal defect, previously a common practice, now is uncommonly used except in children with extremely unbalanced defects in whom a biventricular repair is not possible. Early complete repair is recommended for most patients, usually before 6 months of age. If possible, repair is done electively before the development of severely increased pulmonary vascular resistance or significant atrioventricular valvular insufficiency. If the patient develops significant congestive heart failure early in life, repair should be performed earlier, at 2 to 3 months of age.

Operative Technique

The operative procedure consists of placement of a prosthetic patch to correct the underlying ventricular septal defect (Fig. [17-19 A](#)), reattachment of the atrioventricular valve leaflets in such a way as to create separate left-sided and right-sided valves (Fig. [17-19 B](#)), and closure of the ostium primum atrial septal defect component (Fig. [17-19 C](#)). Care is taken to avoid injury to the conduction bundle, as in repair of incomplete atrioventricular septal defect. The repair may be performed with a single-patch technique, using a single piece of Dacron for the VSD and ASD components, or with a two-patch technique, using separate patches for the VSD and ASD components. The authors prefer the two-patch technique because it allows more precise correction of any atrioventricular valvular insufficiency and may be associated with less late leaflet dehiscence, since the leaflet tissue is not divided. Excellent results also are obtained with the single-patch method.

Results

The operative mortality in repair of complete atrioventricular septal defect is 3 to 5 percent. Factors that increase the risk are the presence of significant preoperative atrioventricular valvular insufficiency, elevated pulmonary vascular resistance, unbalanced anatomy, and associated lesions such as left ventricular outflow tract obstruction or tetralogy of Fallot.

The authors' experience at the New York University Medical Center includes more than 70 patients undergoing complete repair over 15 years, with an operative mortality of less than 5 percent. Many of these patients had increased pulmonary vascular resistance and moderate-to-severe valvular insufficiency preoperatively. At late follow-up the New York Heart Association (NYHA) functional status of 75 percent was class I or II, and 95 percent were free of late valvular insufficiency.

Bando and associates reported on their experience from 1974 to 1995 using the two-patch technique with 203 patients. The operative mortality decreased substantially over the 20-year period, averaging 3 percent for the post-1990 period; the 10-year survival rate was 91.3 percent. After repair, the left-sided valve remained competent in 94 percent of the patients on late echocardiographic follow-up. Similar results were reported by Hanley and associates in 301 patients operated on at Boston Children's Hospital using the single-patch technique, with an operative mortality of 3 percent after 1987 and a late risk of recurrent valvular insufficiency of 7 percent.

CYANOTIC LESIONS

Any intracardiac defect producing right-to-left shunting of unoxygenated venous blood results in systemic oxygen desaturation and cyanosis. Typical cyanotic conditions, such as tetralogy of Fallot, pulmonary atresia, and tricuspid atresia, have significantly decreased pulmonary blood flow. These patients may require a palliative systemic-to-pulmonary shunt to improve pulmonary blood flow if early total repair is not feasible. Other conditions, such as transposition of the great vessels, double-outlet right ventricle, and truncus arteriosus, have the unusual combination of increased pulmonary blood flow and moderate cyanosis.

Palliative Shunts

The concept of improving pulmonary blood flow surgically for patients with cyanotic heart disease was introduced in 1944. Blalock and Taussig demonstrated that dramatic improvement in oxygenation could be obtained in patients with tetralogy of Fallot by anastomosis of the subclavian artery to the pulmonary artery to create an artificial arterial systemic-to-pulmonary shunt. The operation was developed after Taussig had observed that symptoms worsened in tetralogy of Fallot patients whenever a patent ductus arteriosus spontaneously closed. The procedure, which was termed the Blalock-Taussig operation, represents one of the milestones in cardiac surgery. In 1946 Potts described another systemic-to-pulmonary shunt, a direct anastomosis between the descending aorta and the left pulmonary artery. In 1954 Glenn described an anastomosis of the superior vena cava to the right pulmonary artery, and in 1962 Waterston described a technique for a direct shunt or anastomosis between the ascending aorta and the right pulmonary artery. The Potts and Waterston shunts are no longer used, as they tend to overperfuse the lungs; in addition, the Waterston shunt tended to distort the pulmonary artery, and the Potts shunt was difficult to take down.

The classic Blalock-Taussig (BT) shunt is a direct end-to-side anastomosis between the subclavian artery and the pulmonary artery, which is performed on the side opposite the aortic arch to avoid kinking of the subclavian artery. The classic BT shunt has the advantage of providing excellent long-term palliation, because the vessels grow with the patient. It rarely is used today, however, except occasionally in older patients when extended palliation is required. The most widely used arterial systemic-to-pulmonary shunt is the modified Blalock-Taussig shunt (Fig. [17-20](#)). The modified BT shunt involves placement of an interposition graft, usually of 4-mm or 5-mm expanded polytetrafluoroethylene (Gore-Tex), between the subclavian artery and the pulmonary artery. The modified BT shunt can be performed more easily in neonates than the classic BT shunt and provides excellent short-term (1 to 2 years) palliation.

Another option for short-term palliation is a central systemic-to-pulmonary shunt, performed through a sternotomy, using a 3.5-mm or 4-mm Gore-Tex graft from the ascending aorta or the innominate artery to the pulmonary artery. The central shunt is preferred by some because it is technically easy to perform and produces minimal distortion of the pulmonary arteries.

The classic Glenn shunt is a direct end-to-side anastomosis between the divided right pulmonary artery and the side of the superior vena cava with ligation of the cavoatrial junction, which provides a passive venous shunt into the isolated right pulmonary artery. This was most widely used for long-term palliation in patients with tetralogy of Fallot who were poor candidates for total repair and for patients with tricuspid atresia or single-ventricle physiology before widespread use of the Fontan procedure. The Glenn shunt is not feasible early in life, until 3 to 6 months of age, because the pulmonary vascular resistance must drop before passive pulmonary flow is possible. This shunt improves oxygenation while minimizing the risks of long-term volume overload on the left ventricle that are inherent in systemic-to-pulmonary shunts. The most significant complications of the Glenn shunt are incomplete correction of cyanosis and the development of significant intrapulmonary arteriovenous fistulas in the right lung, leading to hemoptysis. The classic Glenn shunt is now used infrequently.

A newer, more physiologically appealing venous-to-pulmonary shunt that has been used with increasing frequency in recent years is the bidirectional Glenn shunt or hemi-Fontan procedure. The bidirectional Glenn shunt is an end-to-side anastomosis between the divided superior vena cava and the pulmonary artery (Fig. [17-21](#)), allowing “bidirectional” flow of unoxygenated superior vena caval blood into both lungs. The procedure is performed using cardiopulmonary bypass or with use of a passive temporary cavoatrial shunt. The bidirectional Glenn shunt improves oxygenation without overperfusion of the lungs, minimizing the risks of pulmonary hypertension and left ventricular volume overload. These advantages are similar to those of the classic Glenn shunt, yet both lungs remain perfused and the patient is better prepared for a late modified Fontan procedure. The bidirectional Glenn shunt has become an acceptable intermediate-stage palliative procedure for patients with tricuspid atresia, single-ventricle complex, or hypoplastic left heart syndrome and for patients with pulmonary atresia and intact ventricular septum who are not candidates for biventricular repair. Jonas has reported excellent results using this approach in patients with hypoplastic left heart syndrome after the stage 1 Norwood operation.

Palliative treatment for patients with tetralogy of Fallot with diminutive pulmonary arteries also has changed significantly. Several groups have proposed transcatheter balloon dilation of the pulmonary valve and arteries combined with coil occlusion of large systemic-to-pulmonary collateral vessels. This catheter-based approach has been used instead of early surgical systemic-to-pulmonary shunting in some patients in an attempt rehabilitate the pulmonary arteries and improve the chances of successful total correction. Early results with palliative transcatheter balloon palliation were reported by Kreutzer, demonstrating increased annular size and significant pulmonary artery growth, which simplifies the subsequent total repair.

The use of palliative systemic-to-pulmonary shunts, venous-to-pulmonary shunts, and other forms of palliation such as transcatheter balloon dilation, has had a highly successful history and has an important role in the treatment of patients with cyanotic congenital heart disease. These procedures increase pulmonary blood flow, improve oxygenation, and induce pulmonary artery growth. Use of intermediate palliative procedures in certain patients lowers the risks associated with subsequent total repair. While early total correction is

the norm in the current cardiac surgical era, newer forms of surgical and catheter-based palliation are selectively used in an attempt to modify pulmonary vascular growth and increase the chances of successful biventricular repair. In patients with single-ventricle physiology and decreased pulmonary blood flow, the bidirectional Glenn shunt is used increasingly as an intermediate palliative step before the modified Fontan procedure. Palliative operations have an important role in the surgical treatment of cyanotic congenital heart disease.

Tetralogy of Fallot

Tetralogy of Fallot was described in 1673 by Steno, but it became well known in 1888 when Fallot emphasized the combination of abnormalities that are regularly present; subsequently it was known as the tetralogy. Effective therapy first became possible in 1944 with the Blalock-Taussig shunt previously described. With the development of extracorporeal circulation, total correction of tetralogy of Fallot became possible and was first performed by Lillehei in 1954. The first repair was done using “cross- circulation” with another human being serving as the pump-oxygenator. The first repair using the “heart-lung machine” pump-oxygenator was done in 1955 at the Mayo Clinic. Tetralogy of Fallot is the most common cyanotic malformation, constituting over 50 percent of all cases of cyanotic heart disease. There are no known causes.

Pathology and Pathophysiology

The four features of tetralogy of Fallot are: (1) malalignment ventricular septal defect, (2) dextroposition of the aorta, (3) right ventricular outflow tract obstruction, and (4) right ventricular hypertrophy; all are the result of a specific developmental abnormality, namely, underdevelopment and anterior malalignment of the infundibular septum. In normal embryonic development, the infundibular septum fuses inferiorly with the muscular septum. In tetralogy of Fallot, the infundibular septum deviates anteriorly and cephalad, creating the large ventricular septal defect at the point of nonunion. The anterocephalad deviation of the septum not only narrows the right ventricular outflow tract but also allows the aortic root to “override” the ventricular septum in a rightward direction, producing the malalignment ventricular septal defect (VSD). The nonrestrictive VSD results in systemic pressures in the right ventricle, while concentric right ventricular hypertrophy results from obstruction of the right ventricular outflow tract.

The VSD usually is a large, malalignment-type, perimembranous defect. The aortic cusps often are visible through the defect, depending on the degree of “overriding.” The standard anatomic details regarding the conduction tissue are of concern during repair of the VSD.

The pulmonary valve leaflets are often thickened, with fused commissures and tethering of one or more leaflets with resulting limited motion (Fig. 17- 22). The anatomic location of the right ventricular outflow tract obstruction may vary from isolated infundibular stenosis to diffuse hypoplasia of the right ventricular outflow tract to pulmonary atresia. Discrete infundibular stenosis is present in about 15 percent of the patients and complete pulmonary atresia in about 20 percent. Most patients have a combination of infundibular outflow tract obstruction and pulmonary annular hypoplasia (see Fig. 17-22). Pure valvular stenosis is unusual and may represent a different embryologic lesion, namely, pulmonary stenosis with ventricular septal defect rather than tetralogy of Fallot.

In patients with markedly diminished pulmonary blood flow and diminutive pulmonary arteries there often is striking enlargement of the bronchial arteries, which are referred to as aortopulmonary collateral arteries. These vessels compensate for diminished pulmonary blood flow but may result in significant varicosities throughout the mediastinum and chest wall, which complicates final repair.

Anomalous coronary arteries are found in 5 percent of patients with tetralogy of Fallot. The anomalous origin of the left anterior descending artery from the right coronary artery, which crosses in the outflow tract, is of particular surgical significance. A right aortic arch occurs in about 25 percent of the patients. An atrial septal defect is found in 10 to 15 percent of the patients—a set of anomalies that is sometimes called *pentalogy* of Fallot.

Patients with tetralogy of Fallot have decreased pulmonary blood flow, cyanosis secondary to right-to-left shunting, and systemic right ventricular pressures with right ventricular hypertrophy. The inability to increase pulmonary blood flow results in severe intolerance to exercise.

The severity of right-to-left shunting and hypoxia is dependent on the degree of outflow tract obstruction and the limitation in pulmonary blood flow. Arterial oxygen saturations of 70 to 85 percent are seen in older children with more balanced lesions; in younger children with severe cyanosis, saturations of 20 to 35 percent may be seen. There often is a precipitous fall in oxygen saturation with exercise.

Clinical Manifestations

Polycythemia seldom develops until after 2 years of age, but later in life patients with uncorrected tetralogy of Fallot develop hematocrit levels as high as 60 to 75 percent. The degree of cyanosis increases significantly in the first few years of life, because visible cyanosis is proportional to the amount of unsaturated hemoglobin in the peripheral circulation. Patients who are cyanotic at birth usually have markedly diminished pulmonary blood flow or pulmonary atresia and usually do not survive infancy unless operation is performed. Patients who become cyanotic in the first year of life have a milder course but usually are symptomatic early. A few patients develop only mild cyanosis later in life—the so-called pink tetralogy. These patients have only moderate reduction in pulmonary blood flow because of a lesser degree of outflow tract obstruction. Chronic hypoxia results in polycythemia and eventual clubbing of the digits.

Most untreated patients with tetralogy of Fallot die from progressive hypoxia with repeated cyanotic “spells” resulting in cardiac arrest, cerebral injury, pulmonary thrombosis, or infection. About 25 percent of untreated patients die in the first year of life, 40 percent by 3 years, and 70 percent by 10 years. Brain abscess is a serious, often lethal, late complication, though it is seen infrequently. The most plausible explanation for the increased susceptibility to brain abscess is the right-to-left shunt, which bypasses the lungs, providing bacteria in the venous blood with direct access to the arterial circulation.

Most patients are symptomatic, with exertional dyspnea and cyanosis the outstanding features. Cyanotic spells are the main risk during infancy. When a spell occurs, the infant becomes deeply cyanotic and comatose. Spontaneous recovery usually occurs, but cardiac arrest or neurologic injury may ensue. Total repair or a palliative shunt, depending on the anatomy of the pulmonary outflow tract and pulmonary arteries, should be performed promptly in these infants.

Squatting is a classic clinical manifestation of tetralogy of Fallot. The physiologic benefit from squatting probably derives from an increase in the systemic vascular resistance, which diminishes right-to-left shunting and forces more blood into the lungs. Walking for short distances interrupted by squatting is a common finding in children with tetralogy of Fallot. Hemoptysis is rare, occurring primarily in children with long-standing cyanosis and significant systemic-to-pulmonary collateral vessels.

On physical examination, the obvious features are cyanosis of varying severity and clubbing of the digits. The heart usually has a normal size, rate, and rhythm. A systolic murmur of grade II to III is commonly present along the left sternal border at the third or fourth intercostal space, and in about one-half the patients it is accompanied by a thrill. With severe pulmonic stenosis or pulmonary atresia, the murmur may be faint or absent because of absence of flow through the pulmonic orifice. The second pulmonic sound is weak or absent, and the aortic second sound is increased.

The chest radiograph shows a normal-sized heart with an unusual boot- shaped contour (the so-called *coeur en sabot* form). This appearance results from the combination of diminutive, concave pulmonary artery segment, a horizontal ventricular septum produced by concentric right ventricular hypertrophy, and a small left ventricle. The pulmonary vascular markings are markedly decreased.

The electrocardiogram usually shows right ventricular hypertrophy of varying severity with right axis deviation. The echocardiogram is almost always diagnostic, demonstrating the size of the *VSD*, the degree of aortic overriding, the extent and degree of right ventricular outflow tract obstruction, and the size of the central and peripheral pulmonary arteries. The most important data provided by cardiac catheterization are more precise details of the pulmonary annular size, the branch pulmonary arteries, and the coronary artery anatomy. These are primarily of interest when the anatomy is marginal for total repair.

Treatment

Infants with tetralogy of Fallot who develop early cyanotic spells and are found to have hypoplastic or discontinuous pulmonary arteries and those who have pulmonary atresia frequently require emergent placement of a systemic-to-pulmonary shunt for palliation. An alternate approach in some patients with underdeveloped pulmonary arteries is palliative balloon dilation of the pulmonary valve or pulmonary vessels in an attempt to prepare the pulmonary vascular bed for early total repair. For the vast majority of patients with tetralogy of Fallot, early total correction is the treatment of choice. Corrective operation can be performed at any time if the child's symptoms are worsening and the pulmonary vascular bed is adequate. For children with minimal symptoms, elective repair is recommended at 6 to 12 months of age.

Operative Technique

Repair is performed through a median sternotomy with extracorporeal perfusion and cardioplegic arrest. If a previous palliative shunt operation has been performed, the shunt is isolated before perfusion is begun and occluded once cardiopulmonary bypass is initiated. Once the pericardium has been opened the outflow tract of the right ventricle is examined for anomalous coronary arteries; an approach is chosen that will avoid dividing any such arteries.

After the heart is arrested, the *VSD* is approached through the right atrium or through a right ventriculotomy, depending on the anatomy and the surgeon's preference. The authors generally approach the VSD through the right atrium, primarily to minimize the size of the incision in the right ventricle. The VSD patch is placed through the tricuspid valve, similar to the approach in standard perimembranous VSD repair.

Several potential zones of obstruction in the right ventricular outflow tract should be evaluated. While the areas of obstruction usually are determined by preoperative studies, the important zones should be reevaluated at the time of operation. These include the pulmonary valve, the pulmonic annulus, the infundibular outflow tract, the main pulmonary artery, and the distal pulmonary arteries. It is important that the surgeon evaluate each area separately, because it is critical that all areas of stenosis in the right ventricular outflow tract and pulmonary arteries be corrected.

After opening the right atrium and repairing the *VSD*, the infundibular outflow tract is inspected, and the main pulmonary artery is opened just above the valve. The main pulmonary artery and the pulmonary bifurcation, the left and right pulmonary arteries, the pulmonary valve, and the pulmonary annulus are all inspected and calibrated with Hegar dilators. A transannular incision is made only if the pulmonary annulus is hypoplastic. It is important to decide whether the annulus is of an adequate size by comparing the measured diameter to that of normal subjects using a nomogram. If the annular size is adequate and leaflet mobility can be restored, the valve is preserved. In such cases, a separate small ventriculotomy is made below the valve to correct any infundibular stenosis, or, alternatively, resection of the infundibular obstruction is performed through the tricuspid valve. When the annulus is hypoplastic, the incision is extended across the annulus, through the area of infundibular obstruction (see Fig. 17-22 B). The incision is only carried onto the ventricle far enough to correct the infundibular stenosis, while preserving as much right ventricular function as possible. The small transannular incision is then closed with an appropriately sized pericardial or synthetic patch, enlarging the outflow tract as necessary (see Fig. 17-22 C). Tailoring the transannular patch to appropriate size for the patient usually prevents

late aneurysmal formation in the patch unless a distal obstruction is present. When the distal pulmonary arteries are severely stenosed or hypoplastic, a valved pulmonary artery homograft may be required to reconstruct the outflow tract. The use of a valve in the circuit minimizes regurgitation of blood into the right ventricle and lowers the risk of long-term right ventricular dysfunction.

After cardiopulmonary bypass is discontinued, intracardiac pressure is measured to confirm that right ventricular outflow tract obstruction has been corrected. The right ventricular systolic pressure should be reduced to less than 60 to 70 percent of the left ventricular pressure. If right ventricular pressure is still elevated above this level, more adequate correction of the ventricular obstruction should be considered, or a valved graft or homograft should be inserted. The right ventricular pressure should not be left at systemic levels without further intervention, because progressive right ventricular failure ensues. In most patients the ratio of right ventricular to left ventricular pressure is less than 0.50 to 0.60 after successful repair, with a pulmonary artery systolic pressure of 20 to 25 mmHg.

Results

The operative mortality is 2 to 5 percent in most centers. Operative risk factors include age less than 3 months, older age at repair with severe polycythemia, pulmonary atresia, absent pulmonary valve syndrome, and the presence of severely hypoplastic or discontinuous pulmonary arteries. After successful repair the risk of late death is low throughout life. Late complications include recurrent *VSD*, recurrent branch pulmonary artery stenosis, progressive right ventricular dysfunction resulting from pulmonary insufficiency, aneurysm formation in the outflow tract patch, and arrhythmias.

Pulmonary Stenosis/Pulmonary Atresia with Intact Ventricular Septum

Isolated pulmonary stenosis is a relatively common defect, constituting 10 percent of congenital heart defects. More than one-half of these patients have pure valvular pulmonary stenosis, and the remainder have varying degrees of associated right ventricular outflow tract obstruction. A more severe form of the disease process, pulmonary atresia with intact septum, results in total obstruction of the outflow tract with atresia of the valve, hypoplasia of the annulus, and differing degrees of hypoplasia and maldevelopment of the right ventricle. Pulmonary atresia with intact septum is less common than pulmonary stenosis, accounting for 1 to 3 percent of congenital heart defects.

Pathology and Pathophysiology

Pulmonary stenosis and pulmonary atresia with intact septum represent a spectrum of pathologic findings, ranging from isolated valvular stenosis to total valvular atresia with hypoplasia of the inlet, body, and outflow tract of the right ventricle. With pulmonary stenosis, the degree of valvular obstruction may vary from mild, clinically insignificant stenosis to critical pulmonary stenosis with a "pinhole" opening, which produces symptoms similar to pulmonary atresia. The valve usually is bicuspid or tricuspid and domed, with fused commissures, although more severe valvular dysplasia is present. The annulus may be normal in size or hypoplastic.

In patients with true pulmonary stenosis, the right ventricle usually is relatively normal, except for secondary right ventricular hypertrophy. Approximately 40 percent of these children have some degree of infundibular obstruction, and 10 percent have severe infundibular obstruction.

The more severe lesion of *pulmonary atresia with intact ventricular septum (PAIVS)* presents in the newborn period with an atretic valve and no forward blood flow. In *PAIVS* the right ventricle is underdeveloped to varying degrees, although a small inlet and infundibular portions usually are absent. The body of the ventricle often is totally obliterated and dysfunctional. In *PAIVS* the right ventricle is classified according to its degree of development as unipartite, bipartite, and tripartite ventricle, depending on the adequacy of the inlet, body, and outlet portions of the ventricle. Knowledge of the right ventricular development is essential, a minimum of a bipartite ventricle is necessary, and a tripartite ventricle is optimal if the right heart is to be used in the circulation. Otherwise the patient must be treated as having single-ventricle physiology.

In patients with *PAIVS*, the myocardium in the underdeveloped right ventricle exhibits a wide range of pathologic anomalies. Typically the ventricle is extremely small, thickened, and hypertensive, with myocardial muscular disarray. In approximately 10 percent of the patients with *PAIVS*, sinusoids connect the right ventricle with the coronary circulation, which results in a serious condition termed *right ventricular–dependent coronary circulation*.

In patients with *PAIVS* the tricuspid valve is often regurgitant, but a functioning valve usually is present. If the tricuspid valve is severely hypoplastic or totally atretic, the disease becomes tricuspid atresia and the patient is treated as having single-ventricle physiology.

With moderate degrees of pulmonary stenosis the physiologic consequences are slow to develop, and significant symptoms usually do not develop until adolescence. Significant forward pulmonary blood flow often is present, and cyanosis usually does not occur. The obstruction produces an elevation in right ventricular pressure with subsequent ventricular hypertrophy. The severity is determined by the gradient; a gradient of less than 50 mmHg is considered mild, and a gradient of 80 to 100 mmHg or more is severe. With severe stenosis suprasystemic right ventricular pressures often develop. Some patients tolerate high levels of right ventricular hypertension for years, while others develop progressive tricuspid insufficiency, right-sided heart failure, and right-to-left shunting across the foramen ovale with resulting hypoxemia and cyanosis.

In patients with critical pulmonary stenosis and in patients with *PAIVS* most forward pulmonary blood flow may be absent. Mixing at the atrial level is necessary to maintain life, with right-to-left shunting across the foramen ovale. If the foramen ovale is of inadequate size it must be stretched shortly after birth with a balloon catheter, a procedure termed *balloon septostomy*. This rarely is required.

Clinical Manifestations

Hypoxia, cyanosis, and acidosis usually develop shortly after birth when the ductus arteriosus begins to close. Ductal patency must be maintained with prostaglandins to keep the child alive until the diagnosis can be established and more definitive treatment initiated. The electrocardiogram may develop right atrial P waves shortly after birth, but in *PAIVS* the right ventricular hypertrophy pattern often is absent. The chest radiograph shows decreased pulmonary blood flow and a flat or concave pulmonary artery segment with a normal or enlarged heart size.

The diagnosis usually is made by echocardiography, which demonstrates critical stenosis with a domed, stenotic pulmonary valve and an adequate right ventricle, or *PAIVS* with an atretic valve and a poorly developed right ventricle. Close attention is given to evaluating the body and outlet portions of the right ventricle, the pulmonary annular size, and the adequacy of the tricuspid valve, because these determine whether or not a biventricular repair is feasible.

Cardiac catheterization is used primarily for intervention such as balloon dilation in patients with critical pulmonary stenosis. In patients with *PAIVS*, diagnostic catheterization usually is required to further evaluate the internal anatomy of the right ventricle and to determine the presence or absence of sinusoids feeding the coronary circulation.

Treatment

The initial treatment of choice for most infants with critical pulmonary stenosis and for adolescents with moderate to severe isolated pulmonary stenosis is balloon dilation in the catheterization laboratory. Colli and associates reported excellent early results with balloon dilation in 90 percent of neonates with critical pulmonary stenosis. Similarly, McCrindle reported excellent long-term results after valvuloplasty in 77 percent of 533 patients with pulmonary stenosis, with follow-up out to 8.7 years.

Patients with hypoplastic outflow tract obstruction or with *PAIVS* are not candidates for balloon valvuloplasty and require surgical correction. The operative risk is high, particularly in patients with *PAIVS*. Initial correction requires the use of cardiopulmonary bypass and the combination of surgical valvotomy and a systemic-to-pulmonary shunt, or a transannular patch to relieve outflow tract obstruction plus a systemic-to-pulmonary shunt. Weldon and Cobanouglu each reported that although repair is successful in the majority of patients, the operative mortality exceeds 20 percent. Hanley reported results in 101 patients from 27 institutions, noting that use of valvulotomy without cardiopulmonary bypass and transannular patching without placement of a concomitant shunt were predictors of poor outcome.

Tricuspid Atresia

Systemic-to-pulmonary shunts for tricuspid atresia were first used in the 1940s, with good short-term improvement but poor long-term results. A significant contribution was made with the introduction of the Glenn shunt, which gave better long-term palliation. The major surgical advance came in 1968 when Fontan successfully separated the right and left circulations in a patient with tricuspid atresia for the first time, introducing the concept of totally passive pulmonary blood flow. Since then variations of Fontan's approach have been developed, and some form of cavopulmonary connection remains the procedure of choice for tricuspid atresia.

Pathology and Pathophysiology

Tricuspid atresia is an important form of congenital heart disease, affecting 2 to 5 percent of children with cyanotic heart disease. The basic abnormalities are total atresia of the tricuspid valve and ventricular inlet, varying degrees of hypoplasia of the body and outlet portion of the right ventricle, and an atrial or ventricular septal defect. The mitral valve and the left ventricle usually are normal. Pulmonary atresia or severe pulmonary stenosis is seen in 85 percent of the cases with normally located great vessels, further limiting pulmonary blood flow. Frequently the right side of the heart is totally hypoplastic, without inlet, body, or outlet chambers. Blood must mix at the atrial level, and the typical patient has totally ductus-dependent pulmonary blood flow.

The aorta and pulmonary artery are situated normally, in about 70 percent of patients with tricuspid atresia, and transposition of the great vessels is present in about 30 percent. These two major groups may be further subdivided according to whether pulmonary blood flow is unrestricted or decreased. In the typical patient with tricuspid atresia and normally situated great vessels, pulmonary blood flow is markedly decreased, with most flow provided by the patent ductus arteriosus. When the aorta and pulmonary artery are transposed, about 70 percent of the patients have unrestricted pulmonary blood flow with overperfusion of the lungs rather than hypoxia. This condition also may be termed *single-ventricle complex*. The degree of hypoxia typically is severe because of the absence of blood flow through the atretic tricuspid valve combined with restricted or absent flow across the septal defect and through the rudimentary right ventricle into the pulmonary artery.

Clinical Manifestations

Most patients become markedly hypoxic and dyspneic shortly after birth, when the ductus arteriosus begins to close; most will die unless palliative shunting is performed. The correct diagnosis is made during the first day of life in more than one-half of infants with tricuspid atresia. In a minority of patients with unrestricted pulmonary blood flow, with normal or transposed great arteries, congestive heart failure and pulmonary congestion are present.

The physical examination is not diagnostic because the murmur varies widely, depending on the size of the ventricular septal defect and the anatomic relationship of the great vessels. The chest radiograph usually shows decreased vascularity. The electrocardiogram is strongly suggestive, showing a typical left-axis deviation resulting from the underdevelopment of the right ventricle. The echocardiogram can establish the diagnosis with certainty, and it also can outline any atrial septal defect or ventricular septal defect

and the relationships of the great arteries. Cardiac catheterization usually is not necessary early in life before palliative treatment, but it should be performed later before definitive repair.

Treatment

An emergency systemic-to-pulmonary shunt often is necessary in the first few days or weeks of life to prevent death from hypoxia. A modified Blalock- Taussig Gore-Tex shunt usually is the simplest and most satisfactory. In some patients a small foramen ovale restricts mixing at the atrial level, and a balloon septostomy is necessary to increase the right-to-left shunt. Surgical enlargement of the atrial septal defect (Blalock-Hanlon procedure) can be performed if balloon septostomy is unsuccessful, but this is infrequently required.

After palliative shunting, the ultimate repair goal is a modification of the *Fontan procedure*, in which a direct connection between the systemic venous circulation and the pulmonary arteries is constructed. A *bidirectional Glenn shunt procedure* (see Fig. [17-21](#)) often is performed at 3 to 8 months of age. This is coupled with a takedown of a previously performed systemic-to-pulmonary shunt. The bidirectional Glenn shunt minimizes volume overload on the left ventricle and becomes the first step of the final corrective *modified Fontan procedure*. The most frequently used modification of the Fontan procedure is the *total cavopulmonary connection* (Fig. [17-23](#)), which is performed by connecting the superior vena cava to the pulmonary artery with a bidirectional Glenn shunt and connecting the inferior vena cava to the pulmonary artery. The inferior caval connection may be performed in two ways: with an intraatrial lateral Dacron tunnel or with an extracardiac conduit.

The direct *atriopulmonary connection* is a modification of the Fontan procedure that is used less frequently because of a higher incidence of associated late atrial arrhythmias and pleural effusions. This procedure is relatively simple to perform, but the results in terms of flow dynamics and clinical outcome are better with the total cavopulmonary connection methods.

All modified Fontan procedures are delayed until 8 to 12 months of age or later because the pulmonary vascular resistance must drop to normal levels for a procedure dependent on passive pulmonary blood flow to be effective. High-risk patients may have their Fontan connection *fenestrated*, which technically involves placing a small “punch hole” or fenestration between the systemic venous circulation (right atrium) and the left atrium. This allows the patient to shunt right-to-left if the pulmonary vascular resistance temporarily increases.

Results

Cetta and colleagues, reporting results from the Mayo Clinic in 839 consecutive patients who underwent the Fontan operation, compared outcomes in 339 patients from 1987 to 1992 to outcomes in the previous 500 patients, who were operated on from 1973 to 1986. In the more recent cohort the mortality was 9 percent, as compared to the earlier cohort's 16 percent; similarly, the 5-year survival rate improved, with the recent cohort at 81 percent, as compared to the earlier cohort's 73 percent. Sharma, in reviewing 202 patients, noted that the use of a fenestrated total cavopulmonary connection instead of a procedure without fenestration resulted in a decrease in operative mortality from 15.9 percent to 5 percent. The best outcomes after the Fontan operation are achieved when the postoperative right atrial pressure stays below 15 to 18 mmHg. Higher right atrial pressures result in severe problems, such as low output syndrome, recurrent pleural effusions, and protein-losing enteropathy. These complications may occur early or late. Poor results are more common when the pulmonary vascular resistance is elevated, when the pulmonary arteries are deformed, or when preexisting conditions result in an elevated left ventricular diastolic pressure. Other late complications include atrial flutter and thrombus of the right atrium. The use of the total cavopulmonary connection method as compared with atriopulmonary connection or other Fontan modifications appears to lower the incidence of late atrial flutter.

Since the Fontan operation physiologically depends on using the venous pressure to perfuse the pulmonary vascular bed, the patient's cardiac physiology is markedly abnormal even after repair. Most patients have abnormal exercise capacity and altered hemodynamics. While the concept of passive pulmonary blood flow with separated circulations represents a major breakthrough in the treatment of patients with tricuspid atresia or single-ventricle physiology, the long-term results are limited in terms of survival and cardiac functional recovery.

Fontan and Kirklin, in 1990, reviewed 334 patients who had undergone the Fontan procedure. The variables predicting survival were identified, after which each optimal condition was used to predict outcome after a “perfect” Fontan operation. With optimal conditions in each category, operative mortality was 8 percent, and the 5-year, 10-year, and 15-year survival rates were 86 percent, 81 percent, and 73 percent, respectively. The late hazard or instantaneous risk of death began to increase after 6 years, and the average New York Heart Association (NYHA) functional status progressively decreased after operation. These data suggest that the late outcome after a Fontan operation is imperfect, presumably because of limitations imposed by the abnormal physiology present. Families of patients undergoing this procedure should be counseled appropriately so that long-term expectations are realistic. The procedure still offers the best chance for long-term survival for patients with tricuspid atresia.

Single-Ventricle Complex

Single-ventricle complex or univentricular heart represents a variety of complex defects in which there is only a single functioning ventricular chamber. This category includes patients with single atrioventricular connection and differing ventricular morphology, mitral atresia with unrestricted aortic outlet, unbalanced atrioventricular septal defects, and a variety of other anatomic configurations in which the basic abnormality is the presence of a single functioning ventricle. Other variations include the type of functioning ventricular chamber (morphologically a “left” or a “right” ventricle); the type of hypoplastic ventricular chamber; different abnormalities in the atrioventricular valves; and the origin of the aorta and pulmonary artery from the normal or hypoplastic ventricular chambers.

The most frequent physiologic abnormalities are hypoxia from the mixing of oxygenated and unoxygenated blood in the single ventricle and pulmonary congestion from unrestricted pulmonary blood flow. The degree of cyanosis varies with the pulmonary blood flow, which depends on which chamber the pulmonary artery arises from and on the degree of anatomic obstruction in the outflow tract to the pulmonary artery.

Clinical Manifestations

Some patients with single-ventricle complex have unrestricted pulmonary blood flow. The physiology resembles that of a large ventricular septal defect but with some degree of cyanosis because of the complete mixing of blood. At the other extreme, severe hypoxia and cyanosis are present early after birth in patients with single-ventricle complex and severely restricted pulmonary blood flow. These patients often require an emergency palliative shunt in infancy. In between these two extremes are patients with moderate degrees of restriction in pulmonary blood flow, with a $Q_p:Q_s$ of approximately 2:1. Such patients do reasonably well in the first few years of life because of the balanced circulation, which provides adequate pulmonary blood flow but does not flood the lungs.

Treatment

Two extremes often are present in the neonatal period; unrestricted pulmonary blood flow with severe pulmonary congestion, which requires urgent pulmonary artery banding, or severe cyanosis and hypoxia, which requires emergency placement of a palliative shunt. After palliative treatment early in life, the final planned surgical correction involves the use of some modification of the Fontan procedure, usually total cavopulmonary connection. The treatment strategy for most patients with single-ventricle complex involves the placement of a bidirectional Glenn shunt at 3 to 6 months of age, as an intermediate step, taking down the pulmonary artery band or previously placed palliative shunt. When the patient is 12 to 18 months of age the bidirectional Glenn shunt is converted to a modified Fontan total cavopulmonary connection, which often is fenestrated if the patient remains high risk.

Historically the results of the modified Fontan procedure are worse when done for single-ventricle complex than when done for tricuspid atresia, with an operative mortality of 10 to 15 percent and a 10-year survival rate of 60 to 70 percent. The results may be slightly better with the staged treatment strategy.

Ebstein's Anomaly

Ebstein's anomaly is uncommon, representing 0.5 percent of all cases of congenital heart disease. There is a nearly 400 times increased frequency of Ebstein's malformation when the mother has taken lithium during the pregnancy. This is challenged by recent epidemiologic studies.

Pathology and Pathophysiology

The basic abnormality is a malformation of the septal and posterior leaflets of the tricuspid valve. The origin of the leaflets is displaced downward to a variable degree, creating a third chamber on the right side of the heart. Both the leaflet tissue and its chordae also are abnormal. The anterior tricuspid leaflet usually is normal but may be unusually large and prominent, and described as “sail-like.” The segment of right ventricular wall between the true annulus of the tricuspid valve and the origin of the displaced leaflets becomes functionally part of the right atrium and has been termed the *atrialized ventricle*. There is a varying degree of hypoplasia of this segment, and in some patients it resembles a true aneurysm that bulges paradoxically. In most patients the atrialized segment has some muscle fibers with little paradoxical motion. The distal functioning right ventricle is small. Some investigators have believed that there is a true deficiency in the right ventricular fibers as well, which contributes to the right ventricular dysfunction in this condition. A patent foramen ovale or ostium secundum defect is almost always present, with right-to-left shunting. The right atrium usually is dilated because of the obstructive nature of the valve, often to a huge size in older patients.

The malformation varies widely in severity, ranging from relatively minor valvular abnormalities to virtual atresia of the valve leaflets with severe regurgitation. The valve and right ventricle also are functionally obstructive in many cases, impeding forward blood flow.

The main physiologic disturbances are restricted pulmonary blood flow, inadequate cardiac output from right ventricular dysfunction, tricuspid insufficiency, and right-to-left shunting at the atrial level. The severity of symptoms varies greatly, depending on the severity of the pathologic abnormality. A variety of arrhythmias commonly occur, with supraventricular tachycardias occurring frequently, and Wolff-Parkinson- White syndrome with accessory pathways and preexcitation occurring in approximately 5 percent of patients with Ebstein's anomaly. Cyanosis of moderate degree occurs in at least 50 percent of patients because of a right-to-left atrial shunt. The degree of cyanosis gradually becomes more severe in older patients with progressive right ventricular failure.

Clinical Manifestations

A significant proportion of infants with Ebstein's anomaly present in the first month of life with tachypnea and cyanosis, probably a manifestation of the elevated pulmonary vascular resistance in the neonatal period. About one-half of patients who are severely symptomatic in the first month of life subsequently die. After the first month, the severity of symptoms decreases, often with loss of cyanosis, and hence clinical disability during childhood often is minimal. A mortality of about 15 percent has been estimated between the ages of 1 and 20 years. The onset of clinical symptoms in patients surviving childhood is a gradual one; the average age of diagnosis is in the midteens. Many adults continue to function reasonably well with milder forms of Ebstein's anomaly, depending on the presence of arrhythmias, cyanosis, and cardiac failure. A few patients have lived to beyond 70 years of age, but only about 5 percent of all patients live beyond 50 years.

A variety of systolic and diastolic murmurs are present, though at one time it was stated that auscultatory findings were highly suggestive, emphasizing a slow cardiac rate with a triple or quadruple rhythm, a systolic murmur of tricuspid regurgitation, and often a low-pitched diastolic murmur. The chest radiograph usually shows cardiac enlargement because of the large right atrium and the atrialized right ventricle. The vascularity in the lung fields usually is decreased. Electrocardiographic abnormalities are considered typical, with conduction disturbances, a prolonged P-R interval, and partial right bundle branch block. When Wolff-Parkinson-White syndrome is present the P-R interval is short and a delta wave is present.

The echocardiogram is diagnostic, outlining the different abnormalities with precision. Cardiac catheterization may be considered in order to evaluate the size and function of the right ventricle, but it must be performed carefully, as fatal arrhythmias have occurred. Electrophysiologic studies with radiofrequency ablation of the aberrant pathway are indicated if Wolff- Parkinson-White syndrome is present.

Treatment

Various forms of valve reconstruction have been described, with varying results, depending on the degree of the anatomic abnormality in the valve. Previously, valve replacement was almost always required, and replacement frequently is necessary in patients with severe valvular deformity. Danielson described experience with 72 patients, in whom valve reconstruction was performed in 81 percent and valve replacement in 19 percent. The atrial septal defect also is routinely closed. Plication of the atrialized ventricle is usually unnecessary but may be used when the atrialized segment is extremely thin and contracting paradoxically. The overall operative mortality in the Mayo Clinic series was 7 percent, and 87 percent of the patients improved to New York Heart Association (NYHA) functional class I or II at 5 years.

Transposition of the Great Arteries

The clinical syndrome of *transposition of the great arteries (TGA)* was described by Taussig in 1938. In 1948 Blalock and Hanlon proposed surgical atrial septectomy to create unrestricted mixing at the atrial level. Because of the excellent results now obtained with balloon septostomy, developed by Rashkind in 1969, surgical creation of an atrial septal defect is rarely necessary. Total correction of transposition by redirecting blood flow at the atrial level was based on work by Arbert in 1955. Senning, in 1957, first completely corrected transposition of the great vessels by repositioning the atrial septum to redirect caval blood through the mitral valve and pulmonary venous blood into the tricuspid valve. In 1964 Mustard developed a method of reconstructing the atrial cavity and redirecting vena caval blood into the mitral valve with an intraatrial baffle. The technique significantly improved the results for correction of transposition of the great vessels and was adopted by most centers as the preferred procedure throughout the 1960s and 1970s, although some continued to favor the Senning procedure.

In 1975 Jatene performed the first successful arterial switch procedure for correction of transposition with coronary artery transfer and reimplantation. This technique had potential long-term advantages since it used the anatomic left ventricle in the systemic circulation and should not have been prone to ventricular dysfunction or significant atrial arrhythmias. Results improved significantly with the arterial switch operation in the 1980s. The arterial switch operation is considered the procedure of choice for the treatment of transposition.

TGA is a frequent disorder, representing 5 to 8 percent of all congenital cardiac malformations and accounting for about 25 percent of deaths caused by congenital heart disease in the first year of life. It is about four times more frequent in males than in females. The cause is unknown.

Pathology and Pathophysiology

TGA results from abnormal division of the bulbar trunk in embryologic development, occurring between the fifth and the seventh uterine week. With transposition, the aorta originates from the right ventricle and the pulmonary artery from the left ventricle (Fig. 17-24). As a result, venous blood returning through the vena cava to the right atrium enters the right ventricle and is ejected directly into the aorta. Oxygenated blood returning from the lungs through the pulmonary veins to the left atrium enters the left ventricle and is expelled through the pulmonary artery back to the lungs. This dual, parallel circulatory arrangement is incompatible with life if there is no communication between the pulmonary and systemic circulations. A patent ductus arteriosus, a patent foramen ovale, or a ventricular septal defect must be present for the patient to survive. A patent ductus is present for a few weeks after birth in more than one-half of the patients. A patent foramen ovale also is frequent, and a ventricular septal defect occurs in approximately 50 percent of patients (TGA with VSD).

Other associated anomalies are common. One of the most frequent, left ventricular outflow tract obstruction resulting in pulmonic stenosis, occurs frequently enough to constitute a well-defined variant of the syndrome for which the prognosis is unusually favorable. A wide variety of other anomalies may occur, including coarctation of the aorta, pulmonary atresia, and dextrocardia.

The two basic physiologic derangements in patients with TGA are hypoxia and progressive pulmonary congestion from unrestricted pulmonary blood flow. Severe and rapidly progressive cardiac failure results, mostly from the unrestricted pulmonary blood flow but also because the coronary arteries are filled with unoxygenated blood, which results in myocardial hypoxia. The severity of the hypoxia and the degree of cyanosis vary with pulmonary blood flow and the nature of any VSD present. Patients with TGA and intact ventricular septum and patients with TGA, VSD, and LVOT obstruction develop severe cyanosis. In patients with TGA and intact ventricular septum, a Rashkind balloon septostomy may be required to ensure adequate mixing.

TGA is a lethal condition if untreated. Patients with TGA and intact ventricular septum, depending on the size of the foramen ovale, die most rapidly—30 percent in 1 week, 50 percent in 1 month, and 90 percent by 1 year. Those with TGA and VSD rapidly develop pulmonary vascular changes because of increased pulmonary flow, often within a few months, and 80 percent die within the first year.

Clinical Manifestations

A high proportion of infants with TGA are cyanotic at birth. More than 90 percent are recognized the first day of life. Pulmonary congestion with cardiac failure is similarly frequent. The combination of cyanosis and increased pulmonary blood flow in a newborn is highly suggestive of TGA with VSD. The most prominent symptoms are cyanosis and dyspnea.

Cyanosis usually is an obvious clinical finding. It is often severe. Signs of pulmonary congestion or heart failure are almost always found, along with cardiac enlargement, hepatomegaly, and rales. A systolic murmur usually is present but is variable and not diagnostic. It can result from any of the different intracardiac communications that may be present. Absence of a murmur, which suggests the absence of any intracardiac communication, indicates a particularly unfavorable prognosis.

The chest radiograph often shows three distinctive abnormalities. The contour of the heart has been described as “egg-shaped,” which results from the prominent right ventricle projecting into the left hemithorax and the dilated right atrium bulging into the right side. The base of the cardiac shadow, termed the waist, may be unusually narrow because of the location of the aorta in front of the pulmonary artery, rather than the normal side- by-side relationship. Pulmonary congestion often is marked.

The electrocardiogram consistently shows severe right ventricular hypertrophy. The presence of left ventricular hypertrophy depends on the pulmonary blood flow and the degree of pulmonary valvular stenosis. The echocardiogram usually is diagnostic, outlining the transposed great arteries, the intracardiac communications, and any associated abnormalities. Cardiac catheterization usually is not required.

Treatment

TGA may be classified into four groups: (1) TGA with intact ventricular septum, (2) TGA with VSD, (3) TGA with VSD plus LVOT obstruction, and (4) complex transposition, which includes any of the previous three forms in association with other severe associated cardiac defects.

The most critically ill neonates are those with TGA and intact ventricular septum, for the only communication between the pulmonary and systemic circulations is through the foramen ovale. In these patients, a Rashkind balloon septostomy often is necessary shortly after birth to allow mixing at the atrial level. In patients with TGA and intact ventricular septum, the arterial switch operation should be performed within the first 7 to 14 days of life, before the left ventricle involutes and loses its ability to support the systemic circulation. Patients with TGA and intact ventricular septum who are more than 2 weeks old may require preliminary banding of the pulmonary artery to induce hypertrophy in the left ventricle before it is feasible for the arterial switch operation to be performed. This approach, first proposed by Yacoub, was popularized by Jonas, who reported that only 7 days of preliminary banding was necessary to induce left ventricular hypertrophy before proceeding to a rapid two-stage arterial switch operation.

When TGA with VSD is present, the arterial switch operation often is done within the first 2 weeks of life to avoid progressive pulmonary congestion. If the lungs are not flooded, operation may be safely delayed for 3 to 6 weeks. The left ventricle usually does not have a problem supporting the systemic circulation when a VSD is present even if the operation is done later, because the ventricle has been working against systemic pressure since birth.

Operative Technique

The surgical technique for the arterial switch procedure (Fig. 17-25) was described in detail by Jatene, and modifications have been described by Quaegebeur, Castañeda, and others. The repair often is performed with the patient in deep hypothermia and circulatory arrest, although some groups use “low-flow” continuous perfusion to minimize risk of neurologic dysfunction.

After cardiopulmonary bypass is initiated and the heart is arrested with cardioplegia, the great vessels are totally transected just distal to the sinotubular ridge (Fig. 17-25 A). A small “button” of aorta that includes the ostium of the coronary artery is resected from the posterior sinus of the anterior great vessel and transferred to the corresponding sinus of the posterior great vessel. A similar transfer is made with the “button” of the anterior right coronary artery (Fig. 17-25 B). Microvascular technique is used to suture the coronary buttons into their new locations on the posterior great vessel (Fig. 17-25 C). The anterior aorta is relocated posteriorly and sutured end-to-end to the posterior great vessel just distal to the coronary artery reimplantation site. The pulmonary artery is brought anteriorly and connected to the anterior great vessel, which exits from the right ventricle.

The subgroup of patients with TGA and VSD with concomitant LVOT obstruction may not be suitable for the arterial switch operation or an atrial correction. This group of patients may require initial palliation with a systemic-to-pulmonary shunt, followed by a Rastelli operation at 4 to 5 years of age. The Rastelli procedure involves use of a prosthetic patch to reroute the anterior aorta to connect internally to the posterior left ventricle, across the VSD. The systemic venous ventricle is connected extraanatomically into the pulmonary artery with a valved homograft conduit or a prosthetic valve and graft.

Results

The operative risk for the Rastelli operation in patients with TGA and VSD with LVOT obstruction is relatively low, with mortality at 5 to 10 percent, but higher than the risk

associated with the arterial switch procedure for other forms of transposition. Because of the need for an extraanatomic valved conduit, the risks of late obstruction of the conduit and degeneration of the valve are ongoing, and reoperations for conduit replacement usually are required throughout life.

For patients with *TGA* and intact ventricular septum and for patients with *TGA* and *VSD*, the arterial switch operation achieves excellent long-term results, with a mortality of less than 5 percent. Wernovsky and colleagues reported results in 470 patients who underwent the arterial switch operation between 1983 and 1992, of which 278 were for *TGA* with intact septum and 192 for *TGA* with *VSD*. The overall operative mortality was 7 percent, with 1-year, 5-year, and 8-year survival rates of 92 percent, 91 percent, and 91 percent, respectively. The operative risk was increased when certain unfavorable coronary artery anatomic configurations were present and when augmentation of the aortic arch was required. The risk of subsequent reintervention for pulmonary artery stenosis was approximately 10 percent, with a peak risk at 9 months postoperatively.

Elkins and associates reported similar late results after the arterial switch operation, with excellent survival rates and preservation of ventricular function for up to 8 years. In another study, Colan and associates aggressively tested left ventricular functional parameters after the arterial switch operation, demonstrating that after follow-up periods as long as 10 years, left ventricular size, function, and contractility continued to be normal with no evidence of time-related deterioration. Kramer and Turley reported that the late incidence of cardiac arrhythmias was less in patients undergoing the arterial switch procedure than in patients receiving Senning or Mustard atrial repairs. The overall late results after the arterial switch operation are extremely encouraging in terms of survival, preservation of ventricular function, and low incidence of late arrhythmias. The arterial switch procedure is now the preferred treatment for patients with transposition of the great arteries.

Double-Outlet Right Ventricle

Double-outlet right ventricle is a congenital malformation in which both great arteries arise from the morphologic right ventricle. It occurs in about 5 percent of patients with congenital heart disease. Modern knowledge of the condition emerged from observations by Kirklin, who first recognized the anatomic problem in 1957 in the operating room and performed a surgical correction by creating an intraventricular tunnel, similar to the treatment used today. *Double-outlet right ventricle (DORV)* became established as the appropriate designation after Witham used the term in a report on the disorder.

Pathology and Pathophysiology

Patients with *DORV* were classified by Lev on the basis of the location of the *VSD* in relation to the great vessels: (1) subaortic, (2) subpulmonic, (3) doubly committed, and (4) uncommitted. The aorta rotates anteriorly to varying degrees in all patients with *DORV*, arising from the right ventricle. The great vessels are usually side by side, although in extreme cases the aorta is completely anterior. In *DORV* and subaortic *VSD* with pulmonary stenosis the pathology merges into the spectrum of tetralogy of Fallot. When the aorta rotates to a greater degree anteriorly and the pulmonary artery begins to rotate posteriorly, in some cases overriding the *VSD*, a special condition of *DORV* and subpulmonic *VSD* termed *Taussig-Bing syndrome* occurs. The aorta and the pulmonary artery arise from the right ventricle, allowing some mixing of venous and arterial blood to occur with some degree of bidirectional shunting in all cases. The amount of cyanosis varies with the degree of restriction to pulmonary blood flow.

Clinical Manifestations

Three characteristic types of physiology occur. In patients with *DORV* and a large subaortic *VSD* or doubly committed *VSD*, the clinical presentation is identical to that of a large, isolated *VSD*, with markedly increased pulmonary blood flow. These patients develop congestive heart failure early and have a propensity for pulmonary hypertension and early pulmonary vascular resistance changes. They typically do not have appreciable cyanosis.

The second typical clinical syndrome occurs in patients with *DORV* and subaortic *VSD* with pulmonary stenosis. This condition overlaps with tetralogy of Fallot, and physiologically the patients are identical. The predominant clinical findings are hypoxia and cyanosis from markedly restrictive pulmonary blood flow.

The third clinical variant is the Taussig-Bing syndrome, *DORV* with subpulmonic *VSD*. The aorta usually is anterior and the pulmonary artery posterior, overriding the *VSD*. Anatomically and physiologically these patients resemble patients with transposition of the great arteries and *VSD*. Patients with Taussig-Bing syndrome typically have a combination of increased pulmonary blood flow with pulmonary congestion and moderate hypoxia with cyanosis. *DORV* with subpulmonic *VSD* and pulmonary atresia can occur, which resembles *TGA* with *VSD* and pulmonary atresia.

Echocardiography can almost always determine the diagnosis. Cardiac catheterization is not routinely performed if the patient has straightforward *DORV* and subaortic *VSD* with increased pulmonary blood flow. In patients whose anatomic configuration is less certain, catheterization may be necessary for delineation of the exact anatomic details before repair is performed or to determine the pulmonary vascular resistance.

Treatment

Most forms of *DORV* with subaortic *VSD* or doubly committed *VSD*, with or without pulmonary stenosis, can be corrected satisfactorily with an intracardiac tunnel to channel blood from the left ventricle across the *VSD* to the aorta. The right ventricular outflow tract is then enlarged either with a patch or with a homograft valved conduit as necessary. In patients with Taussig-Bing syndrome (*DORV* with subpulmonic *VSD*) an intracardiac tunnel repair may be difficult. Some surgeons have proposed repair by use of the arterial switch procedure along with *VSD* closure to redirect blood through the neo-aorta.

Repair procedures for *DORV* and simple subaortic *VSD* with or without pulmonic stenosis have an operative mortality of 2 to 5 percent. Repair procedures for more complex forms of *DORV*, including Taussig-Bing syndrome, have an operative mortality of 5 to 10 percent.

Truncus Arteriosus

Truncus arteriosus is a rare malformation accounting for less than 3 percent of congenital cardiac defects. The lesion results from a failure of the fetal truncus to separate into the aorta and pulmonary arteries, resulting in a single arterial trunk. In this condition the entire circulation, including the aortic valve, the aorta, the coronary arteries, and the pulmonary arteries, arise from the common arterial trunk. A single truncal semilunar valve is present, which may be bicuspid (30 percent), tricuspid (50 percent), or quadricuspid (20 percent). There is always an underlying ventricular septal defect.

Pathology and Pathophysiology

Truncus arteriosus is classified according to the origin of the pulmonary arteries (Fig. 17-26): In Type I truncus arteriosus there is a single main pulmonary trunk off the aorta; in Type II the right and left pulmonary arteries originate from the dorsal wall of the truncus arteriosus from separate orifices; in Type III the pulmonary arteries arise as separate ostia; and in Type IV the pulmonary blood supply is provided by systemic aorta- to-pulmonary collateral vessels arising from the descending aorta. Type IV truncus is another way of classifying tetralogy of Fallot and pulmonary atresia with discontinuous pulmonary arteries and major systemic aorta- to-pulmonary collaterals. In most patients the ductus arteriosus is absent; if a ductus is present, usually it is large with a corresponding decrease in size of the aortic isthmus. Interrupted aortic arch Type B is present in 10 percent of patients with truncus arteriosus.

The physiologic abnormality is severe, with 50 percent of patients dying in the first month of life and 90 percent within the first year. Death results from unrestricted pulmonary blood flow with severe pulmonary congestion, congestive heart failure, and progressive pulmonary vascular changes. These patients generally develop early dyspnea and respiratory distress. Severe incompetence of the truncal valve also may occur, which worsens the degree of early heart failure.

Shunting is bidirectional, because the aorta receives blood from the right ventricle and the left ventricle. Arterial oxygen desaturation is always present, with the degree of cyanosis varying with the volume of pulmonary blood flow. In infancy the oxygen saturation usually is above 80 percent, so cyanosis is minimal. Severe pulmonary vascular disease develops rapidly, often before 6 months of age. As this progresses, arterial oxygen saturation decreases and cyanosis becomes progressively more prominent.

Clinical Manifestations

The chest radiograph shows cardiomegaly and pulmonary congestion. Right and left ventricular hypertrophy are evident on the electrocardiogram. The echocardiogram is diagnostic, outlining the single vascular trunk originating from the base of the heart. Cardiac catheterization and angiography define the anatomy precisely, including the origin of the pulmonary arteries and the presence of insufficiency of the truncal valve. The pulmonary vascular resistance also can be determined, which is especially important in older patients.

Treatment

In the procedure developed by McGoon the pulmonary arteries are detached from the truncus, the right ventricle is opened, the ventricular septal defect is closed with a patch, and a homograft valve conduit is used to reconstruct flow into the pulmonary vascular bed. Operation should be performed promptly once the diagnosis is made, preferably within the first month of life.

In 1985 DiDonato described operative results for 167 patients over a 17- year period. There were 48 hospital deaths (29 percent mortality). Of the 119 surviving patients 84 percent were alive after 5 years, and 69 percent after 10 years. Sharma reported experiences with 23 patients, 16 of whom were less than 1 year of age. There were only three operative deaths, two of which occurred in critically ill infants operated on under 1 month of age. Ebert described experiences with 106 infants with 11 operative deaths. Of the 86 long-term survivors, 15 required a later operation for a change of the conduit because of body growth or pseudointimal proliferation in the conduit. There were no mortalities at the time of conduit change.

The operative mortality with this procedure is in the range of 5 to 10 percent. The main causes of perioperative death are ventricular failure, truncal valve insufficiency, and postoperative pulmonary hypertensive crisis. Patients with concomitant interrupted aortic arch have an increased risk. Late complications include the need for reoperation for pulmonary conduit change, which persists throughout life, and the development of progressive insufficiency in the abnormal truncal valve.

OTHER COMPLEX MALFORMATIONS

Hypoplastic Left Heart Syndrome

Lev first described the pathologic findings of aortic hypoplasia in 1952. In 1958 Noonan and Nadas described the clinical syndrome and termed the lesions *hypoplastic left heart syndrome (HLHS)*. *HLHS* encompasses a group of malformations, including aortic hypoplasia or atresia and a poorly developed or absent left ventricle. *HLHS* accounts for 2 to 4 percent of congenital heart defects and for more than 20 percent of congenital cardiac deaths. While the cause is unknown, approximately 25 percent of patients with *HLHS* have an identifiable genetic defect.

Pathology and Pathophysiology

The pathology of *HLHS* includes aortic stenosis, hypoplasia, or atresia, which produces severe left ventricular outflow tract obstruction with almost no forward blood flow. The ascending aorta and proximal aortic arch are diminutive, providing retrograde flow to the coronary arteries. The left ventricle is severely hypoplastic or absent, and the myocardial muscle fibers are in disarray, with severe endocardial fibroelastosis. The mitral valve is hypoplastic or totally atretic in 85 percent of the patients, and approximately 15 percent have a severely malaligned common atrioventricular valve.

Mixing of blood must occur at the atrial level, because no forward blood flow occurs through the hypoplastic left side of the heart. Blood leaves the heart through the large right ventricle and pulmonary artery, which is always enlarged, and proceeds to the lungs and, through the patent ductus arteriosus, to the systemic circulation. Cerebral and cardiac perfusion are retrograde through the atretic aortic arch and ascending aorta.

Shortly after birth oxygenation and perfusion usually are adequate until the ductus arteriosus closes. In some cases the lungs are overperfused, and the patient remains well oxygenated but becomes acidotic because of poor systemic perfusion.

Clinical Manifestations

Most children appear deceptively normal at birth. Typically the child only becomes symptomatic when the ductus arteriosus begins to close, at 24 to 48 h after birth, as they develop cyanosis, tachypnea, and respiratory distress. Severe acidosis develops and the child's color becomes ashen from poor perfusion. Death occurs promptly if the ductus arteriosus is not reopened with prostaglandin infusion. More than 95 percent of patients with *HLHS* die within 2 to 4 weeks, while a small percentage survive because the ductus remains patent.

Physical examination reveals signs of congestive heart failure such as rales and hepatomegaly. Peripheral pulses often are diminished, and perfusion is poor. The chest radiograph shows cardiomegaly with significant pulmonary congestion, and the electrocardiogram shows an absence of left-sided forces, right-axis deviation, and right ventricular hypertrophy. The echocardiogram usually is diagnostic, but it must be done meticulously to outline all of the pathologic anatomy. Color Doppler imaging is used to assess the physiology. Cardiac catheterization is not routinely necessary. In some patients the diagnosis is made prenatally because the lesions are readily identifiable by fetal echocardiography.

Treatment

The initial treatment is to maintain ductal patency with prostaglandin E₁. Acidosis is corrected with sodium bicarbonate. Because the outlook is poor even with surgical therapy, immediate and detailed counseling with the family is done to determine a treatment plan.

The best results have been obtained with a staged palliative treatment plan as described by Norwood. The initial operation is performed in the first week of life with the patient in deep hypothermia and circulatory arrest. The goal of this staged treatment is similar to that for all patients with single-ventricle physiology, that is, to provide passive pulmonary blood flow with a modified Fontan procedure.

The initial palliative stage 1 Norwood procedure involves establishing unobstructed flow from the right ventricle to the systemic circulation by anastomosis of the pulmonary artery to the aortic arch, usually with augmentation of the ascending aorta and arch. Atrial mixing is established by resecting the atrial septum, and controlled pulmonary blood flow is established by a systemic-to-pulmonary modified Blalock-Taussig shunt.

Previously the second stage was a modified Fontan procedure, performed at 12 to 18 months of age after the pulmonary vascular resistance had dropped to normal. A high mortality rate occurred during the interval between operations using this approach. Today the second stage is a bidirectional Glenn shunt, which is performed when the patient is 4 to 6 months of age. Cardiac catheterization is performed before the second stage to evaluate the aortic arch and aortic outflow tract, the pulmonary arteries, and the pulmonary vascular resistance. During the second-stage procedure, the previously placed Blalock-Taussig shunt is taken down, and the pulmonary arteries are augmented as necessary to correct any anatomic obstruction. The final stage is a completion Fontan procedure (total cavopulmonary connection), which is performed approximately 1 year after the second stage.

Results

Survival from the initial stage 1 Norwood procedure exceeds 80 percent at most centers. Subsequent mortalities for stage 2 and stage 3 are 5 to 10 percent each. In 1992 Norwood reported results in 354 patients with *HLHS*, noting an overall survival of 70 percent. Late complications are similar to those associated with the Fontan procedure.

Another viable approach to patients with *HLHS* is cardiac transplantation. This method of treatment is limited by the availability of infant organs. Survival rates for infants treated by transplantation is similar to that for infants treated by the Norwood approach. Aggressive operative treatment of children with HLHS has resulted in late survival rates similar to those obtained in patients treated for pulmonary atresia with intact ventricular septum and for truncus arteriosus.

Total Anomalous Pulmonary Venous Return

Pathology and Pathophysiology

In 1942 Brody published a pathologic study of 100 cases of anomalous pulmonary venous drainage, 35 of which were cases of total anomalous pulmonary venous return (TAPVR). The condition is classified according to the path of the anomalous venous drainage, which is *supracardiac* in 40 to 50 percent of cases, *intracardiac* in 25 percent, *infracardiac* in 25 percent, and *mixed* in about 5 percent. In most cases the anomalous veins enter a common pulmonary venous sinus or channel, which returns the pulmonary venous blood to the right side of the heart. In supracardiac TAPVR, the common venous channel usually is a vertical vein, which enters the innominate vein. Occasionally, the supracardiac vertical vein enters the superior vena cava directly. With intracardiac TAPVR, the anomalous pulmonary veins typically enter the coronary sinus. In patients with infracardiac or infradiaphragmatic drainage the common venous channel traverses the diaphragm and enters the portal system. An atrial septal defect is almost always present and a patent ductus arteriosus is a common associated abnormality.

The pathophysiology commonly found in TAPVR is pulmonary venous obstruction producing severe pulmonary congestion and respiratory distress. Symptoms are often severe, resulting in death in 50 percent of untreated infants within 3 months and in about 80 percent within the first year. Some degree of pulmonary venous obstruction may be present in any of the drainage types described above, but obstruction usually is present when drainage is infracardiac. In infants without significant pulmonary venous obstruction and with an adequate atrial septal defect, the physiology is that of a large left-to-right shunt, similar to a large atrial septal defect. The left ventricle often is small and relatively underdeveloped because of decreased flow, although it develops normally after correction.

Clinical Manifestations

Severe tachypnea is the dominant symptom in a seriously ill infant with TAPVR. Infants with severe obstruction often have severe pulmonary congestion and hypoxemia, requiring intubation and respiratory support. Diminished peripheral perfusion from decreased left-sided cardiac output also may be present. The diagnosis often is unclear initially, and therefore total anomalous drainage should be considered in any severely tachypneic infant. Cardiac murmurs are not diagnostic. Patients with infracardiac drainage may present very early in life with symptoms of pulmonary venous obstruction. Operation is recommended at the time of diagnosis in most patients, because the operative risk increases significantly after critical obstruction develops.

The chest radiograph may show classic abnormalities because of dilation of the common venous channel, innominate vein, and superior vena cava. The well-recognized double contour is termed the “snowman” appearance.

Two-dimensional echocardiography often can establish the diagnosis and outline the abnormal channels, but cardiac catheterization and angiography also are necessary. An MRI study may define the pathway of the abnormal venous drainage. At catheterization, a classic finding is that blood from the right atrium, pulmonary artery, and femoral artery have an identical oxygen content because of mixing in the right atrium.

Treatment

Operation must be performed urgently in critically ill infants and should be scheduled promptly in all other patients. Total repair usually is done with the patient in hypothermia and circulatory arrest. Operative correction includes construction of a large (2.5 to 3.0 cm) side-to-side anastomosis between the common venous trunk and the left atrium, followed by closure of the atrial septal defect and ligation of the left vertical vein. Supracardiac drainage usually is approached transatrially, whereas infracardiac drainage may be repaired by lifting the heart and performing part of the anastomosis from outside of the heart and part from within the atrium. When anomalous veins enter the coronary sinus (intracardiac type), surgical reconstruction is simpler, consisting of creating a large opening between the coronary sinus and the left atrium and performing a patch closure of the atrial septal defect in such a way that coronary sinus flow is directed into the left atrium.

Results

The operative mortality is 5 to 10 percent in infants. After repair the left ventricle grows, and most patients develop normal cardiac function. Late risks include recurrent pulmonary venous obstruction. With current techniques and the use of absorbable suture material for the pulmonary venous anastomosis, the risk of recurrent venous obstruction is approximately 3 percent. The long-term functional results are excellent. In the 15 to 20 percent of patients with a large pulmonary blood flow who are operated on after 1 year of age, operative mortality is less than 1 percent.

Corrected Transposition

The basic characteristics of this unusual malformation were described by Anderson in 1957, with additional contributions by Schiebler in 1961.

Pathology and Pathophysiology

In this malformation the anatomic right ventricle and the anatomic left ventricle are switched or inverted; the lesion also may be called *ventricular inversion*. The defect arises from a malrotation of the embryonic heart tube, which bends to the left (*D*-ventricular loop). The tricuspid and mitral valves “follow” the inverted ventricles, resulting in a right-sided atrioventricular valve that is morphologically a mitral valve and a left-sided atrioventricular valve that is morphologically tricuspid. The aorta arises from a morphologic right ventricle, and the pulmonary artery arises from a morphologic left ventricle. Because the systemic venous blood reaches the pulmonary trunk (by traversing a morphologic mitral valve and left ventricle) and the pulmonary venous blood reaches the aorta (by traversing a morphologic tricuspid valve and right ventricle), the “double discordance” results in a physiologically normal (or “corrected”) circulation.

The significance of the malformation lies primarily in the associated defects and in the propensity of the tricuspid valve to become insufficient. The most frequent associated defect

is a ventricular septal defect, which is present in approximately 80 percent of cases. Another frequent finding is the presence of conduction abnormalities. Normal atrioventricular conduction is present in less than one-half of the patients, and progression to heart block is common. Pulmonic stenosis frequently occurs, which may be severe in some patients. The final associated malformation is left-sided (tricuspid) atrioventricular valvular insufficiency. This gradually develops as a consequence of the tricuspid valve's outflow entering the systemic circulation.

Clinical Manifestations

Conduction defects may cause problems in infancy; 5 to 10 percent of patients are born with a complete heart block, and heart block appears in about 2 percent of the patients each year, with about 30 percent eventually developing complete block.

A large ventricular septal defect usually is present, which produces classic left-to-right shunting and pulmonary congestion. Closure of the VSD is indicated. Severe pulmonary vascular disease develops in most patients with a large VSD unless significant pulmonic stenosis also is present. When pulmonic stenosis is present pulmonary flow is restricted, and the patient is protected from pulmonary overperfusion. In approximately 30 percent of patients, the pulmonic stenosis is severe enough to cause hypoxia and cyanosis, resulting in the need for early total correction or a palliative shunt.

The electrocardiogram usually is abnormal, characteristically indicating conduction disturbances and right ventricular hypertrophy. The echocardiogram usually is diagnostic. Cardiac catheterization may be necessary in older patients.

Treatment

Closure of the VSD is technically difficult because of the uncertainty of the conduction tissue, which tends to course anteriorly and superiorly on the right side of the superior septal tissue. A standard transatrial approach through the right atrium and tricuspid valve is preferred. Heart block is not unusual after operation, with an incidence of 10 to 20 percent. Patients with severe pulmonic stenosis often require placement of an extracardiac valved homograft to the pulmonary artery, because the pathologic anatomy precludes an incision across the stenotic pulmonic valve. When the left-sided tricuspid valve is insufficient, valve repair or replacement is necessary.

Results

The combined series reported by Kirklin and Barratt-Boyes includes a total of almost 100 patients, with an operative mortality of 10 to 15 percent and a 10-year survival rate of approximately 75 percent. In recent years the operative mortality has been less than 10 percent in many centers. Late complications include the ongoing need for conduit change, left ventricular failure, left-sided atrioventricular valvular insufficiency, and progressive conduction disturbances.

OTHER ANOMALIES

Anomalous Origin of the Left Coronary Artery

Anomalous origin of the left coronary artery is a rare malformation, occurring in about 1 of every 300,000 live births and representing about 0.25 percent of patients with congenital heart disease. The clinical features described by Bland in 1933 emphasize a similarity to myocardial infarction in adults. A significant contribution was made in 1959 by Sabiston, who demonstrated that the flow of blood in the anomalous left coronary artery was retrograde into the low-pressure pulmonary artery. Ligation of the anomalous artery subsequently became a form of treatment. Apley, in 1957, recommended ligation of the left coronary followed by bypass with the left subclavian artery. Cooley, in 1966, recommended detaching the coronary artery and connecting it to the aorta with a saphenous vein graft, but late vein graft stenosis has limited the effectiveness of this approach. The creation of an intrapulmonary-artery tunnel for reimplantation of the left coronary artery onto the aorta was proposed by Takeuchi in 1979 and has been quite successful. The most widely used technique is a direct coronary transfer method, proposed by Grace in 1977. Concomitant mitral valve repair frequently is required because of secondary mitral insufficiency.

Clinical Manifestations

Patients become symptomatic early. Most patients develop myocardial infarction and left ventricular failure within 3 months after birth. Only 10 to 20 percent of untreated infants live more than 1 year because of abundant collateral circulation from the right coronary artery. Symptoms usually are mild for the first few weeks after birth because of the elevated pulmonary vascular resistance in the neonatal period. Subsequently, symptoms progress rapidly. Symptoms of tachypnea, sweating, poor feeding, respiratory distress, and heart failure are a result of progressive myocardial ischemia with myocardial infarction, left ventricular failure, and progressive mitral valve insufficiency.

Physical examination may reveal cardiac enlargement without murmur, or with a murmur of mitral insufficiency. The chest radiograph may show extensive enlargement of the left ventricle with pulmonary congestion. The electrocardiogram usually is diagnostic, with inverted T waves or prominent Q waves in the anterolateral leads. Transesophageal echocardiography is useful in confirming the diagnosis and in demonstrating poor contractility, absence of the normal origin of the left coronary artery from the aorta, and, sometimes, mitral insufficiency. Cardiac catheterization and angiography usually are done before repair.

Treatment

Infants with this malformation are at risk for sudden death and progressive myocardial failure, and operative repair is indicated once the diagnosis is made. Because of the excellent experience with coronary artery transfer in the arterial switch operation, the coronary transfer method described by Grace is the treatment of choice. The procedure is performed with the patient on cardiopulmonary bypass and cardioplegic arrest. The left main pulmonary artery is transected just distal to the sinotubular junction, as in the switch operation. Typically the left main coronary arises from the posterior sinus. The ostium is excised from the sinus with a small "button" and reimplanted onto the appropriate point of the lower medial ascending aorta. The posterior pulmonary sinus may be augmented with a small patch of pericardium, and the pulmonary artery is closed. If significant mitral insufficiency is present, mitral valve annuloplasty is performed.

Results

The operative mortality is around 10 percent, depending on the severity of left ventricular dysfunction and the amount of irreversible myocardial damage. Postoperatively, surviving patients often have dramatic improvement in left ventricular function, with more than 95 percent of patients returning to New York Heart Association (NYHA) class I functional status. Late patency of the coronary transfer approaches 100 percent.

Vascular Rings

Vascular rings comprise an uncommon type of congenital defect in which an anomalous arterial formation can result in compression of the esophagus or trachea. Patients are frequently symptomatic, and surgical therapy is effective with little morbidity or mortality. Embryologically, the vascular rings result from some variation in the normal formation of the aorta and pulmonary artery from the embryonic aortic arches. In the normal embryo the first two aortic arches disappear, and the fifth arch never fully develops. The third, fourth, and sixth arches are significant in normal development. The right common carotid artery arises from the third arch, the innominate artery from the right fourth, the transverse aortic arch from the left fourth, and the ductus arteriosus from the sixth.

Pathology

Five types of vascular anomalies have been noted: (1) double aortic arch, (2) right aortic arch with left ligamentum arteriosum, (3) retroesophageal subclavian artery, (4) anomalous origin of innominate artery, and (5) anomalous origin of left common carotid artery. *Pulmonary artery sling*, which is another form of vascular ring that produces severe, symptomatic tracheal compression, is considered separately below.

A double aortic arch, with one limb anterior to the trachea and the other limb posterior to the esophagus, is the most severe of the vascular rings, usually producing symptoms in early infancy. One arch usually is smaller than the other. When the descending aorta is left-sided, the posterior arch is typically the larger one; when the upper descending aorta is right-sided, the anterior arch is likely to be larger. A right aortic arch with a retroesophageal ductus arteriosus or ligamentum arteriosus, or a right arch with a retroesophageal left subclavian artery and a Kommerell (ductal) diverticulum may produce symptomatic tracheal compression. A left-sided aorta with a retroesophageal right subclavian artery is a common anomaly but usually does not cause symptoms. The last two of the five anomalies, anomalous origin of the innominate artery or of the left common carotid artery, are very rare. When these conditions produce symptoms, they are from direct compression, as a true vascular ring often is not present.

Clinical Manifestations

Most symptoms from vascular rings result from compression of the trachea. Difficulty in swallowing from compression of the esophagus is rare. Infants with a double aortic arch often develop difficulty in breathing during the first few months of life and become critically ill. Stridor is the most frequent prominent symptom. Periodic episodes of serious respiratory distress with "crowing" respirations occur. During these attacks the infant lies in hyperextension while gasping for breath. Feeding often precipitates such episodes, perhaps from flexion of the neck or aspiration. Infants quickly become underweight and malnourished.

Most patients with vascular rings requiring surgical treatment are seen in infancy. Those with mild symptoms that develop after 1 year of age may spontaneously recover as they grow older. The most common symptoms are related to intermittent respiratory compression, exacerbated by a respiratory infection or feeding. Recurrent episodes of pneumonia also are relatively common. Difficulty in swallowing, if present, is mild. A mild clinical picture is produced by the retroesophageal subclavian artery, which may cause mild, intermittent dysphagia. Some patients who are mildly symptomatic in infancy spontaneously recover with growth.

The chest radiograph usually is normal unless pneumonia is present. Examination of the esophagus with a barium swallow can establish the diagnosis, demonstrating a typical area of esophageal compression. The diagnosis is established with an MRI scan, or with enhanced MR angiography, which outlines the vascular anatomy and demonstrates any tracheal compression or tracheal stenosis present. Catheterization and arteriography are unnecessary. Bronchoscopy usually is performed to confirm segmental tracheal compression and to rule out diffuse tracheomalacia.

Treatment

If no symptoms are present, no treatment is needed. If symptoms are mild and of uncertain cause, a period of observation may be prudent to ensure that other medical problems are not responsible. If clear symptoms are present, operation should be performed promptly, because death from airway obstruction can easily occur, particularly in patients with complete vascular rings.

Operative Technique

If the child is in respiratory distress, the airway is secured before the child is fully asleep. A rigid pediatric bronchoscope should be in the operating room. Although the optimal incision varies with the type of pathology, an incision through the fourth intercostal space on the appropriate side usually is selected. An important principle is to dissect the aorta and the aortic arch completely, identifying the innominate artery, the left common carotid artery, the subclavian artery, the ligamentum arteriosus, and, in the case of double aortic

arch, the anterior and posterior arches. Opening the pericardium can facilitate identification of these vessels. The vagus and phrenic nerves should be identified and preserved.

With a double aortic arch, the smaller of the two arches should be divided. Usually, with a left descending aorta, the anterior arch is smaller and can be divided between the left common carotid and left subclavian artery. In some cases the divided anterior arch may produce some mild compression; if so, it should be sutured to the posterior surface of the anterior chest wall. If the posterior arch is smaller, it can be divided behind the esophagus. With a right descending thoracic aorta, the posterior arch usually is the smaller of the two, and it is divided.

With a right aortic arch and a retroesophageal ligamentum or ductus arteriosus, division of the ligamentum or ductus is all that is necessary. In patients with a retroesophageal left subclavian artery and a Kommerell diverticulum, the diverticulum should be resected to relieve compression.

Results

The operative risk is primarily related to the age of the patient and the severity of compression of the trachea. The operative mortality should be less than 1 to 2 percent. After the patient recovers from operation, most symptoms should quickly resolve, and the long-term results are excellent.

Pulmonary Artery Sling

Pulmonary artery sling is a rare congenital malformation in which the left pulmonary artery arises from the right pulmonary artery, coursing to the left between the trachea and the esophagus to reach the left pulmonary hilus, thus forming a sling or ring around the trachea. The trachea often is segmentally narrowed at the site of compression. In approximately 50 percent of the patients severe tracheal stenosis is present with complete cartilaginous rings. This occurs from abnormal intrauterine development of the trachea, possibly from vascular compromise. The presence of severe tracheal stenosis with complete tracheal rings greatly worsens the prognosis and increases the difficulty of the repair. The most severe cases have long, funnel-shaped stenosis or diffuse tracheal hypoplasia with complete rings for the entire length. Other cardiac anomalies also are present in nearly one-half of reported patients.

Clinical Manifestations

Most infants with pulmonary artery sling develop severe symptoms in the first few months of life, with feeding difficulty, wheezing, stridor, and severe respiratory distress. The diagnosis may be suspected from abnormalities visible on the chest radiograph, with a density separating the trachea from the esophagus on the lateral view. An esophageal barium swallow usually is diagnostic, showing anterior indentation of the esophagus just above the carina tracheae. MRI is the diagnostic imaging technique of choice. It outlines the vascular anatomy and the severity and length of the tracheal stenosis. If the diagnosis remains uncertain, catheterization and angiography are performed.

Bronchoscopy should be performed routinely to evaluate the severity of the tracheal malformations. This is probably the most important determinant of operative strategy and prognosis. Older patients are occasionally seen with minimal or no symptoms. Such patients often require no specific treatment.

Treatment

The operative procedure is relatively simple in the absence of severe tracheal stenosis. The repair, performed through the left lateral thoracotomy, entails dividing the anomalous pulmonary artery at its origin and reanastomosing it to the main pulmonary artery anteriorly. The ligamentum arteriosum also is divided at this time. This procedure also may be done through a median sternotomy.

When significant tracheal stenosis is present the procedure becomes more complicated. Segmental tracheal stenosis should be resected at the time of sling repair, reanastomosing the trachea end-to-end. Jonas reported that the use of absorbable polydioxanone suture (PDS) allowed growth of the tracheal anastomosis with excellent long-term results. In patients with more diffuse tracheal stenosis from complete rings, the operative repair is difficult. Several methods of repair have been proposed. Idris, Bando, and de Lorimier all reported successful repairs using an anterior pericardial tracheoplasty, which involves making an incision along the length of the trachea, followed by tracheal augmentation. Additional buttressing and stenting with cartilage was suggested by de Lorimier, and Murphy proposed the use of vascularized pericardial grafts. Grillo and Tsang both reported use of a slide tracheoplasty technique for long-segment stenosis with excellent success. Any technique for repair of pulmonary artery sling with long-segment tracheal stenosis requires a sternotomy and cardiopulmonary bypass.

Results

The operative risk and the long-term prognosis are primarily determined by the nature and degree of disease present in the trachea. When tracheal stenosis is absent or segmental, the success rate of repair is approximately 98 percent, with most patients remaining asymptomatic. Late occlusion of the pulmonary artery has been reported in some patients. In patients with long tracheal stenosis with complete rings, the operative results are less predictable. Operative mortality is approximately 10 percent in these patients, and there is a small but significant incidence of late recurrent tracheal problems.

CHAPTER 18 - Acquired Heart Disease

Aubrey C. Galloway
Richard V. Anderson
Eugene A. Grossi
Frank C. Spencer
Stephen B. Colvin

CLINICAL EVALUATION

The importance of the history and physical examination cannot be overemphasized in the evaluation of a patient with acquired heart disease for potential surgery. It is imperative that the surgeon be well aware of the patient's functional status and the clinical relevance of each symptom, because many operative decisions depend on the accurate assessment of the significance of a particular pathologic finding. With the number of available diagnostic tests rapidly increasing, appropriate sequencing of the diagnostic work-up requires clinical perspective and diagnostic acumen that are obtained through the history and physical examination. The associated risk factors or concomitant diseases that can significantly influence the patient's operative risk for cardiac or noncardiac surgery must be accurately identified. Specific physical findings, such as prior saphenous vein stripping, previous thoracic surgery, or peripheral vascular disease, must be accurately identified preoperatively.

History

The classic symptoms of heart disease are fatigue, angina, dyspnea, edema, cough or hemoptysis, palpitations, and syncope. When a patient describes or complains of any of these symptoms, the clinical scenario leading to the symptom must be explored in detail, including symptom intensity and duration, provocation, associated symptoms, and conditions that lead to relief. The initial goal is to determine whether a symptom is cardiac or noncardiac in origin as well as to determine the clinical significance of the complaint. An important feature of cardiac disease is that myocardial function or coronary blood supply that may be adequate at rest may be completely inadequate with exercise or exertion. Chest pain or dyspnea that occurs primarily during exertion frequently is cardiac in origin, while symptoms that occur at rest but not during exercise frequently are not.

In addition to evaluating the patient's primary symptoms, the history should include family history, past medical history (prior surgery, prior myocardial infarction, or concomitant hypertension, diabetes, and other associated diseases), personal habits (smoking, alcohol or drug use), functional capacity, and a detailed review of systems. After the patient's symptoms have been carefully assessed, appropriate diagnostic studies may be ordered and interpreted. The classic symptoms are outlined in detail below.

Fatigue

Easy fatigability is a frequent but nonspecific symptom of cardiac disease that can arise from many causes. In some patients easy fatigability probably reflects a generalized decrease in cardiac output or low-grade heart failure. Subjective easy fatigability is a vague and nonspecific symptom.

Angina

Angina pectoris is the hallmark of myocardial ischemia secondary to coronary artery disease, although a variety of other conditions can produce chest pain. Classic angina is precordial pain described as squeezing, heavy, or burning in nature, lasting from 2 to 10 min. The pain usually is substernal, often radiating into the left shoulder and arm but occasionally occurring in or radiating into the midepigastrium, jaw, right arm, or interscapular region of the back. True angina typically is provoked by exercise, emotion, sexual activity, or eating and is relieved by rest or nitroglycerine. Angina is present in its classic form in 75 percent of the patients with coronary disease, while 25 percent of patients with coronary disease have atypical symptoms, with a small but significant number of patients developing "silent" ischemia.

Angina also is a typical symptom of aortic stenosis, occurring secondary to the combination of left ventricular hypertrophy, increased intracardiac pressure, increased ventricular wall tension (leading to higher oxygen requirements), and decreased cardiac output. This combination results in a myocardial oxygen supply–demand mismatch with resultant ischemia and angina.

Noncardiac causes of chest pain that may be confused with angina include esophageal reflux or spasm, costochondritis (Tietze's syndrome), musculoskeletal pain, ulcer disease, biliary disease, pleuritis, pulmonary embolus, pulmonary hypertension, pericarditis, and aortic dissection.

Dyspnea

The physiologic change in most patients with heart failure is a rise in intracardiac pressure followed by cardiac enlargement, usually a combination of dilatation and hypertrophy. This is a manifestation of Starling's law of the heart: increased work can be achieved in response to an increase in diastolic fiber length. Symptoms develop subsequently as different compensatory mechanisms fail. This concept is important because abundant data indicate that operation should be considered for many diseases on the basis of physiologic abnormalities, such as a progressive drop in left ventricular ejection fraction or a reduction of cross-sectional area of an aortic or mitral valve below 1.0 cm², rather than from the presence of symptoms. Delaying operation until symptoms are severe often results in irreversible ventricular injury, which in turn can be a major cause of death in the first few years after a technically successful operation.

The normal left ventricular end-diastolic pressure is less than 12 mmHg. Pressures in the range of 12 to 20 mmHg represent moderate disease, while pressures of 20 to 25 mmHg or higher represent severe disease. Because the oncotic pressure of plasma is approximately 25 mmHg, as left atrial pressure rises, pulmonary congestion develops when the left atrial pressure approaches the oncotic pressure of plasma. The tolerance for pulmonary congestion depends on several factors, including the capacity of the pulmonary lymphatics to resorb fluid. Dyspnea is one of the cardinal symptoms of left heart failure. It can be graded with the degree of exertion required to initiate dyspnea, as opposed to dyspnea at rest that represents a severe form of heart disease. With mitral stenosis, dyspnea appears as an early sign because of restriction of flow from the left atrium into the left ventricle. With other forms of heart disease, however, dyspnea is a late sign because it develops only after the left ventricle has failed and the end-diastolic pressure rises significantly. Dyspnea with mitral insufficiency, aortic valvular disease, or coronary disease represents relatively advanced pathophysiology, in contrast to mitral stenosis, in which dyspnea occurs relatively early in the disease process.

A number of other respiratory symptoms represent different degrees of pulmonary congestion. These include orthopnea, paroxysmal nocturnal dyspnea, cough, hemoptysis and pulmonary edema. Dyspnea occasionally represents an "angina equivalent," occurring secondary to ischemia-related ventricular dysfunction.

Edema

Left-sided heart failure can result in fluid retention and pulmonary congestion, subsequently leading to pulmonary hypertension and progressive right-sided heart failure. A history of exertional dyspnea with associated edema frequently is from heart failure. Primary right heart failure occasionally results from right ventricular injury and dysfunction or from primary tricuspid valve disease. Right atrial pressure, normally less than 5 to 8 mmHg, may be elevated up to the range of 15 to 30 mmHg and sometimes higher. Retention of more than 7 to 10 pounds of fluid results in visible edema of the lower extremities, which is almost always symmetric bilaterally. Jugulovenous distention and hepatomegaly develop with severe right heart failure. With chronic severe failure, generalized fluid retention may be acute, with marked deformities from accumulation of 20 or more pounds of edema fluid, with ascites and massive hepatomegaly.

Palpitations

Palpitations are secondary to rapid, forceful, ectopic or irregular heartbeats. Palpitations often are innocuous, but they should not be ignored, because they might represent significant or potentially life-threatening arrhythmias. The underlying cardiac arrhythmia ranges from premature atrial or ventricular contractions to atrial fibrillation, atrial flutter, paroxysmal atrial or junctional tachycardia, or sustained ventricular tachycardia. Atrial fibrillation is one of the most common causes of palpitations, occurring frequently in patients with mitral stenosis, and results from left atrial hypertrophy evolving from the sustained elevation in left atrial pressure. With other forms of heart disease, arrhythmias are less common, occurring sporadically. They are more frequent in older patients, probably from intrinsic disease in the atrioventricular conducting mechanism, resulting in "sick sinus syndrome" or intermittent heart block, and in patients with ischemic cardiomyopathy, probably as a manifestation of diffuse myocardial scarring. Severe, life-threatening forms of ventricular tachycardia or ventricular fibrillation may occur in any ischemic patient from ongoing ischemia or scarring. Palpitations caused by a slow heart rate often are from complete or intermittent atrioventricular nodal block.

Syncope

Syncope, or sudden loss of consciousness, usually is a result of sudden decreased perfusion of the brain. The differential diagnosis includes: (1) transient heart block with asystole or ventricular fibrillation (Adams-Stokes syncope or syndrome), (2) malignant tachyarrhythmias, (3) ventricular fibrillation, (4) aortic stenosis, (5) hypertrophic cardiomyopathy, (6) atrial myxoma with transient mitral valve obstruction, (7) primary pulmonary hypertension, (8) seizure disorder, (9) carotid artery or cerebrovascular disease, and (10) vasovagal reaction (fainting). Any episode of syncope must be worked up thoroughly, because these events can result in sudden death.

Functional Classification

An important part of the history is the assessment of the patient's overall functional status or the degree of cardiac disability. This generally is a good approximation of the severity of the patient's underlying cardiac disease. The *New York Heart Association (NYHA)* has developed a classification of patients with heart disease based on symptoms that has been useful in evaluating clinical course and operative risk. A more detailed grading system for patients with angina pectoris was developed by the Canadian Cardiovascular Society (CCS). These classification systems are adequate for the majority of patients. When a more precise functional analysis is necessary, the specific activity scale proposed by Goldman and based on the estimated metabolic cost of various activities is used. The NYHA and CCS classifications are outlined in Table 18-1.

Physical Examination

A few basic physical abnormalities are discussed briefly here, because abnormal physical findings are best discussed in conjunction with the specific disease causing them. In some cardiac diseases, physical abnormalities are virtually diagnostic of the disease and the severity of the problem, while in others, such as coronary disease, the absence of any physical abnormality can be seriously misleading. Conducting a thorough physical examination before performing any surgical procedure is critical if the surgeon is to deliver optimal care. Previously overlooked physical findings can lead the surgeon to suspect a concomitant disease process, in which case additional work-up or altered management can lessen the risk of the proposed operation.

The important parts of the preoperative general and cardiovascular examinations are as follows:

General

The patient must be assessed for overall body size and phenotype, level of body fat, musculoskeletal deformities, and prior surgical scars, because abnormal anatomy or prior

surgery may influence the operative approach.

Generalized muscular wasting can occur in patients with chronic, severe, congestive heart failure from the combination of low cardiac output and an inability to eat, resulting in malnutrition from lack of calories and protein. These severely ill patients are especially susceptible to infection after operation.

Vascular

The peripheral vascular examination is important for all surgical patients, but particularly for patients undergoing cardiac surgery. The vascular examination involves assessment of pulses, an evaluation of peripheral perfusion, and assessment of skin quality and hair loss. The venous system is evaluated, and venous insufficiency or varicose veins are noted. If varicosities are present in the greater saphenous system, the lesser saphenous veins and cephalic veins should be evaluated and preserved.

If the surgeon is considering the use of a radial artery for a cardiac procedure, Allen tests should be performed bilaterally to assess the contribution of the ulnar artery to the palmar arch. In questionable cases, digital plethysmography of the fingers with and without radial artery occlusion should be performed.

Auscultation for carotid and abdominal bruits should be performed in all patients, and the abdomen should be palpated for aneurysmal masses. Significant abnormalities are evaluated by vascular Doppler studies, ultrasonography, or scanning modalities.

Cardiac

A cardiac murmur heard during auscultation frequently establishes the diagnosis of valvular heart disease. An apical diastolic rumble is diagnostic of mitral stenosis, while a parasternal diastolic murmur suggests aortic insufficiency. Systolic murmurs, including the basal systolic murmur of aortic stenosis and the apical systolic murmur of mitral insufficiency, are classic findings. Underlying valvular conditions may be completely unsuspected and the patient referred for coronary bypass or an unrelated general surgical procedure. Whenever an unsuspected murmur is found by the surgeon before operation, additional diagnostic work-up is indicated, usually with echocardiography.

The initial adaptation to underlying valvular heart disease usually is cardiac enlargement. This often is detected in the physical examination. The finding of a forceful apical impulse in the anterior axillary line indicates long-standing disease. Less obvious signs of cardiac enlargement may be seen on the chest x-ray, the electrocardiogram (ECG), or, most precisely, the echocardiogram, which can define the exact size of the cardiac chambers and the thickness of the heart muscle.

DIAGNOSTIC STUDIES

Electrocardiography and Radiology

The electrocardiogram and the chest x-ray are the two classic diagnostic studies. The electrocardiogram is used to detect rhythm disturbances, heart block, atrial or ventricular hypertrophy, ventricular strain, myocardial ischemia and myocardial infarction. The chest x-ray is excellent for determining cardiac enlargement and pulmonary congestion. A cardiothoracic ratio above 0.5 represents severe cardiomegaly. Analysis of the pulmonary circulation may show several abnormalities. Pulmonary venous congestion develops when left atrial pressure is chronically elevated above the upper normal limit of 12 mmHg, seen typically with severe mitral stenosis. The signs of pulmonary congestion include engorged pulmonary veins and congestion of pulmonary alveoli. Fluid accumulating in the interlobar planes forms transverse linear opacities perpendicular to the surface of the pleura (Kerley lines). Their presence usually indicates a left atrial pressure exceeding 20 mmHg.

Marked enlargement of the pulmonary arteries may occur from an increase in pulmonary blood flow or an increase in pulmonary vascular resistance with pulmonary hypertension. Normally the central pulmonary arteries are three to four times larger than the peripheral arteries. With an increase in pulmonary blood flow, as with an atrial septal defect, central and peripheral arteries are symmetrically enlarged. With pulmonary hypertension, the central pulmonary arteries may become strikingly enlarged while the peripheral arteries do not.

Echocardiography

Echocardiography, which has become the most widely used cardiac diagnostic study, incorporates the use of ultrasound and reflected acoustic waves for cardiac imaging. Two-dimensional (2-D) color Doppler echocardiography is now widely available. These studies give accurate dynamic imaging of the cardiac chambers and assessment of valvular configuration or mobility. Doppler flow velocity and frequency are assigned colors, allowing a visual evaluation of direction and velocity of intracardiac blood flow. Intracardiac pressures, valvular insufficiency, and transvalvular gradients can be estimated from Doppler measurements. Color Doppler information can be superimposed onto the 2-D image to provide a graphic illustration of the directional intracardiac flow pattern and an assessment of valvular insufficiency.

Transthoracic 2-D color Doppler echocardiography has become an excellent noninvasive screening test for evaluating myocardial thickness or hypertrophy, cardiac chamber size, cardiac wall motion, intracardiac and pulmonary artery pressures, internal cardiac anatomy, and the degree of valvular stenosis or insufficiency. Corrective operation for valvular disease frequently is performed on younger patients on the basis of these studies.

Transesophageal echocardiography, which is done by placement of the 2-D transducer in a flexible endoscope, improves the image quality by minimizing scatter from the chest wall and is particularly valuable in evaluation of the left atrium, the mitral valve, and the aortic arch. Transesophageal echocardiographic studies are used when more precise imaging is required or when the diagnosis is uncertain after the transthoracic study.

Dobutamine stress echocardiography has evolved as an important noninvasive provocative study. This study is used to assess cardiac wall motion in response to inotropic stimulation, as wall motion abnormalities reflect underlying ischemia. Several reports have documented the accuracy of dobutamine stress echocardiography in identifying patients with significant coronary artery disease. The predictive value of a positive test for myocardial infarction or death after noncardiac surgery is approximately 10 percent, while 20 to 40 percent will have some cardiac event. A negative test is 93 to 100 percent predictive that no cardiac event will occur.

Radionuclide Studies

The most widely used myocardial perfusion screening study is the thallium scan, which uses the nuclide thallium-201. Initial uptake of thallium-201 into myocardial cells is dependent on myocardial perfusion, while delayed uptake depends on myocardial viability. Reversible defects occur in underperfused, ischemic, but viable zones, while fixed defects occur in areas of infarction. Fixed defects on the thallium scan suggest nonviable myocardium and may be of prognostic value.

The *exercise thallium test* is used widely to identify inducible areas of ischemia and is 95 percent sensitive in detecting multivessel coronary disease. This is the best overall test to detect myocardial ischemia, but it requires that the patient be able to exercise on the treadmill. The study also gives excellent, specific information about the patient's cardiac functional status.

The *dipyridamole thallium* study is a provocative study using intravenous dipyridamole, which induces vasodilation and consequently unmasks myocardial ischemia in response to stress. For patients who cannot exercise, this is probably the most widely used provocative study for risk stratification. In patients undergoing noncardiac surgery the predictive value of a positive dipyridamole thallium study is 5 to 20 percent for myocardial infarction or death, while a negative study is 99 to 100 percent predictive that a cardiac event will not occur. This is a very effective screening study for moderate- to high-risk patients who are undergoing a general surgery procedure.

Global myocardial function is evaluated by the *gated blood pool scan* (equilibrium radionuclide angiocardiology) using technetium-99m. This study can detect areas of hypokinesis and measure left ventricular ejection fraction, end-systolic volume, and end-diastolic volume. An exercise-gated blood pool scan is an excellent way to assess a patient's global cardiac response to stress. The ejection fraction increases with exercise, but with significant coronary artery disease or valvular disease the ejection fraction may stay unchanged or even drop. The resting gated blood pool scan is an excellent way to determine the degree of prior cardiac injury and to assess baseline cardiac function, and the exercise gated blood pool scan assesses the functional response to stress.

Positron-Emission Tomography (PET) Scan

The PET scan is a special radionuclide imaging technique used to assess myocardial viability in underperfused areas of the heart. The technique may be more sensitive than the thallium scan for this purpose. The PET scan is based on the myocardial metabolism of glucose or other compounds tagged with positron-emitting isotopes. The PET scan is most useful in determining whether an area of apparently infarcted myocardium may be "hibernating" and capable of responding to revascularization. These data can be used to determine whether patients with congestive heart failure might improve with operative revascularization.

Cardiac Catheterization

The cardiac catheterization study remains the gold standard for cardiac diagnosis. Complete cardiac catheterization includes the measurement of intracardiac pressures, measurement of cardiac output, localization and quantification of intracardiac shunts, determination of internal cardiac anatomy and ventricular wall motion by cineradiography, and determination of coronary anatomy by coronary angiography (Fig. 18-1).

The cardiac output usually is calculated using the Fick oxygen method, in which cardiac index is calculated as follows:

Cardiac index (L/min/m²) = oxygen consumption (mL/min/m²) / arteriovenous oxygen content difference (mL/min)

For determining the arteriovenous oxygen difference, the oxygen content is calculated separately in the arterial and venous circulations by the formula:

Oxygen content (mL oxygen/L blood) = hemoglobin (g/100 mL) × percent hemoglobin saturation × 1.36 (mL oxygen/g hemoglobin) × 10.

Calculation of systemic vascular resistance (SVR) is by the formula:

SVR = (mean systemic arterial pressure - mean right atrial pressure) × 80 / systemic blood flow (cardiac output)

The normal SVR is 1,200 dynes·sec·cm·sec·cm⁻⁵ The pulmonary vascular resistance (PVR) is calculated by the formula:

PVR = (mean pulmonary artery pressure - mean left atrial pressure) × 80 / pulmonary blood flow (equal to the cardiac output when no shunt is present)

The normal PVR is 70 to 80 dynes·sec·cm⁻⁵.

The area of a cardiac valve can be determined from measured cardiac output and intracardiac pressures using Gorlin's formula that relates the valve area to the flow across the valve divided by the square root of the transvalvular pressure gradient ($A = f/k \times \text{square root of pressure gradient}$). The Gorlin formula indicates that a small valve area might be manifested as a small transvalvular pressure gradient when the cardiac output is low, demonstrating the danger of basing decisions on transvalvular gradient alone. Estimations of the significance of an obstructing valvular lesion should be based on the calculated valve area obtained from precise measurements in a cardiac catheterization laboratory. In an adult the normal mitral valve area is 4 to 6 cm² and the normal aortic valve area is 2.5 to 3.5 cm².

Coronary angiography is essential for the diagnosis of coronary artery disease and is routinely performed before a coronary artery bypass operation (see Fig. 18-1). The posterior descending artery and the atrioventricular (AV) nodal artery arise from the right coronary artery in 80 to 85 percent of patients, and the right coronary artery is termed dominant in these cases. The left coronary system supplies the major portion of left ventricular myocardium in all cases. In 15 to 20 percent of cases the circumflex branch of the left coronary system also supplies the posterior descending branch and the AV nodal artery and is termed dominant, while 5 percent are codominant.

Preoperative Assessment of General Surgical Patients

Preoperative cardiac risk stratification for patients undergoing noncardiac surgery has been identified as an important part of the preoperative evaluation of the general surgery patient. The joint American College of Cardiology/American Heart Association task force has produced guidelines and recommendations that are summarized here. The preoperative cardiovascular evaluation involves an assessment of clinical markers, the patient's underlying functional capacity, and various surgery-specific risk factors.

The *clinical markers* that predict an increased risk of a cardiac event during noncardiac surgery are divided into three grades. *Major* predictors include unstable angina (Canadian class III or IV), recent myocardial infarction with ongoing ischemic risk, decompensated heart failure, significant arrhythmias, and severe valvular disease. *Intermediate* predictors are mild angina (Canadian class I or II), old myocardial infarction, compensated heart failure, and diabetes. *Mild* predictors are advanced age, hypertension, prior stroke, abnormal ECG, and poor functional status.

Various *surgical risk factors or procedures* expose the patient to greater or lesser risk of a cardiovascular event. *High-risk* procedures include emergent major procedures in the elderly, major vascular procedures (i.e., thoracic or abdominal aortic or peripheral vascular) and long procedures with large anticipated fluid shifts (e.g., pancreatectomy, hepatic resection, abdominal-perineal resection, etc.). *Intermediate-risk* procedures include any intraabdominal or intrathoracic operation, carotid endarterectomy, orthopaedic, prostate, and head and neck procedures. *Low-risk* includes endoscopic, breast, cataract, and superficial operations.

On the basis of the clinical markers, the patient's functional class, and the proposed surgical procedure, the patient is assigned a high, intermediate, or low cardiac risk and managed appropriately. Sometimes further risk stratification is required, such as in patients with intermediate-level cardiac risk factors who are undergoing a high-risk surgical procedure. These patients should probably undergo exercise stress testing or provocative testing (dipyridamole thallium or dobutamine echocardiography) before operation. In patients who are considered to be at high cardiac risk because of clinical markers or noninvasive testing, coronary angiography may be recommended before surgery. Coronary artery disease is then managed according to the classic indications. In patients who are thought to be at low or moderate cardiac risk, medical management alone is sufficient.

Because of the common atherosclerotic etiology and the close association between clinically relevant coronary artery disease and peripheral vascular disease, all patients undergoing major vascular surgery should be screened closely, either by history or by provocative testing. Those with a positive clinical history, a decreased ejection fraction from previous myocardial infarction, or with exercise or provocative tests suggestive of ischemia should undergo coronary angiography before the vascular surgery, as outlined by Pasternack and others. The underlying coronary disease should be appropriately treated, medically or with revascularization, using classic indications. This aggressive screening approach followed by appropriate intervention in patients with significant coronary artery disease has greatly lowered the operative risk of patients undergoing major vascular surgery.

MEDICAL THERAPY

Coronary Artery Disease

Atherosclerosis is a multifactorial disease resulting in accumulation of lipids, smooth muscle cells, and connective tissue in the vessel wall. This process results in the formation of obstructive lesions in the aorta, the peripheral vessels or the coronary arteries. Atherosclerosis is the leading cause of death in the Western world and acute myocardial infarction accounts for 25 percent of the deaths in the United States each year. Risk factors for coronary artery disease include smoking, obesity, hypertension, diabetes, hypercholesterolemia, hyperlipidemia, sedentary life-style, Type A personality, and male gender. The most important factor in the long-term treatment of coronary disease is the modification of risk factors, including the immediate cessation of smoking, control of hypertension, weight loss and reduction of total serum cholesterol to less than 175 to 200 mg/dL and low-density lipoprotein (LDL) cholesterol to less than 100 mg/dL. If dietary control of cholesterol cannot be achieved in patients with coronary disease, evidence suggests that the use of medications (such as HMG-CoA reductase inhibitors) to lower cholesterol can slow disease progression significantly and lower the risk of subsequent cardiac events.

Angina is the principal manifestation of coronary artery disease. Mild stable angina sometimes is treated successfully with sublingual nitroglycerin for pain relief. More significant angina usually is treated with a combination of aspirin and beta-blockers. Aspirin presumably works through its antiplatelet affect, while beta-blockers limit ischemia through a reduction in myocardial oxygen consumption and tension-time index. Both agents limit the number of cardiac events and improve survival after myocardial infarction. If angina symptoms are unresponsive to beta blockers, second-line therapy is begun with a calcium antagonist or long-acting nitrate. For severe angina "triple therapy" with beta blockers, a calcium antagonist, and a nitrate can be used. A progression of angina despite good medical therapy usually is an indication for cardiac catheterization, as is a change in the frequency or severity of angina. Some cardiologists use a stress test evaluation in patients with angina for risk stratification, and cardiac catheterization is recommended if significant areas of the heart become ischemic at a low work load.

Unstable angina represents a medical-surgical emergency; this condition can progress to acute myocardial infarction and death. Patients with unstable rest angina are admitted to the hospital and treated with aspirin, beta blockers, and intravenous heparin, with close monitoring for cardiac arrhythmias or recurrent pain. Myocardial oxygen demands should be minimized by obtaining a heart rate of 50 to 60 beats/min and a systolic blood pressure of 100 to 110 mmHg. If angina is not controlled, intravenous nitroglycerin and calcium antagonists may be added. When hypotension or congestive heart failure complicate unstable angina, further monitoring with a Swan-Ganz catheter and an arterial pressure line can be helpful in maximizing therapy. Urgent cardiac catheterization is indicated for unstable angina to assess the underlying coronary pathology and to plan revascularization when appropriate.

Acute myocardial infarction, resulting from acute thrombosis of a coronary artery, occurs in 900,000 people in the United States each year, with 225,000 deaths. The American College of Cardiology/American Heart Association task force management guidelines were reported by Ryan and associates and are summarized here. Patients with acute myocardial infarction should be given oxygen, sublingual nitroglycerin, pain relievers, and aspirin on arrival in the emergency department. Early treatment with thrombolytic therapy (streptokinase, tissue plasminogen activator, anistreplase) or transluminal angioplasty within the first 4 to 6 h of an acute infarction decreases mortality rate by 20 to 25 percent, and more if initiated within 1 to 2 h. Immediate revascularization is indicated whenever feasible. Long-term survival after acute infarction is improved by treatment with beta blockers and aspirin, which are begun within 2 to 4 h after admission to the hospital. Contraindications to thrombolytic therapy are cerebrovascular disease, advanced age, or recent surgery; contraindications to beta blockade are heart failure, heart block, and bronchospasm.

After admission to the hospital the patient should be monitored for 24 h. Arrhythmias may be from electrical instability, pump failure, or conduction disturbance. While routine arrhythmia prophylaxis is not indicated, ventricular arrhythmias should be promptly treated with lidocaine, and bradycardia or complete heart block should be treated with atropine and a transvenous pacemaker. Most patients receive intravenous nitroglycerine for 24 h along with aspirin and beta blockers. If the patient does not have hypotension or other contraindications, an angiotensin-converting enzyme (ACE) inhibitor should be started within hours of admission to lower myocardial oxygen requirements by unloading the left ventricle.

Postinfarction angina or recurrent ischemia should be treated with intravenous heparin, nitroglycerin, beta blockade, and urgent cardiac catheterization. Emergent revascularization by catheter-based therapy or coronary bypass surgery is indicated for postinfarction angina or for recurrent ischemia after thrombolytic therapy. This carries a low risk, around 1 to 2 percent. Postinfarction patients with heart failure or with poor ventricular function should undergo catheterization before discharge. While there is variability in the routine use of catheterization in patients with uncomplicated infarction and good left ventricular function, available data suggest that routine catheterization does not reduce the incidence of reinfarction or death. Patients with uncomplicated infarction and good ventricular function should have a modified stress test before discharge or a complete stress test in 2 to 4 weeks. If the patient develops spontaneous ischemia or if the stress test is positive for reversible ischemia, cardiac catheterization is indicated; otherwise, medical therapy is continued.

Cardiogenic shock develops in 10 to 15 percent of patients with acute myocardial infarction, but is less frequent after successful thrombolytic therapy. Patients with cardiogenic shock are monitored closely with a Swan-Ganz catheter and an arterial pressure line and evaluated for mechanical abnormalities such as papillary muscle rupture, cardiac rupture, or ventricular septal defect. Inotropic support frequently is necessary and mechanical support with an intraaortic balloon pump is used if hypotension persists or if the cardiac index remains less than 1.5 L/min/m². Immediate cardiac catheterization is indicated and revascularization should be performed if feasible in areas of myocardium that are not irreversibly damaged. Patients with cardiogenic shock who undergo early revascularization by angioplasty or surgery have a survival rate of 60 to 70 percent, compared to a mortality rate of over 75 percent with medical therapy alone.

Congestive Heart Failure

Valve replacement is indicated when congestive heart failure occurs in patients with valvular heart disease. Medical therapy often is necessary while preparations are made for operation. In such cases digitalis and diuretics are used to increase myocardial contractility and to control volume overload. Afterload reduction, which increases forward blood flow and relieves pulmonary congestion, has been found to be even more important, often allowing the heart to shrink in size and to remodel. ACE inhibitors, such as captopril or enalapril, or intravenous vasodilators, such as sodium nitroprusside, are the agents of choice for afterload reduction. Acutely ill patients in congestive heart failure awaiting valve replacement should be monitored in an intensive care unit while heart failure is treated with a combination of diuretics, afterload reduction, and gentle inotropic support.

When chronic congestive heart failure occurs from presumed cardiomyopathy, a search for reversible causes, such as ischemia, "hibernating myocardium," valvular disease, or ventricular aneurysm is mandatory. When reversible causes are not found, the cornerstone of medical therapy for chronic congestive heart failure has become afterload reduction with ACE inhibitors. Afterload reduction minimizes cardiac work, increases forward flow, diminishes pulmonary congestion and improves long-term survival, resulting in beneficial myocardial remodeling and a decrease in cardiac size. Diuretics are used to control fluid and salt retention, and digitalis is used to increase the force of cardiac contraction.

EXTRACORPOREAL CIRCULATION—MYOCARDIAL PROTECTION

Historical Background

The pioneering imagination and efforts of Gibbon were largely responsible for the development of extracorporeal circulation (cardiopulmonary bypass with pump-oxygenators). In 1932 Gibbon initiated laboratory investigations that continued for over 20 years until the first successful open heart operation in human beings was performed by him in 1953. A bubble oxygenator using a blood-gas interface was later developed, and for the past decade the membrane oxygenator has been used almost routinely.

Pumps

The initial heart-lung machine used a simple roller pump, originally developed by DeBakey. A variety of other pumps have been used since, such as the centrifugal pump (Fig. 18-2) that was developed to minimize trauma to blood elements. In recent years the focus of perfusion technology has been on the development of devices that improve end-organ perfusion while producing less trauma to the patient's blood. A significant advance was the introduction of biocompatible circuits to perfusion technology. This concept involves coating the plastic circuits with heparin or other biocompatible materials that minimize the need for anticoagulation and lessen the activation of complement and other inflammatory cytokines during extracorporeal circulation.

Oxygenators

Since 1985 the disposable membrane oxygenator has been the most widely used type. The hollow-fiber membrane oxygenators improved the efficiency of gas exchange while minimizing trauma to the blood elements. Many newer oxygenators are coated with biocompatible materials such as heparin to further diminish activation of inflammatory mediators. Pump oxygenators usually require a priming volume in the range of 1,000 to 1,800 mL. Usually the use of blood is avoided because of the risk of transmission of hepatitis or acquired immunodeficiency syndrome (AIDS), so the pump-oxygenator and extracorporeal circuit usually are filled with a crystalloid solution. A hemodiluted hematocrit level of 20 to 22 percent probably is optimal during hypothermic cardiopulmonary bypass because of viscosity and shear stress, with improved microvascular perfusion. If the hematocrit level decreases below 18 to 20 percent, blood is added to the pump oxygenator.

Technique of Perfusion

Sufficient heparin is given to elevate *activated clotting time (ACT)* well above 600 s, starting with a heparin dose of 3 to 4 mg/kg. Heparin requirements may be less, however, when heparin-bonded systems are used. Venous blood is aspirated by gravity drainage through large cannulae through the right atrium. Oxygenated blood is returned to the arterial circulation, usually through a cannula in the ascending aorta. Initial perfusion is done at a flow rate of about 2.4 to 3.0 L/min/m², which is the normal cardiac index. Because oxygen consumption decreases with hypothermia, flow rates may be diminished as the patient is cooled. Safe bypass flow rates for 30°C are 1.8 to 2.3 L/min/m², for 25°C 1.5 to 1.8 L/min/m², and for 20°C 1.2 to 1.5 L/min/m². Oxygen flow through the oxygenator is adjusted to produce an arterial oxygen tension above 100 mmHg. Systemic temperature is controlled with a heat exchanger in the circuit; the temperature usually is lowered to 20 to 32°C, although lower temperatures occasionally are necessary for some complicated procedures. Spilled intrapericardial or intracardiac blood is aspirated with a suction apparatus, filtered, and returned to the oxygenator. A cell-saving device is used routinely to aspirate spilled blood before and after bypass. Aspirated blood is washed and reinfused in order to avoid blood transfusion.

During perfusion a number of parameters are monitored. Arterial pressure and central venous pressure are monitored through intravascular catheters. A Swan-Ganz catheter may be inserted to monitor pulmonary artery pressures and cardiac output after bypass.

The blood pressure varies widely among patients during perfusion. It usually decreases sharply with the onset of perfusion, apparently from vasodilatation, and then subsequently rises to above 60 mmHg. The importance of the actual level of mean arterial pressure when the flow rate is adequate is uncertain as long as the patient does not have significant carotid or cerebral vascular disease. Because cerebral autoregulation of blood flow becomes ineffective below a mean pressure of 50 to 60 mmHg, perfusion pressure usually is maintained above 50 mmHg, though with moderate hypothermia (25 to 30°C) an arterial pressure of 45 to 50 mmHg has no harmful physiologic effects. In elderly patients with less autoregulation and in patients with carotid disease the perfusion pressure is maintained at higher levels, usually more than 65 mmHg. After 15 to 30 min of perfusion, perfusion pressure may gradually rise from progressive vasoconstriction.

Oxygen and carbon dioxide tensions are periodically measured in the venous blood returned to the oxygenator and the oxygenated blood returned to the patient. Preferably, the arterial oxygen tension should be above 100 mmHg and the carbon dioxide tension 30 to 35 mmHg. Venous blood returning to the heart-lung machine with the described flow rate usually will have an oxygen saturation of more than 50 percent. With flow rates and oxygen saturations in this range, metabolic acidosis of a significant degree does not occur. A drop in venous oxygen saturation or systemic acidosis suggests underperfusion, and bypass flow rates should be increased accordingly.

Heparin is metabolized gradually by the body and so additional heparin is given each hour of perfusion, as necessary, to keep the ACT above 600 s, usually 1 mg/kg of body weight. During perfusion the lungs are kept stationary in a partially inflated position.

Termination of Perfusion

When the operation is completed and the patient is systemically rewarmed to normothermic levels, perfusion is slowed and stopped. Before discontinuing bypass, the surgeon should check several important variables: ECG (for rate, rhythm, and ST segment changes), potassium level, hematocrit level, contractility of the heart, and hemostasis of the suture lines. As the perfusion flow rate is slowed, blood is infused from the pump to restore normal intracardiac pressures and to maintain an adequate blood pressure and cardiac output. Close observation of the heart for arrhythmias and adequate contractility is essential at this phase. Atrial pressure or pulmonary artery pressure is monitored. Intraoperative transesophageal echocardiography is useful in assessing myocardial wall motion and cardiac function. If a Swan-Ganz catheter is in place in the pulmonary artery, cardiac output is measured and attempts are made to maintain the cardiac index at a normal level. In many patients the pulmonary capillary wedge pressure (PCWP) provides a reasonable guide to left atrial pressure or preload. The preload should be optimized with fluids. If cardiac output and systemic blood pressure are inadequate despite an optimal preload, inotropic support is begun, usually with amrinone, dobutamine, or dopamine. Epinephrine and norepinephrine are reserved as second- or third-line agents. A decreased peripheral resistance because of vasodilation is treated with alpha agonists, such as phenylephrine hydrochloride (Neo-Synephrine).

Heparin is neutralized with protamine, giving sufficient protamine to return the activated clotting time as closely as possible to prebypass levels. Usually this requires 4 to 5 mg/kg of protamine, given in divided doses. If a coagulopathy is present, the activated clotting time may not return to prebypass levels, indicating the need for infusion of coagulation products, such as fresh frozen plasma, cryoprecipitate, or platelets. This occurs infrequently in routine cases but is more common as the complexity of the procedure and the length of the pump time increases. In longer procedures when a coagulopathy is noted and fibrinolysis may be present, aminocaproic acid is administered, but this is not used routinely.

Trauma from Perfusion

Extracorporeal circulation (cardiopulmonary bypass) inevitably produces some trauma to the blood, primarily from exposure of blood to plastics in the oxygenator and the extracorporeal circuitry, as well as from the use of suction to aspirate intracardiac blood. Minimizing the injury to blood during oxygenation is the rationale for using a membrane oxygenator rather than a bubble oxygenator. Trauma to blood from the pump itself has been minimized by the newer, less traumatic, centrifugal pumps. Tolerance for longer periods of perfusion, up to 4 h, is surprisingly good. Beyond this period, the number of complications from perfusion exponentially increases.

Significant changes in bodily functions occur during extracorporeal perfusion. These changes mainly involve a generalized systemic inflammatory response and probably are from the activation of complement and other acute-phase inflammatory components by the extracorporeal circuits. The severity of the inflammatory response and the level of subsequent end-organ dysfunction are related to the length of the pump time, with complement and cytokine activation leading to an up-regulation of white blood cell adhesion molecules and in the ability of white blood cells to release superoxide. White blood cell up-regulation or "priming" produced by extracorporeal circulation results in increased capillary permeability throughout the body, with the "primed" white blood cells placing the patient in a potentially vulnerable state for 24 to 48 h, during which any secondary insult may result in various levels of multiorgan dysfunction. Other effects may include confusion, renal insufficiency, decreased oxygen exchange, low-grade hepatic dysfunction, and hyperamylasemia. Current research is focused on minimizing the body's systemic inflammatory response during extracorporeal circulation by coating circuits with biocompatible materials or by blocking specific cytokines. Steroids and protease inhibitors, such as aprotinin, also minimize the inflammatory response to bypass.

A low-grade coagulopathy is not uncommon after cardiopulmonary bypass, but it is reduced with the newer materials. This coagulopathy also is related to the length of the pump time. Platelet dysfunction may occur because of the activation of platelets by artificial surfaces during bypass. Low levels of consumptive coagulopathy and hyperfibrinolysis from plasmin activation may be present. These findings generally do not become clinically relevant in the routine case but may become significant during longer, more complex procedures. The use in recent years of biocompatible surfaces has minimized the number of complications related to blood trauma and increased the safety of cardiopulmonary bypass. Similarly, the use of aminocaproic acid to decrease fibrinolysis and the protease inhibitor aprotinin may significantly lessen coagulopathic bleeding after prolonged extracorporeal circulation.

Myocardial Protection

The development of cold, hyperkalemic solutions for inducing cardioplegia, intraoperative cardiac arrest with myocardial preservation, was a major advance in cardiac surgery. This is based on the concept that a cold, potassium-arrested heart has a slow metabolic rate, allowing the surgeon to work precisely on the heart with a return of good cardiac function after completion of the procedure. The ability to protect the heart, combined with the increased ease of performing complex cardiac procedures in a dry, quiet field, greatly augments the safety and effectiveness of virtually all cardiac operations. This factor alone is probably responsible for the greatly improved results and wide applicability of cardiac surgery. Many of the complications in earlier years were probably because of myocardial injury and infarction. With current cardioplegia techniques the heart can be stopped and protected for 2 to 3 hours, allowing time for complicated procedures and nearly total recovery of cardiac function.

Crystalloid and blood cardioplegic solutions are widely used, with the exact components of the cardioplegic mixture varying among institutions. With periods of cardiac arrest for 60 to 90 min, there seems to be little measurable difference in the two techniques, but with the cold blood cardioplegia technique the heart can be safely arrested for longer periods if good distribution of the cardioplegic solution and uniform myocardial cooling are achieved.

The most widely used blood cardioplegic solution was developed by Buckberg and associates. This cardioplegic solution has a hematocrit level of 15 to 18 percent, providing red blood cells for oxygen delivery and a pH buffering effect. The cardioplegic solution is cooled to a temperature of 5 to 8°C to slow the basal metabolic rate of the myocardium and to lower oxygen consumption. A potassium concentration of 20 to 30 mEq/L in the initial cardioplegia injection induces mechanical arrest and ECG silence and also slows oxygen use because of a lack of wall tension. Subsequent maintenance injections given throughout the procedure have a potassium concentration of 8 to 10 mEq/L, which maintains hyperkalemic arrest. Other additives include CPD to lower calcium concentration and prevent calcium-induced reperfusion injury, buffer (tromethamine [THAM]) to scavenge hydrogen ions and prevent damage from tissue acidosis, and glucose, which provides metabolic substrate and makes the solution hyperosmolar to minimize edema.

In the setting of acute infarction or when ongoing myocardial ischemia is present Buckberg recommends that a form of resuscitative cardioplegia be used in which amino acids are added to the cardioplegic solution to provide substrate enhancement and that the final injection of cardioplegia be delivered at 37°C, allowing the heart to "repay" oxygen debt and repair cellular damage before resuming full contractile function. In experimental studies this technique has been found to minimize reperfusion damage of ischemic myocardium and

to enhance myocardial functional recovery. Similarly, mechanical unloading of the ischemic heart during the initial reperfusion interval has minimized reperfusion damage. Recent work has focused on the role of pharmacologic agents in providing “preischemic conditioning” of the heart, a technique that may additionally reduce the level of intraoperative myocardial injury.

The method used for intraoperative myocardial protection at New York University (NYU) is as follows. After the aorta is clamped, blood cardioplegic solution is infused at a rate sufficient to produce an aortic root pressure of 60 to 90 mmHg (200 to 400 mL/min), which should rapidly produce hyperkalemic arrest and ECG silence. Alternatively, retrograde delivery of cardioplegia through the coronary sinus of the heart is used, achieving a coronary sinus pressure of 20 to 30 mmHg. Retrograde administration of cardioplegic solution through the coronary sinus venous system has been a major advance in patients with severe disease, as this technique avoids maldistribution of cardioplegic solution from coronary artery stenosis. Cardioplegic solution distribution and myocardial cooling are confirmed by measuring regional myocardial temperatures in four regions of the myocardium (right ventricle and anterior, lateral, and posterior walls of the left ventricle), continuing infusion of cold blood until the “warmest” zone has cooled below 10 to 15°C. Topical hypothermia with cold saline irrigation is then used to prevent cardiac rewarming. Cardioplegic solution is reinfused after each anastomosis or after every 20 to 30 min. The left heart is kept in an empty, decompressed state by emptying the right heart with a large-lumen cannula or with a vent. Crooke and associates reported complete recovery of cardiac function after 2 h of protected cardiac arrest using the blood cardioplegia technique. With this and other, similar methods of myocardial protection longer, more complicated cardiac surgical repairs are now routine, and postoperative low cardiac output syndrome is exceedingly rare.

POSTOPERATIVE CARE AND COMPLICATIONS

General Considerations

Postoperative cardiac surgical care is a prime example of applied principles of cardiovascular physiology. Five key areas are involved: (1) hemodynamic evaluation, (2) electrocardiographic assessment, (3) blood loss, (4) ventilation and pulmonary care, and (5) general care, including fluid and electrolytes, nutrition, wound care, renal function, and rehabilitation.

After heart surgery, patients are observed in a specialized recovery room or intensive care unit. The ECG is monitored continuously, as are the arterial and intracardiac pressures. The Swan-Ganz pulmonary artery catheter is equipped with a thermistor for thermodilution measurement of cardiac output. Accurate hemodynamic profiles can be established on each patient as outlined below in the section on hemodynamic evaluation.

Initial laboratory information should include levels of hemoglobin, hematocrit, electrolytes, blood urea nitrogen, creatinine, and creatine phosphokinase isoenzyme, platelet count, *prothrombin time (PT)*, *partial thromboplastin time (PTT)*, and arterial blood gas and mixed venous blood gas pressures. The blood gases, hematocrit, and potassium determinations are repeated serially for 6 h, depending on the stability of the patient. Flow sheets are used to chart hourly laboratory reports, blood pressure, pulse, hemodynamic data, fluid input and output, and blood loss. Chest x-rays are periodically made to evaluate the mediastinal shadow and the lung fields.

Early postoperative complications include bleeding, tamponade, arrhythmias, myocardial infarction, graft occlusion, coronary spasm, low cardiac output syndrome, cardiac arrest, and stroke. Other complications include delayed bleeding, postpericardiotomy syndrome with pericardial effusion, tamponade, arrhythmias, renal dysfunction, ileus, ischemic bowel, gastrointestinal hemorrhage, pneumothorax, respiratory insufficiency, pneumonia, wound infection, wound dehiscence, and chronic cardiac dysfunction. While the incidence of serious complications is relatively low (3 to 6 percent), depending on patient and operative variables, every complication can be potentially life-threatening and is associated with significant morbidity.

While cardiologists, anesthesiologists, intensivists, and others are important members of the team and essential to the long-term care of the patient, the surgeon is responsible for the patient's overall care. The surgeon is best positioned to understand the subtleties of the patient's intraoperative physiology, technical problems encountered during a procedure, the adequacy of the myocardial protection, and other events that have a profound effect on the patient's clinical course. A strong commitment to the patient is an essential part of medical ethics and good patient care and should guide all actions.

Hemodynamic Evaluation

The adequacy of cardiac function is the key question in any patient after a cardiac operation. Adequacy of cardiac output is reflected in the blood pressure and the urine output, but exact measurement of cardiac output is far more precise. This can be done with a thermodilution technique if a Swan-Ganz catheter has been inserted, and this is the mainstay of treatment in any seriously ill patient. A normal cardiac index is 2.5 to 3.0 L/min/m². A cardiac index below 1.7 to 1.8 L/min/m² is an ominous finding, often resulting in death from inadequate perfusion of peripheral organs unless cardiac output can be increased. The classic clinical findings of low cardiac output with inadequate oxygen transport are the familiar ones of hypotension, vasoconstriction, oliguria, and metabolic acidosis. Untreated low cardiac output is ultimately fatal from progressive renal failure or arrhythmias.

When evaluating low cardiac output, the first consideration is to exclude cardiac tamponade or hypovolemia from intrathoracic bleeding. When these two factors have been excluded, the physiologic causes of low output should be reviewed in terms of preload, afterload, and intrinsic contractility of the heart. If the patient is hypovolemic, therapy consists of infusion of sufficient fluids to elevate left atrial pressure or pulmonary capillary wedge pressure to an appropriate level. As defined by the Starling principle, cardiac stroke volume rises with a rise in left atrial pressure. The cardiac output can be plotted against preload, assuming pulse and afterload are constant, to determine the “optimal” filling pressure of the heart.

Afterload reduction consists of reduction in peripheral vascular resistance with specific drugs to cause vasodilatation. If peripheral vascular resistance is elevated above the normal 1,200 dynes·sec·cm⁻⁵, afterload reduction should be one of the initial forms of therapy. The most commonly used drugs for intravenous infusion are sodium nitroprusside (Nipride) or nitroglycerin. Vasodilation, or decreased peripheral resistance, should be treated with vasoconstrictors to maintain an adequate perfusion pressure. Afterload should be controlled to keep the systolic blood pressure above 100 mmHg but below 150 mmHg and the mean arterial blood pressure above 70 mmHg but below 90 to 95 mmHg with a nearly normal vascular resistance (1,200 dynes·sec·cm⁻⁵).

Once bleeding and tamponade are excluded and preload and afterload have been optimized, a wide variety of inotropic agents may be used to augment myocardial contractility. Our first preference usually is amrinone or dobutamine, augmented if necessary with small amounts of norepinephrine, metaraminol, or phenylephrine when the peripheral vascular resistance is low. The alpha-adrenergic agents frequently are administered directly into the left atrium to minimize pulmonary hypertension. Dopamine and epinephrine are useful second-line inotropic agents.

If cardiac rhythm is not satisfactory, cardiac pacing should be used to maintain an adequate rate and rhythm. If a sinus mechanism is too slow or absent, atrial pacing or atrial-ventricular pacing is valuable for augmenting cardiac output. An optimal heart rate to maximize cardiac output without unduly increasing myocardial oxygen consumption is 80 to 90 beats/min.

If low cardiac output persists despite optimizing preload, afterload, and inotropic support, an intraaortic balloon pump may be necessary. The balloon pump (see Intraaortic Balloon Pump below): (1) decreases afterload, which improves the cardiac output while lowering wall tension and oxygen requirements; (2) decreases preload in the failing heart, lowering wall tension and oxygen demand; and (3) provides diastolic counterpulsation to augment systemic blood pressure and diastolic coronary perfusion. The balloon pump lowers oxygen consumption by approximately 20 percent while augmenting cardiac output by about 700 mL/min/m². The need for a balloon pump can be determined in the operating room by performing serial measurements of cardiac output after the cessation of cardiopulmonary bypass. If the cardiac index remains below 1.5 to 1.7 L/min/m² despite significant administration of inotropes, an intraaortic balloon usually is recommended.

An unexpected fall in cardiac output in the recovery room is frequently because of a correctable mechanical problem. A thorough search for various causes of low output syndrome is essential before resorting to mechanical support. If correctable problems are not present and the low output syndrome does not respond to a combination of inotropes and a balloon pump, temporary placement of a left ventricular assist device may be necessary.

Electrocardiographic Assessment

The postoperative ECG is important for determining heart block, bundle branch block, infarction (Q waves), ischemia (ST-segment elevation, T-wave inversion), or other signs of intraoperative injury. The ECG should be repeated periodically, and patients with signs of ischemia or injury should be monitored in the intensive care unit. Acute ischemia or evolving infarction should be treated initially with nitrates or calcium blockers. If ECG changes do not resolve promptly, a return to the operating room to rule out graft occlusion should be considered, particularly if the patient is unstable or hemodynamically compromised. In addition to standard 12-lead ECGs, continuous monitoring of the cardiac rhythm for at least 2 days after operation is important. The patient is monitored in the recovery room or intensive care unit for 24 h. Once transferred to the ward, some form of telemetry with an appropriate alarm mechanism usually is used for an additional 24 h. Life-threatening arrhythmias may develop unexpectedly despite the presence of a normal cardiac output and without any other signs of circulatory failure. Delayed detection of a significant arrhythmia is a major cause of unexpected death after cardiac operations. Bradyarrhythmias and heart block are not uncommon postoperatively, and for this reason temporary cardiac pacing wires are routinely left in the right ventricle and right atrium for several days.

Ventricular extrasystoles and ventricular tachycardia are more serious because their appearance may herald the development of ventricular fibrillation. Hypokalemia should always be considered because patients in cardiac failure preoperatively may have significant depletion of body stores of potassium from chronic diuretic therapy. The serum potassium level should be kept well above 4.0 mEq/L. Continuous intravenous lidocaine, 1 to 4 mg/min, is a valuable form of therapy for temporary control of ventricular arrhythmias. Procainamide generally is used as a second-line agent and bretylium as a third-line agent for serious ventricular arrhythmias.

The treatment of atrial fibrillation, the most common postoperative arrhythmia, begins with heart rate control and includes the use of intravenous digitalis in conjunction with a beta blocker or a calcium-channel blocker. Once rate control has been achieved, a class IA antiarrhythmic agent, such as procainamide or quinidine, can be used to attempt “chemical cardioversion,” or the patient can be given anticoagulation therapy with warfarin and discharged. A significant number of patients with persistent postoperative atrial fibrillation spontaneously convert to normal sinus rhythm within 6 weeks; for those who do not, electrical cardioversion can be used. Atrial fibrillation resulting in hemodynamic instability should immediately be treated with cardioversion at 50 to 100 J. Virtually all antiarrhythmic agents cause serious side effects in a small proportion of patients, particularly when administered intravenously, so these patients require careful periodic monitoring.

Cardiac Arrest

Complete circulatory collapse in the postoperative cardiac surgical patient can occur without warning. If effective circulation is not restored within minutes, the brain and myocardium suffers anoxic injury that may become irreversible. Determining the cause of the circulatory arrest may indicate a specific therapy; however, treatment should not be delayed if the exact cause is unknown. A high incidence of survival without any permanent disability is possible when cardiac arrest is recognized promptly, circulation is quickly restored, and the underlying cause is treatable. Frequent causes of cardiac arrest after cardiac surgery include cardiac tamponade, arrhythmias, ischemia or graft occlusion, hypoxia, and drug toxicity.

Cardiac tamponade is a serious complication after cardiac surgery. It may occur early in the postoperative period from the accumulation of intrapericardial blood. Later in the postoperative course, tamponade can occur from a pericardial effusion. The classic findings of tamponade include: (1) elevation of central venous pressure; (2) equalization of central venous pressure, pulmonary artery diastolic pressure, and left atrial pressure; and (3) a pulsus paradoxus of more than 10 mmHg during inspiration. Extreme cases of tamponade may present with life-threatening hypotension or sudden circulatory collapse; the diagnosis should be strongly considered in any patient with hypotension and a low cardiac output. A widening of the mediastinal shadow on chest x-ray or detection of significant pericardial effusion by echocardiography is suggestive of the diagnosis. No single test can exclude tamponade short of surgical exploration. Because of this, any patient with suspected tamponade should be returned promptly to the operating room for definitive diagnosis and treatment. Any patient in extremis with suspected tamponade should have his or her chest opened or subxiphoid drainage performed at the bedside in order to rule out tamponade, which is treated effectively by clot and fluid removal.

Ongoing ischemia and myocardial injury secondary to poor intraoperative myocardial protection are probably the two most common causes of postoperative ventricular fibrillation. Ischemia and ventricular irritability may be from graft occlusion, preoperative ischemia or injury, intraoperative injury, coronary spasm, or a nonbypassed area of myocardium.

An electrolyte imbalance, such as a deficiency of potassium or magnesium, also can cause serious arrhythmias leading to cardiac arrest or ventricular fibrillation. A serum potassium level below 3.0 mEq/L can produce severe cardiac irritability postoperatively, though the precise influence is determined by the coexisting concentration of calcium ions and the presence of acidosis or alkalosis along with the patient's body temperature.

Difficulties with ventilation and hypoxia can lead to cardiac arrhythmias from low arterial oxygen tension and progressive metabolic acidosis. Inadequate ventilation from pneumothorax, from dislodgment of the endotracheal tube, or from plugging of the airway with secretions are common causes.

Drugs may induce bradycardia, heart block, ventricular fibrillation, or cardiac arrest, from toxicity or an idiosyncratic reaction. Digitalis is a common offender because of its widespread usage. The sensitivity of the myocardium to digitalis varies with a number of factors, one of the most important of which is the concentration of potassium. Procainamide and quinidine are examples of drugs with known proarrhythmic effects.

Profound bradycardia from any cause (heart rate < 60 beats/min) may result in escape beats leading to ventricular fibrillation and cardiac arrest. Ventricular arrhythmias may progress to bigeminy, ventricular tachycardia, and ventricular fibrillation. This well-known sequence is the reason for constant monitoring of the ECG postoperatively.

General Considerations for Treatment

Through the efforts of the American Heart Association, Advanced Cardiac Life Support (ACLS) has been taught to almost every health care worker in the United States. ACLS guidelines include specific algorithms for the treatment of cardiac arrest and other causes of circulatory arrest. Although the treatment of cardiac arrest described in the remainder of this section apply mainly to postoperative cardiac surgery patients, the principles discussed follow ACLS guidelines and also are applicable to noncardiac surgical patients.

Cerebral anoxia associated with circulatory arrest produces brain injury within 3 to 4 min, so the diagnosis must be made and treatment begun rapidly to avoid serious brain injury. Periods of anoxia for 6 to 8 min may produce extensive but reversible brain injury, whereas longer periods regularly cause irreversible injury. Closed-chest massage and ventilation should be started promptly. The ABCs of cardiopulmonary resuscitation (CPR) are: airway, breathing, and circulation.

The immediate first steps in CPR are to secure an adequate airway and provide prompt ventilation (*breathing*). Cardiac massage for more than a few seconds without securing the airway and providing adequate ventilation (breathing) is futile. The mouth and throat are cleared of secretions, and ventilation is quickly accomplished by mask inflation with an oral airway. This can be begun immediately and continued until endotracheal intubation is achieved. With a laryngoscope, an endotracheal tube can easily be inserted by a physician or other trained personnel. In some patients, such as those with a short, thick neck, the anatomy is such that intubation is difficult even for highly experienced staff. Unless intubation can be accomplished quickly and with certainty, oral insufflation should be continued until a cricothyroidotomy has been performed.

An infrequent but serious error can occur when the endotracheal tube is inadvertently placed in the esophagus. Because of this possibility, immediate auscultation of the lungs for breath sounds is essential after attempted intubation. If any uncertainty remains after auscultation, the tube should be removed and intubation should be repeated. A tightly fitting face mask can provide a method of temporary ventilation. If endotracheal intubation is difficult, requiring repeated attempts, or simply cannot be performed, a cricothyroidotomy should be performed promptly. The patient cannot recover unless the airway is rapidly controlled and ventilation established.

The third step is to provide effective perfusion (*circulation*) with closed-chest massage or with inotropes or pressors. Effective CPR depends on adequate intermittent compression of the heart between the sternum and the vertebral column. The patient must be on a firm surface, which can be accomplished by placing a board under the back. The heel of the hand should be applied over the lower third of the sternum with the other hand above it to depress the sternum 3 to 4 cm intermittently. Massage should be at a rate of about 60/min. The sternal compression should be brisk, depressing the sternum sharply and then releasing it to permit cardiac filling. Mechanical ventilation must be synchronized with massage.

In the postoperative cardiac surgery patient with cardiac arrest closed-chest massage may be initiated immediately as part of a resuscitative effort, which also may include defibrillation and the administration of pharmacologic agents. If cardiac activity is not quickly restored or if the cardiac arrest is thought to be a result of a mechanical cause, such as tamponade or hemorrhage, the sternotomy incision is reopened immediately at the bedside and internal cardiac massage is instituted. Open cardiac massage is highly effective if instituted promptly. For this reason, postoperative resuscitative efforts employing closed cardiac massage and external defibrillation are quickly aborted unless immediately successful. Rarely, open-chest massage may be effectively continued for more than an hour until the basic condition causing refractory arrhythmias or cardiac arrest is corrected. More commonly, the patient is returned to the operating room once the chest is opened and cardiopulmonary bypass is initiated for support. After the patient is resuscitated the surgeon must determine if further therapy such as mechanical support or additional bypass grafting is indicated.

Drugs and Fluids

Epinephrine, sodium bicarbonate, and calcium are the most useful pharmacologic agents. The protocols suggested by the ACLS program are followed. Epinephrine 1mg may be given intravenously or by direct intracardiac injection. Calcium chloride (3 to 4 mL of 10% solution) is another powerful stimulant of myocardial contraction. Calcium administration in cardiac arrest may be valuable in some circumstances but harmful in others and should not be used indiscriminately. Lidocaine is given primarily for ventricular arrhythmias, followed by bretylium or procainamide for refractory ventricular tachycardia. Medications usually are ineffective if severe myocardial anoxia or significant acidosis is present. Anoxia can be corrected only by the combination of effective cardiac massage and ventilation. Large amounts of sodium bicarbonate may be required to treat the acidosis. Excessive use of drugs before the hypoxia and acidosis have been treated is probably futile.

Small amounts of fluid should be rapidly infused because vasodilatation usually is present. An intravenous infusion of a vasoconstrictor, norepinephrine or phenylephrine (Neo-Synephrine), is often helpful in order to maintain perfusion pressure. Blood transfusion may be required in the postoperative patient for volume resuscitation and improved oxygen-carrying capacity.

Defibrillation

Ventricular fibrillation can be differentiated from asystole only by the ECG or by direct inspection of the myocardium. Initial treatment of cardiac arrest should include a precordial thump, because it is often effective in converting ventricular tachycardia or ventricular fibrillation. Intravenous lidocaine is promptly administered. If this is not effective quickly and an ECG is not available, empiric defibrillation can be tried briefly, because most resuscitations are effective when defibrillation is done promptly. Asystole is treated by pacing the heart with a transcutaneous pacemaker, a transvenous pacemaker if access is readily available, or a temporary pacing lead that can be placed directly on the myocardium if the chest is open.

Closed-chest defibrillation usually is done by applying electrodes over the base and apex of the heart. Defibrillation is best done with a direct current of 200 to 360 J. When open-chest defibrillation is used, the electrodes are applied directly to the heart and an impulse of 20 to 40 J is delivered. Vigorous cardiac massage should precede defibrillation to oxygenate the myocardium sufficiently. Perfusion pressure must be maintained to obtain successful defibrillation because ongoing subendocardial ischemia occurs when the perfusion pressure is inadequate. Correction of acidosis with bicarbonate can be confirmed by blood gas determinations. Intramyocardial injection of epinephrine may stimulate myocardial tone and improve the chances of successful defibrillation. Unless a massive myocardial infarction has occurred, it should be possible to defibrillate the majority of fibrillating hearts, though the ensuing cardiac arrest may be refractory to therapy. The most significant factor influencing survival is the institution of defibrillation within 1 min of onset of fibrillation or the ability to defibrillate with less than five shocks.

After restoration of an adequate heart beat and blood pressure, the critical question is the extent of injury to the heart and to the central nervous system. A thorough search for reversible causes of the arrhythmia is undertaken immediately. If ischemia or graft occlusion is suspected, the patient is taken for cardiac catheterization or back to the operating room.

A detailed neurologic evaluation to elicit specific normal and abnormal reflexes should be done promptly. Permanent brain injury is frequent after more than 5 min of cardiac arrest, even though experimentally cerebral neurons can tolerate nearly 20 min of normothermic ischemic anoxia. Intravenous steroid therapy usually is given for 24 to 48 h to minimize cerebral edema, although the efficacy is difficult to measure. If serious cardiac or cerebral injury is not present after resuscitation, the prognosis is excellent. This fact is the basis for the enthusiastic development of widespread training in cardiopulmonary resuscitation by all physicians, paramedical personnel, and lay people, for most effective resuscitation is accomplished when begun within 1 to 2 min after onset of cardiac arrest.

Blood Loss

Blood conservation and minimization of bleeding associated with cardiac surgery begin preoperatively. Preoperative work-up routinely includes a PT, PTT, and platelet count. Patients with a history of abnormal bleeding or with chronic passive congestion of the liver receive full coagulation profiles and evaluation by a hematologist. Patients taking warfarin are instructed to discontinue the drug 3 to 4 days before operation so that the PT can return to normal.

Because blood conservation is highly desirable, many patients operated on electively are able to donate autologous blood 1 to 3 weeks before surgery. Often erythropoietin is used after autologous donation to enhance the patient's red blood cell mass. Donor-directed blood units are solicited from family and friends. Intraoperatively, patients with a large blood volume and an adequate hematocrit level may have 1 unit of fresh whole blood removed before bypass. The unit is saved and reinfused after bypass in order to take advantage of the fresh plasma and uninjured platelets. All blood in the operative field is collected during the procedure, either by suction into the cardiopulmonary bypass pump or into a cell-saver device. Similarly, mediastinal blood shed postoperatively through the chest tubes is collected sterilely and reinfused. By reinfusion of blood from the pump, cell saver, and

chest tubes, the need for blood transfusion associated with heart surgery has been diminished significantly, and many patients avoid transfusion altogether.

Postoperative Bleeding

For most open-heart cases coagulopathy is nonexistent and the postoperative blood loss is low. On completion of cardiopulmonary bypass, heparinization is reversed with protamine and chest closure is initiated only after hemostasis has been achieved. The normal postoperative blood loss should range from a total of 300 to 800 mL. Blood loss in excess of 300 to 500 mL/h or over 1 to 1.5 L total usually indicates active surgical bleeding and is associated with a high incidence of hemodynamic compromise or cardiac tamponade. For this reason it usually is mandatory that patients with active bleeding or with a total blood loss greater than 1 to 1.5 L be returned to the operating room to control any active bleeding and avoid tamponade. If surgical bleeding is not found and a coagulopathy is present, appropriate treatment is initiated.

In some patients the effects of cardiopulmonary bypass can be damaging to the blood coagulation system, resulting in abnormal bleeding. The incidence of coagulopathy is related most strongly to the duration of cardiopulmonary bypass, but coagulopathy also is more frequent when hemodilution is excessive, after severe hypothermia, in patients who received aspirin or recent thrombolytic therapy, and in reoperations in which ongoing blood loss from scar tissue results in progressive loss of coagulation factors.

The diagnosis of coagulopathy is made by the operating surgeon with the observation of abnormal bleeding from the operative field in the absence of a surgical source. Laboratory tests can confirm the diagnosis, but treatment should not be delayed until test results return because this might worsen the coagulation deficit with fatal consequences. Nonsurgical causes of abnormal bleeding after heart surgery include: (1) inadequate neutralization of heparin from insufficient protamine; (2) a functional platelet deficit from aspirin effect or from the activation of platelets by the cardiopulmonary bypass circuit; (3) dilutional coagulopathy from the combination of crystalloid priming volume and transfusions; (4) a consumptive coagulopathy from a low-grade activation of the clotting factors by the bypass oxygenator and circuit; and (5) abnormal fibrinolysis.

Treatment of coagulopathy is urgent. Hypothermia should be corrected and extra protamine should be given until the activated clotting time returns to normal or until no further drop is seen in the activated clotting time. If abnormal bleeding persists, transfusion of platelets, fresh frozen plasma, and cryoprecipitate are given until the clotting deficit is corrected. Antifibrinolytic agents such as *e*-aminocaproic acid may be given to correct fibrinolysis. Heparin-bonded circuits and oxygenators are used to minimize coagulopathy in high-risk cases. The pharmacologic prevention of coagulopathy is more effective if the protease inhibitor aprotinin or the antifibrinolytic agent *e*-aminocaproic acid is administered preoperatively.

Ventilatory and Pulmonary Insufficiency

Nearly all cardiac surgical patients return to the recovery room intubated. While ventilating a patient after heart surgery, the physician should periodically assess the breath sounds, particularly in the posterior bases of the lungs, to determine the adequacy of ventilation. Tidal volumes on the respirator usually are set at 10 mL/kg, but occasionally up to 15 mL/kg is necessary in patients with chronic obstructive disease. For most cases, auscultation of the bases and determination of lung compliance (static lung compliance = tidal volume/end inspiratory pressure) are the best ways to determine the optimal tidal volume, with the maximum lung compliance considered optimal compliance for most cases. The adequacy of ventilation and oxygenation is then checked by periodic blood gas determinations. For patients with marginal oxygenation the optimal tidal volume and positive end-expiratory pressure (PEEP) may be better determined on the basis of oxygen delivery, with oxygen delivery equal to cardiac output times arterial oxygen content.

Weaning the patient is done via the intermittent mandatory ventilation (IMV) mode or via progressive continuous positive airway pressure (CPAP) trials. Criteria for extubation include adequate blood gases on CPAP, with an inspired oxygen of less than 50 percent, a respiratory rate of less than 15 to 20 breaths/min, a spontaneous tidal volume of 5 mL/kg, a forced vital capacity of 10 mL/kg, and a negative inspiratory pressure of 15 mL of water as determined by bedside pulmonary function tests. The patient should be awake enough to control the airway. Most patients can be extubated within 6 to 12 h of surgery.

Postextubation pulmonary care involves use of the incentive spirometer, coughing, and deep breathing. Control of secretions is essential. Difficult cases might require the use of inhaled bronchodilators, such as the β_2 -adrenergic agonist albuterol, or the use of intravenous aminophylline. Rarely, a short course of steroids is beneficial. Tracheobronchitis should be treated promptly with antibiotics. Observation of daily sputum specimens is important in infected patients, because clearing of the sputum and a drop in the white blood cell count indicate effective therapy. Clearing of secretions by coughing or suctioning is essential if the patient with tracheobronchitis is to recover. Flexible bronchoscopy has been effective in assessing the adequacy of suction and for evaluating the clearance of secretions in the refractory ventilator-dependent patient with tracheobronchitis.

Operation on the patient with a long history of smoking and with chronic obstructive pulmonary disease poses a special problem. These patients should be strongly counseled on the need to stop smoking preoperatively with the aid of transdermal nicotine patches if necessary. Evidence suggests that discontinuing smoking for even 1 week is markedly beneficial. Poor pulmonary function, however, usually does not prohibit cardiac surgery. For example, if a patient can function, albeit poorly, with substandard pulmonary reserve and critical aortic stenosis, the patient's overall cardiorespiratory function should significantly improve after correction of the valvular pathology. Sternotomy has relatively little deleterious effect on pulmonary reserve. A study by Bevelaqua and colleagues noted that heart patients with poor pulmonary function had more short-term postoperative pulmonary complications than other patients but did not have a higher overall hospital mortality rate.

With current preoperative preparation and intraoperative management, significant postoperative impairment of pulmonary function is uncommon, except in patients with preexisting pulmonary disease or advanced cardiac failure. Most patients are now extubated within 8 to 12 h, although mechanical ventilation for 24 to 72 h is well tolerated by most patients. If periods of ventilation longer than 3 or 4 days are anticipated, a cricothyroidotomy or tracheostomy should be considered. In addition to providing patient comfort and safety and eliminating dead space, pulmonary toilet is more effective when done through a tracheostomy or cricothyroidotomy. Ventilatory support for more than a short time seldom is necessary except in chronically ill or elderly patients in whom simple physical weakness may significantly impair the effectiveness of breathing and coughing. These patients may require ventilatory support for days or even weeks.

General Care

Nutrition

The need for adequate postoperative nutrition cannot be overemphasized, particularly in elderly or chronically ill patients. The sick postoperative heart patient may require 25 to 35 kcal/kg/day. Care should be taken to give adequate protein in patients with normal renal and hepatic function, and special formulas are available for patients with kidney or liver failure. Ill patients who remain intubated in the intensive care unit should have nutritional support started early as tube feeding or as intravenous hyperalimentation.

Wound Care

Early postoperative care of the surgical wound consists of the use of a sterile occlusive dressing for the first 24 h. Wounds may be painted twice a day with a povidone-iodine solution or dressed sterilely and examined daily for redness, drainage, or sternal instability. Prophylactic antibiotics are started preoperatively and continued for 24 to 48 h postoperatively, usually until indwelling catheters and chest tubes have been removed. The prophylactic antibiotic used should be chosen on the basis of the organisms commonly causing infection in that hospital.

All fever should be recorded and the patient examined for signs of infection. A moderate fever of 100 to 101°F is common in the first 1 to 2 days, usually resulting from the systemic inflammatory response induced by the extracorporeal circulation and the stress of major surgery or from atelectasis. A fever occurring from 3 to 7 days postoperatively with a normal white blood cell count is frequently from postpericardiotomy syndrome, which results from a combination of a generalized inflammatory response and localized irritation of the pericardium from surgical trauma. Postpericardiotomy syndrome may be associated with a friction rub and pericardial or pleural effusions. The syndrome can be treated with nonsteroidal anti-inflammatory agents or, occasionally, with a short course of steroids. Significant fevers should be evaluated with a chest x-ray and blood and urine cultures.

A serious sternal wound infection occurs in 1 to 2 percent of all open heart operations. Risk factors include diabetes, obesity, impaired nutrition, chronic obstructive pulmonary disease, prolonged ventilatory support, harvest of bilateral internal mammary arteries, older age, low cardiac output, excessive mediastinal bleeding, reexploration for bleeding, multiple transfusions, and prolonged cardiopulmonary bypass. The incidence is highest in diabetics receiving bilateral internal mammary artery grafts. Signs of infection include redness or pain in the wound, purulent drainage, sternal instability, fever, and an elevated white blood cell count. The diagnosis is made easily by sternal aspiration. Early diagnostic sternal aspiration is strongly recommended for any patient with persistent localized sternal pain or unexplained sepsis. *Staphylococcus aureus* and *Staphylococcus epidermidis* are the most common organisms isolated. Treatment requires prompt operation with debridement and closure over antibiotic irrigation/drainage catheters or debridement followed by immediate or delayed closure with muscle flaps. The mortality rate from a sternal infection after cardiac surgery is 10 to 20 percent.

Renal Function

Close attention to renal function is necessary. The urine output for most adults should be 0.5 to 1 mL/kg/h. The blood urea nitrogen and creatinine levels are followed for several days postoperatively. Patients with a marginal urine output or with borderline renal function may benefit from low-dose (3mg/kg/min) dopamine. Some degree of salt and fluid retention often is present during postoperative days 3 to 5, even in patients with normal renal function, and diuretics may be necessary until the patient returns to preoperative weight. In patients with progressive renal dysfunction early dialysis is indicated to control volume overload and to minimize the risk of arrhythmias and infection. Permitting the blood urea nitrogen level to rise above 90 to 100 mg/dL may result in serious cardiac arrhythmias and immunocompromise. The mortality rate for patients with anuric renal failure after heart surgery exceeds 25 percent.

Rehabilitation

Most patients recover uneventfully after heart surgery and do not require a rigorous rehabilitation program. Recommendations include daily walking in the halls and a progressive walking schedule of up to 2 miles/day after discharge. The patient should follow normal moderate activities for the first 6 to 8 weeks. More vigorous exercise should be preceded by an exercise stress test, which is recommended after 2 to 3 months; this amount of time is required for the patient to recover physically and intellectually. Elderly and debilitated patients should receive a more regimented rehabilitation effort, beginning with physical therapy during the hospital stay and often continuing with a formalized rehabilitation program for the first 2 to 3 weeks after discharge.

CORONARY ARTERY DISEASE

Historical Data

Starting in the late 1930s different investigators attempted to increase the blood supply of the ischemic heart by developing collateral circulation with vascular adhesions. Beck was the leading investigator, trying different methods for many years, but ultimately all failed. A separate ingenious concept arose in 1946 when Vineberg developed implantation of the internal mammary artery into a tunnel in the myocardium. Vineberg applied this clinically in 1950 and continued for many years. The artery remained patent in over 90 percent of patients, but the amount of flow through the artery was small, and the procedure was eventually abandoned. Coronary endarterectomy without bypass grafting was attempted by Longmire in 1956 with short-term success but a high reocclusion rate from progressive fibrosis in the arterial wall. Patch graft reconstruction of coronary arteries, as proposed by Senning in 1961, was attempted subsequently by Effler and colleagues with disappointing results.

In the 1960s the development of the coronary bypass operation was a dramatic medical milestone. In the United States the principal credit for developing coronary artery bypass belongs to Favalaro, Effler, and associates from the Cleveland Clinic who did the first series of coronary bypass grafts beginning in 1967 using cardiopulmonary bypass and vein grafts to bypass the right coronary artery. Johnson and associates showed that similar grafts could be effectively used for the left coronary system. These were quantum achievements that launched the modern era of coronary bypass grafting.

An additional breakthrough, which was not recognized initially as being particularly significant, came in 1968 when Green performed the first left internal mammary artery to the left anterior descending artery bypass using cardiopulmonary bypass and an operative microscope. This followed earlier experimental work by Spencer, who had demonstrated the feasibility of this type of anastomosis in 1964 in a canine model. Kolessov had independently performed internal mammary artery to left coronary artery bypass grafting on the beating heart in Russia in 1967, although his work was largely unknown for many years. The internal mammary artery was not widely used at first, but since the early 1980s, after 10-year angiographic follow-up studies reported long-term patency rates exceeding 90 percent, it has been widely adopted.

Since 1975 coronary artery bypass surgery has become one of the most widely applied surgical procedures in the United States. The bypass operation has had a monumental impact on the treatment of coronary artery disease and came to symbolize the technical advances of Western medicine. Over 350,000 coronary bypass procedures are performed yearly in the United States alone.

Etiology and Pathogenesis

Atherosclerosis is the fundamental cause of coronary artery disease. The disease is multifactorial, involving serum lipids and cholesterol metabolism, local vascular mitogens such as platelet-derived growth factor, basic fibroblast growth factor, or transforming growth factor beta and other risk factors, such as smoking, hypertension, and diabetes, which lead to injury of the vessel wall. Atherosclerosis is more common in males than in females, with a 4:1 ratio. The frequency of coronary artery disease varies widely throughout the world, and it is less common in populations with an average blood cholesterol below 200 mg/dL. The frequency is lowest in Japan, where the average blood cholesterol is near 160 mg/dL. The United States has the second highest frequency in the world.

The basic lesion is a segmental plaque within the coronary artery. This segmental localization makes bypass grafts feasible. Involvement of small distal vessels usually is less extensive, while arterioles and intramyocardial vessels usually are free of disease. The proximal anterior descending artery frequently is stenosed or occluded, with the distal half of the artery remaining patent; the right coronary artery often is stenotic or occluded throughout its course, but the posterior descending artery and left atrial-ventricular groove branches are almost always patent. The circumflex artery often is diseased proximally, but one or more distal marginal branches usually are patent.

The popular terminology of single-, double-, or triple-vessel disease refers to the number of coronary arteries involved. In over 50 percent of patients, “triple-vessel” disease is present.

Clinical Manifestations

Myocardial ischemia from coronary artery disease can produce several serious events: angina pectoris, myocardial infarction, congestive heart failure, or sudden death. Angina is the most frequent symptom, but myocardial infarction or sudden death can appear without warning. Congestive heart failure usually results as a sequela of myocardial infarction, with significant muscular injury resulting in ischemic myopathy.

Angina pectoris, the most common symptom, is manifested by periodic discomfort, usually substernal and typically appearing with exertion, after eating, or with extreme emotion. Characteristically these symptoms subside within 3 to 5 min or are dramatically relieved by sublingual nitroglycerin. In about 25 percent of patients the symptoms are not typical and may radiate to bizarre areas, such as the teeth, the shoulder, or the epigastrium. Establishing a diagnosis of angina in these patients is difficult and perhaps impossible without diagnostic studies. Physical examination usually is normal. Differential diagnosis includes anxiety states, musculoskeletal disorders, and reflux esophagitis or esophageal spasm.

The risk of sudden death varies with the extent of disease and the degree of impairment of ventricular function, ranging from 2 to 10 percent. Death apparently results from ventricular fibrillation in many cases, or from myocardial infarction with acute decompensation.

Myocardial infarction is the most common serious complication, with 900,000 cases occurring in the United States annually. With modern therapy the mortality rate is 5 to 8 percent. Most deaths occur in the first 1 to 2 h, often before the patient ever reaches a hospital. With modern treatment in coronary care units and early reperfusion the fatality rate is small.

In a small proportion of patients congestive heart failure eventually develops, resulting from multiple infarctions that ultimately destroy over 40 percent of the left ventricular muscle mass. When areas of salvageable myocardium are still present, often manifested as angina associated with the heart failure, significant improvement can be obtained with revascularization. In contrast, with late-stage chronic congestive failure, because of diffuse myocardial scarring, the outlook is ominous. Bypass grafting may be futile in these circumstances unless reversible ischemia can be demonstrated on PET scan or thallium scan or unless there is a mechanical defect that can be corrected, such as mitral valve insufficiency or ventricular aneurysm. Cardiac transplantation is required in this group of patients with severe ischemic cardiomyopathy and nonreversible ischemia.

Preoperative Evaluation

A general history and physical examination should be performed in every patient along with a chest x-ray and an ECG. The resting ECG is normal in over 50 percent of patients. The other commonly used diagnostic tests—radionuclide studies, stress or provocative stress tests, and echocardiography—were described earlier (see Diagnostic Studies). The usual purpose of these studies is to assess the level of ischemia in response to stress, the functional significance of the coronary disease, and the level of cardiac function. These studies are often used to decide whether or not cardiac catheterization and subsequent revascularization is indicated.

For patients with coronary artery disease cardiac catheterization remains the cornerstone of evaluation, for it outlines the location and the severity of the coronary disease, accurately assesses ventricular function, and determines the presence of associated valvular pathology. The three most important prognostic factors determined angiographically are the number of vessels involved, the location and severity of the stenoses, and the ventricular function as measured by the left ventricular ejection fraction.

“Angiographically significant” stenosis is considered present when the diameter is reduced by more than 50 percent, corresponding to a reduction in cross-sectional area greater than 75 percent. The number, location, and severity of the coronary stenoses are used to determine the subsequent mode of therapy, i.e., bypass surgery, angioplasty, or medical therapy.

The long-term course of coronary disease is determined by the balance between two opposing factors, the rate of progression of the atherosclerotic stenoses versus the rate of development of the collateral circulation. Ventricular function probably reflects the ability of the heart to develop sufficient collateral circulation to compensate for the arterial stenoses present. Collateral vessels develop in response to an “ischemic gradient,” probably from chemical mediators or ischemia-induced growth factors that stimulate collateral vessel growth, but this physiologic ability varies widely; some patients with extensive triple-vessel disease have normal ventricular function with occluded coronary arteries and well-developed collaterals, while others with less severe disease have marked impairment in cardiac function and no collaterals.

Ventricular function usually is expressed as the left ventricular ejection fraction, with 0.55 to 0.70 considered normal; 0.35 to 0.55, moderately depressed; and below 0.35, especially below 0.20, severely depressed. An ejection fraction below 0.35 is often associated with intermittent congestive heart failure, and below 0.20 to 0.25, with severe heart failure. When a ventriculogram is evaluated, the contraction of individual segments of ventricular wall—i.e., regional wall motion—is separately analyzed. Segmental wall motion is classified as normal, hypokinetic (impaired), akinetic (little or no visible contraction), or dyskinetic (paradoxical contraction, as with a left ventricular aneurysm). Regional wall motion abnormalities are used to help determine zones of injury, while the global ejection is used to determine the overall cardiac function, operative risk, and the long-term prognosis.

Although angiography and ventriculography are the most precise methods for evaluating coronary disease, several limitations of the technique also should be emphasized, for erroneous decisions can be made easily. An angiogram indicates the severity and complexity of the disease but is not an absolute guide to “operability.” Other clinical and diagnostic data must enter into this decision. It is often a serious error to conclude from the ventriculogram that a diseased artery supplying an akinetic zone should not be bypassed because that segment of the ventricle is “scar.” Other studies, such as the PET scan or thallium scan, may reveal reversible ischemia in these areas that would then benefit from revascularization. A patient is not “inoperable” because the global ventricular function is severely depressed. If a significant amount of myocardium has signs of reversible ischemia and is thought to be viable but “hibernating,” the patient usually will benefit from operative revascularization.

Coronary Bypass Indications

The indications for coronary artery bypass usually involve one of three general categories: (1) chronic angina of varying severity, (2) unstable angina, and (3) complications of acute myocardial infarction or postinfarction angina.

Chronic Angina of Varying Severity

There is general agreement that patients with severe angina not responding to medical therapy should be electively operated on. The proper therapeutic choice is less clear when patients present with significant coronary disease but with less severe symptoms. Usually the coronary artery disease was detected because of mild angina or because of a positive stress test. Since angina is not severe, revascularization to improve symptoms or quality of life is not an issue. The key question in these patients is: “Will survival be improved by revascularization?” Factors such as the severity and distribution of the coronary stenoses and degree of myocardial dysfunction are used to determine which patients will benefit from operative revascularization, since patients with extensive disease and poor ventricular function do not do well with medical therapy. Other tests that evaluate the functional significance, the amount of myocardium at risk and the level of activity that induces ischemia are useful for assigning risk levels to patients to determine potential benefit from surgical therapy.

Three historical randomized studies attempted to answer the question of which patients with less severe angina would obtain a survival benefit from coronary bypass.

(1) *The Veterans Administration Cooperative Study.* This study involved 668 males treated between 1972 and 1974. The study demonstrated improved long-term survival in patients with left main disease treated with surgical therapy. Since this trial most patients with significant left main disease have been treated with coronary bypass revascularization regardless of their symptoms because of the survival advantage shown.

(2) *The European Coronary Surgery Study Group.* This study (1973–1976) randomized men under 65 years of age, 57 percent with mild angina and 42 percent with moderate angina, into medical or surgical therapy. Equal survival rates were found in patients with single-vessel disease. In patients with double-vessel disease in which a proximal anterior descending artery lesion was present and in patients with triple-vessel disease, a long-term survival advantage was noted in patients treated surgically. The study recommended

initial surgery for patients with double- vessel disease and a proximal anterior descending artery lesion and for patients with triple-vessel coronary disease.

(3) Coronary Artery Surgery Study (CASS) . This multicenter study was done in the United States from 1975 to 1979, randomizing initial treatment for patients with mild angina and operable coronary disease. Patients treated medically could be crossed over to surgery at the discretion of the cardiologist for worsening angina. After 10 years, results suggested that survival was improved by surgery in patients with triple-vessel disease when cardiac function was depressed. No survival advantage was demonstrated from early surgery in patients with single-, double-, or triple-vessel disease when ventricular function was normal. Survival was calculated on initial intent for treatment, and a significant number of patients initially treated medically eventually had surgery. For example, 38 percent of those with triple-vessel disease treated medically eventually required operation. Initial surgical treatment was recommended for patients with triple-vessel disease and depressed ventricular function regardless of symptoms. On the basis of these data, patients with minimal symptoms and good ventricular function can be safely treated medically, as long as surgery is recommended promptly when symptoms progress.

Other, nonrandomized trials and studies involving the overall CASS registry (of both randomized and nonrandomized patients) have suggested that surgical intervention might improve survival and event-free interval in other patients with triple-vessel disease. Similarly, studies have suggested that patients with double- or triple-vessel disease who become ischemic at a low cardiac workload during stress testing have a poor prognosis with medical therapy and might benefit from early surgical intervention.

A study by Jones and associates (see Angioplasty Versus Bypass Surgery below) evaluated the long-term benefits of bypass surgery and angioplasty versus medical therapy in 9,263 patients with documented coronary artery disease treated between 1984 and 1990. Treatment was nonrandomized, with 2,449 patients receiving medical therapy, 3,890 patients receiving bypass surgery, and 2,924 patients receiving angioplasty. Both interventional treatment groups had better long-term survival than the medical therapy group for all levels of disease severity.

While most patients with mild angina do well with initial medical therapy, coronary artery bypass results in improved survival in patients with more severe symptoms of ischemia, in patients with left main disease, and in patients with triple-vessel disease with depressed left ventricular function or a poor response to stress testing. Bypass operation is recommended in these patients. Some patients with triple-vessel disease and good ventricular function and some patients with double-vessel disease and a tight (>95 percent) proximal anterior descending artery stenosis do better with surgical therapy, especially when ischemia is easily inducible at a low workload.

Unstable Angina

“Acute coronary insufficiency” exists when angina is persistent or rapidly progressive despite optimal medical therapy. This occurs from an acute physiologic state in which the blood flow to a segment of myocardium is seriously jeopardized, but necrosis has not yet occurred. It probably represents instability of a coronary artery plaque, with elevation of the plaque, local thrombus, and spasm, resulting in a sudden decrease in regional blood flow. All agree that a change in angina pattern or unstable angina is a medical emergency. The patient should be promptly hospitalized in a coronary care unit and managed as outlined in the section Medical Therapy. If myocardial oxygen demand is lowered and collateral blood flow increased adequately to compensate for the ischemia, angina subsides and recovery is prompt. These patients should receive aspirin and heparin in addition to standard medical therapy. Cardiac catheterization should be performed promptly. Most patients with unstable angina require revascularization with angioplasty or coronary bypass, with the form of therapy based on the anatomy. Untreated patients with unstable angina have a high incidence of myocardial infarction or death—hence the term “preinfarction angina.”

Operation After Acute Infarction or for Postinfarction Angina

The treatment of myocardial infarction was described in the section Medical Therapy. The indications for surgical therapy after acute infarction include a subendocardial infarction with multivessel coronary disease and postinfarction angina, hemodynamic instability, or heart failure after acute infarction with associated left main disease or multivessel disease unsuitable for angioplasty. Cardiogenic shock after myocardial infarction is an indication for emergency cardiac catheterization and angioplasty or coronary bypass, because complete revascularization of the noninfarcted zones of the heart is necessary for survival. Other indications for operative therapy after myocardial infarction include the mechanical complications of myocardial infarction, such as ventricular septal defect, ruptured papillary muscle with acute mitral insufficiency, and myocardial rupture. Most stable patients with a myocardial infarction undergo a stress test before discharge or at 6 weeks. Cardiac catheterization is done if the stress test is positive. Coronary bypass may be recommended if left main or triple-vessel disease is present and in some cases when proximal anterior artery descending lesions are found and angioplasty is not advisable.

Congestive Heart Failure as a Contraindication

The only absolute contraindication to coronary bypass operation is chronic congestive failure and ischemic cardiomyopathy with no signs of angina or reversible ischemia on PET or thallium scanning. In this situation the majority of the left ventricular muscle is already necrotic, so cardiac transplantation is the only therapy likely to help. In contrast, intermittent ischemia-induced congestive failure, manifested by intermittent episodes of pulmonary edema with angina or ECG changes, is not a contraindication to operation but actually a strong indication for immediate operation. This indicates a serious degree of myocardial ischemia that can easily progress to an irreversible stage or death. The intermittent episodes probably evolve from an acute ischemic episode that elevates end-diastolic pressure sufficiently to produce pulmonary edema.

While a severely depressed ejection fraction of 0.20 to 0.25 or less results in an increased operative risk, it is not a contraindication to surgery. This erroneous concept probably arose from earlier experiences with ineffective myocardial preservation that produced some degree of infarction during operation. Jones and associates reported experiences with 188 patients with an ejection fraction below 0.35, about 24 percent of whom had ejection fraction lower than 0.20. The operative mortality rate was only 2.1 percent. Pigott and Kouchoukos reported results for 192 patients with an ejection fraction less than .35, of whom 77 were operated on and 115 were treated medically. Seven-year actuarial survival was 63 percent in the surgical group versus 34 percent in the medical group. Recurrent infarction developed in 19 percent of the medical group, compared to 7 percent of the surgical group.

Similar results were found in an NYU evaluation of 157 patients with ejection fractions of less than .30 who underwent coronary bypass grafting. Angina was present in 55 percent, but severe congestive heart failure was the predominant symptom in 24 percent. The overall operative mortality rate was 7 percent, and the cumulative 4-year survival rate was 67 percent. While congestive heart failure and pulmonary hypertension had a negative impact on long-term survival, 4-year survival was approximately 50 percent in patients with severe congestive heart failure and pulmonary hypertension.

Angioplasty Versus Bypass Surgery

Transluminal coronary angioplasty, developed by Gruentsig in 1978, significantly changed the treatment of patients with coronary artery disease. Over 400,000 angioplasties are performed each year in the United States. Angioplasty is used primarily for patients with single- or double- vessel involvement and discrete coronary stenoses, although the indications for angioplasty (catheter-based therapy) have continually expanded as the technology has advanced. Directional atherectomy and coronary stenting have improved the results over those achievable with traditional balloon angioplasty, lowering the restenosis rate to approximately 20 to 30 percent. Angioplasty has become a widely used alternative therapy for many patients with coronary artery disease, including many patients with multivessel disease.

Several large studies have compared results after bypass surgery and angioplasty in an attempt to outline the most appropriate therapy for various subgroups of patients. Two significant studies and a metaanalysis of three additional large randomized trials are summarized here:

(1) The BARI Trial (Bypass Angioplasty Revascularization Investigation). This NIH-sponsored trial randomized patients with multivessel coronary disease to either coronary artery bypass graft (CABG, N = 914) or percutaneous transluminal coronary angioplasty (PTCA, N = 915). The patients all had multivessel disease that was suitable for angioplasty in the opinion of the invasive cardiology team, excluding patients with diffuse multivessel disease who were thought to be unsuitable. The average follow-up time was 5.4 years. In-hospital event rates for CABG and PTCA, respectively, were 1.3 and 1.1 percent for mortality, 4.6 and 2.1 percent for myocardial infarction, and 0.8 and 0.2 percent for stroke. The 5-year survival rate was 89.3 percent for CABG and 86.3 percent for PTCA. Within 5 years, 8 percent of those assigned CABG required additional revascularization procedures, 54 percent of those assigned to PTCA required additional revascularization, and 31 percent required surgery. For diabetic patients, 5-year survival was 80.6 percent after CABG and 65.5 percent after PTCA ($p = .003$).

(2) Duke University Nonrandomized Trial. This report by Jones and associates was a long-term survival study involving 9,263 patients treated at Duke University between 1984 and 1990, comparing medical therapy, coronary artery bypass surgery, and angioplasty. CABG and PTCA had better survival rates than medical therapy in all anatomic subgroups, but the survival benefit was stronger for PTCA in patients with single-vessel disease and in patients with double-vessel disease without a tight (<95 percent) left anterior descending artery stenosis. CABG provided better survival rates than medical therapy or PTCA in patients with triple-vessel disease and in those with double-vessel disease and a tight (≥95 percent) left anterior descending artery stenosis.

(3) Metaanalysis of Randomized Trials. Sim and associates reported a metaanalysis based on 3,077 patients from randomized trials other than BARI that compared results of PTCA with CABG. The initial procedure risk was found to be 15 percent higher after CABG than after PTCA, and the periprocedural risk of myocardial infarction was 38 percent higher after CABG than after PTCA. For patients who survived the initial procedure the subsequent risks of both cardiac death and nonfatal myocardial infarction were only two-thirds as high (odds ratio = 0.67, $p = .02$) for CABG patients as for PTCA patients.

Summary

The overall results in comparisons of CABG and PTCA for the treatment of patients with coronary artery disease demonstrate that PTCA and CABG are equally safe and both provide excellent relief of angina. Patients undergoing PTCA have less procedure-related pain, a shorter hospital stay, fewer periprocedural infarctions, and equal immediate relief of angina compared with CABG patients. PTCA may offer an early survival advantage over CABG in patients with single-vessel disease and in some patients with double- vessel disease with less than 95 percent stenosis of the left anterior descending artery. Revascularization is less complete with PTCA, and restenosis is a significant problem, leading to a higher need for subsequent procedures. Approximately one-half of the patients undergoing PTCA require a subsequent intervention within 5 years, and approximately one-third need bypass surgery.

CABG provides more complete revascularization and better long-term relief of angina. After CABG less than 10 percent of patients need subsequent revascularization within 5 to 7 years. CABG results in improved survival in diabetic patients, in some patients with triple-vessel disease, and, possibly, in patients with double-vessel disease and a tight (≥95 percent) left anterior descending artery stenosis.

Silent Ischemia

Better therapy is needed to prevent the development of extensive ventricular injury from coronary disease, the so-called bad left ventricle with an ejection fraction of 0.20 to 0.25, or even lower. It is disconcerting that these patients often have had good medical management because their coronary disease was first recognized years earlier, and they have had neither recurrent major infarctions nor severe angina. Despite periodic medical observation and therapy, the disease has silently progressed. Methods other than severity of angina need to be used to identify these patients and to allow bypass operation to be performed earlier. It is likely that these patients have had ongoing asymptomatic silent ischemia.

Periodic stress testing in patients with known coronary disease is indicated. The stress thallium study or 24-h digital ECG ischemic monitoring may be helpful. Patients with significant silent ischemia or a positive stress test should undergo cardiac catheterization and revascularization if a significant amount of myocardium is at risk.

Ischemic Cardiomyopathy

Patients with ischemic cardiomyopathy and intractable congestive heart failure have been treated by cardiac transplantation with 1-year and 5-year survival rates of approximately 90 and 60 percent, respectively. When reversible ischemia is demonstrable in patients with congestive heart failure, standard bypass operation should be used, which results in a similar 5-year survival rate.

Carpentier, Magovern, and others have tried a procedure termed cardiomyoplasty to augment left ventricular function in patients with ischemic cardiomyopathy. This procedure relies on programmed stimulation of the latissimus dorsi muscle for biomechanical cardiac assistance, subsequently wrapping the muscle around the heart and stimulating synchronized muscular contraction to augment the stroke volume of the heart. Cardiomyoplasty has mixed results with little demonstrable long-term benefit.

Operative Technique of Coronary Artery Bypass

The standard coronary artery bypass operation is performed through a median sternotomy incision (Fig. 18-3), using cardiopulmonary bypass, moderate systemic hypothermia (28 to 32°C), and cold cardioplegia for intraoperative myocardial protection (see Myocardial Protection above).

Historically, *vein grafts* were used in the majority of cases (Fig. 18-4). The saphenous vein graft is still used as the conduit for several of the distal bypasses in most patients with multivessel disease. When using vein grafts, the greater saphenous vein is harvested from the leg, and ligatures or hemoclips are applied to the side branches. The optimal diameter for a vein graft is approximately 4.0 mm. Care is taken to avoid significant trauma to the vein, which is gently flushed with a dilute heparin-crystalloid solution, but not overdiluted. If the greater saphenous vein is not available or if the vein quality is poor, the lesser saphenous vein and the cephalic vein are acceptable alternatives. For patients requiring several grafts the incision can extend over the entire length of the leg, depending on the number of grafts needed.

The proximal saphenous–aortic anastomosis connects each vein graft to the ascending aorta. This is done after completion of the distal grafts or before bypass is started, with subsequent serial construction of the distal anastomoses. In some patients, particularly those with significant atherosclerotic disease in the ascending aorta, all distal and proximal anastomoses are done during the single cross-clamp time to avoid placement of the partial occlusion clamp on the diseased aorta.

The number of distal coronary anastomoses usually varies from two to six. With the heart stopped and cold, a small, 5- to 6-mm arteriotomy is performed in the coronary artery, entering a soft area of the vessel beyond the obstruction. An end-to-side saphenous–coronary anastomosis is performed with continuous 7-0 monofilament cardiovascular suture, using a microvascular suturing technique. Optic magnification at 3 to 4 power is routinely used, allowing for a precise anastomosis on the still, arrested heart.

The *left internal mammary artery* (internal thoracic artery) is used as the primary conduit in the vast majority of patients, usually to graft the left anterior descending artery (Fig. 18-5 A). The mammary artery is taken down from the internal surface of the left anterior chest wall as an in situ pedicle graft. This is a living conduit that remains connected proximally to the native subclavian artery. The mammary artery remains metabolically active and enlarges with time in response to demand and runoff. The mammary artery is resistant to intrinsic atherosclerotic disease and rarely becomes stenotic secondary to atherosclerosis.

Because of these favorable characteristics expanded use of the mammary artery as a conduit has been advocated in recent years, and bilateral mammary grafting has been employed with increasing frequency in nondiabetic patients. After attaching the distal vein grafts, the mammary bypass grafts are performed end-to-side with continuous 7-0 or 8-0 suture. Occasionally, sequential mammary bypass grafts are performed, constructing side-to-side anastomoses to multiple vessels.

Since Grondin reported in 1984 the alarming deterioration of vein grafts between 5 and 10 years after operation but showed that the internal mammary artery grafts remaining patent without late deterioration in 90 to 95 percent of patients, a wider application of left internal mammary grafting has become the standard of care. Certain facts regarding internal mammary grafting were established: (1) The 10-year patency rate is reproducibly 95 to 98 percent (Fig. 18-5 B) with no signs of deterioration or late stenosis after the first few postoperative months. The internal mammary artery seems to be relatively immune to atherosclerosis. (2) A patent mammary artery can enlarge substantially over a number of years, perhaps responding to a decrease in peripheral resistance in the coronary vascular bed as atherosclerosis occludes adjacent vessels. This striking ability to enlarge with time indicates the possibilities with multiple anastomoses constructed from a single mammary artery. (3) Data indicate that bilateral or sequential mammary grafts can be performed in good-risk patients without significant morbidity. In several significant reports, Lytle and associates described experiences with bilateral mammary grafting in 500 patients with little increase in morbidity.

Loop and associates compared longevity in patients who received one mammary graft with those in whom only vein grafts were used. The series included 2,306 internal mammary grafts and 3,625 vein grafts. There was a statistically significant difference in survival at 10 years, gradually becoming apparent between 5 and 10 years after operation. Results suggest that use of a single mammary bypass can lower the incidence of recurrent symptoms at 10 to 15 years, and these results might be improved even more by using double mammary grafts in appropriately selected patients.

Available data concerning “free” mammary artery grafts, in which the artery is divided and reimplanted into the aorta, identical to the method used with a saphenous vein graft, suggest reasonably good results over 10 years. Patency rates for the free mammary graft of approximately 70 to 80 percent at 10 years is slightly better than vein graft patency, but not as good as the patency of in situ mammary pedicle grafts. Free mammary grafts are used when the mammary artery is not of adequate length to reach its destination as an in situ graft.

Alternative Conduits

Encouraged by the success of the internal mammary graft, surgeons have explored the use of other arterial conduits in an attempt to achieve better long-term patency rates than those obtainable with saphenous vein grafts. The most widely used has been the *radial artery graft*. Use of the radial artery was revived by Acar and Carpentier in 1992 when late results showed excellent 15-year patency in several patients. An Allen test and Doppler studies are performed routinely beforehand to assure blood flow to the hand, with the radial artery harvested as a free graft. Because the radial artery has a tendency to spasm, intravenous calcium-channel blockers are used intraoperatively. Reports by Acar, Chen, and others have demonstrated early patency rates of 93 to 96 percent.

The *right gastroepiploic artery* has been used as an in situ pedicle graft and as a free graft. Similar to the radial artery, the gastroepiploic artery has a tendency to spasm, and the early patency rate has been reported to be approximately 95 percent. The *inferior epigastric artery* also has been used as a free graft with similar patency rates. The inferior epigastric artery is only 10 to 12 cm in length and 1.5 to 2.0 mm in diameter and therefore is suitable for use only into a diagonal or high marginal branch.

Cardiac surgery has expanded the use of arterial conduits in an attempt to improve the long-term patency of bypass grafts. While this concept is appealing, late angiographic results with alternative arterial conduits are necessary before it can be accurately determined whether this approach results in better late patency rates than vein grafts.

Coronary endarterectomy, as advocated by Johnson and associates, is possible as an adjunct to bypass grafting in patients with diffuse coronary disease but rarely is necessary, because segmental areas of the coronary arteries usually are adequate for bypass grafting. Most patients with diffuse disease are better served with multiple grafts than with endarterectomy, even if only a part of the vessel has runoff, because endarterectomy has an increased risk of late occlusion from progressive fibrosis. In selected patients a long endarterectomy is performed, which allows subsequent grafting of an otherwise nonbypassable vessel.

After discontinuing cardiopulmonary bypass, flow rates are measured in the grafts with a flow probe to assess graft patency, usually finding a mean flow rate of 50 to 150 mL/min if the vessel has an adequate runoff. The flow rate may be used for comparison later if the patient's clinical status changes.

Postoperative Management

Care initially is given in the recovery room or intensive care unit, with the patient progressing to a monitored intermediate care unit and then to a standard room. Most patients without complications are discharged from the hospital in 5 to 7 days. Activity is increased gradually over 6 to 8 weeks, usually with a progressive walking program over the first 2 to 3 weeks at home. Older patients, however, often need a more formalized cardiac rehabilitation program. Full activity is resumed after 6 to 8 weeks. If vigorous exercise is planned, a stress test is recommended. Long-term management should include antiplatelet therapy with aspirin and aggressive risk factor management. If necessary, cholesterol-lowering agents should be used to achieve the targeted serum cholesterol levels. Hypertension and diabetes are treated, and smoking should be avoided.

Early Results

Operative Mortality

The operative mortality rate for coronary artery bypass is 1 to 3 percent, with the risk varying with the number of risk factors present. The Society of Thoracic Surgeons has a National Cardiac Surgery Database to determine nationwide results and establish preoperative risk variables. These include female gender, age over 65 years, diabetes, renal failure, systemic or pulmonary hypertension, peripheral vascular disease or prior stroke, cardiomegaly, chronic obstructive pulmonary disease, immunosuppressive therapy, prior cardiac surgery, prior noncardiac surgery, recent thrombolysis or percutaneous transluminal coronary angioplasty, prior myocardial infarction, unstable angina, arrhythmias, cardiogenic shock, preoperative inotropes, preoperative intraaortic balloon pump, preoperative heart failure or NYHA functional class IV status, emergency surgery, triple-vessel or left main disease, concomitant valvular heart disease, low ejection fraction (< 0.50), and an elevated left ventricular end-diastolic pressure (Table 18-2). Numerous attempts have been made to develop equations based on statistical methods to predict the “expected risk” for patients or groups of patients according to the number of risk factors present. These approaches have had some success but have not been uniformly reliable.

Operative Morbidity

The most frequent perioperative complications after coronary bypass surgery are myocardial infarction, bleeding, and stroke, which occur in approximately 2 to 4 percent of patients. Other complications include sternal infection, tamponade, aortic dissection, reoperation for graft occlusion, cardiac arrhythmia, cardiac arrest, renal failure, gastrointestinal complications, respiratory failure, and multiorgan failure.

Stroke is a serious complication that occurs with an overall frequency of 2 percent, but with an incidence as high as 10 percent in patients in their seventies and eighties. The most common cause of stroke probably is embolization of atherosclerotic debris from the ascending aorta or aortic arch, although carotid artery disease and emboli from the heart are other potential causes.

Asymptomatic carotid disease is seldom a significant cause of perioperative stroke. Carotid artery disease is surgically treated primarily in the patients with acute ischemic symptoms. If the patient has cerebral symptoms from carotid disease and significant coronary symptoms, the procedures may be done concomitantly. If the coronary symptoms are mild and carotid disease severe, carotid endarterectomy is done first with awake anesthesia and good monitoring. Unless carotid symptoms are present, there are sparse data showing a benefit from performing carotid endarterectomy concurrently with coronary bypass. Exceptions may be patients with unilateral total carotid occlusion and subtotal stenosis of the contralateral carotid and some patients with stenoses with more than 95 percent occlusion in the dominant hemisphere. These patients may benefit from a combined procedure despite the absence of cerebral symptoms.

Considerable attention has been focused on previously unrecognized atherosclerotic disease in the aorta as a source of emboli and cause of perioperative stroke, especially in older patients. Use of intraoperative echocardiography has been very helpful in this regard because this technique can readily detect intraluminal atheroma that are removed or avoided at the time of surgery. In patients over 70 years of age a special aortic arch cannula often is used, with the tip placed beyond the orifice of the left subclavian artery to avoid dislodgment of atherosclerotic material from the transverse arch by the jet of blood emerging from the perfusion cannula. In patients with palpable disease of the aorta or demonstrable intraluminal disease by transesophageal echocardiographic evaluation, the aorta may be surgically explored using the technique of circulatory arrest. The aorta can be readily explored through an appropriately placed 3- to 5- cm aortotomy and loose atherosclerotic debris removed. The aortic cross-clamp then can be placed in an appropriately selected site that is free of debris. Other maneuvers to avoid embolization include placement of the aortic cannula into a nondiseased area on the aorta using intraoperative palpation and transesophageal echocardiography for guidance. Partial-occlusion clamps should not be placed on diseased areas; in some cases all proximal and distal anastomoses are done while the cross-clamp is in place to avoid undue manipulation of the aorta. In rare patients with extensive disease, the aorta is replaced or the entire operation is performed during circulatory arrest. Awareness of the risks inherent in the diseased aorta allows the use of various techniques that lower the risk of perioperative stroke.

Late Results

Relief of Angina

Relief of angina is the most dramatic aspect of coronary bypass surgery. Angina is completely relieved or markedly decreased in over 90 to 95 percent of patients. Persistent angina almost always indicates that a graft has become occluded or a significantly diseased artery was not bypassed.

Early recurrent angina is rare after bypass surgery; reintervention is required in less than 10 percent of patients within 5 years. Recurrent angina occurs more frequently between 5 and 15 years, paralleling the development of late graft occlusion. If significant angina recurs, angiography should be done promptly. In the majority of patients, recurrent angina is the result of one of two causes—stenosis or occlusion of a bypass graft, or progression of disease in the native circulation. Either situation can be treated with repeat bypass grafting or angioplasty. Close control of risk factors postoperatively minimizes the risk of recurrent angina, as does the use of an internal mammary graft.

Graft Patency

With a proper operative technique, combined with the preoperative use of antiplatelet therapy, early vein graft patency rates exceed 95 percent. Early graft patency is determined mainly by operative technique and by the size of the runoff vessel, with small (< 1 mm) vessels occluding more frequently. In the first 5 years after operation, the vein graft patency remains relatively stable, decreasing 1 to 2 percent per year because of intimal hyperplasia in the vein, with a 5-year patency rate of approximately 80 to 85 percent. Intimal hyperplasia can be worsened by trauma to the vein or overdistention at the time of operation, a process that might be related to liberation of growth factors locally or to an enhanced genetic expression of mitogenic signals.

In the period from 5 to 15 years after operation there is a significant increase in atherosclerotic disease in the vein grafts, resulting in a 10-year vein graft patency rate of approximately 60 percent, with significant atherosclerosis occurring in many of the remaining patent grafts. Late graft patency is improved with long-term antiplatelet therapy (aspirin) and by controlling cardiac risk factors. Cessation of smoking and control of cholesterol are particularly important, because late graft occlusion is five to seven times higher in smokers and patients with persistent hypercholesterolemia.

In the past few years the use of the internal mammary artery has increased markedly, including the more frequent use of bilateral and sequential mammary grafts. The 10-year patency rate is over 95 percent for a left internal mammary artery graft and 80 to 90 percent for a right internal mammary artery graft. Failures are primarily technical, because the mammary artery develops little late graft atherosclerosis. The impact of alternative arterial conduits on late graft patency remains to be determined, but early results suggest that arterial grafts may remain patent longer than vein grafts.

Progression of Atherosclerosis

Late angiographic studies have reported a serious progression of atherosclerosis in the native coronary arteries in a certain proportion of patients, ranging from 5 to 10 percent per year and ultimately affecting over one-half of the patients. The need to control cardiac risk factors cannot be overemphasized. Diabetes must be tightly controlled, and the discontinuation of smoking is essential. Weight loss is strongly encouraged in obese patients. Moderate exercise is recommended as long as revascularization is complete and the cardiac function is adequate.

Large studies have demonstrated that reduction in total plasma cholesterol and low-density lipoprotein (LDL) cholesterol levels results in a significant reduction in the progression of atherosclerosis, demonstrating a 2 percent reduction in coronary risk for each 1 percent reduction in plasma cholesterol level. Postoperatively patients are placed on a low-fat, low-cholesterol diet, and ingestion of meat or foods high in saturated fats is minimized. Attention is given to total cholesterol and to the ratio of high-density lipoprotein (HDL) to LDL cholesterol levels. The total cholesterol level should be lower than 200 mg/dL or the LDL cholesterol less than 100 mg/dL; lipid-lowering drugs should be used as necessary to achieve these goals.

Improvement in Ventricular Function

With earlier techniques of cardiac surgery, improvement in impaired ventricular function could not be demonstrated after surgery, probably because of inadequate myocardial protection. With the today's techniques of myocardial preservation the ejection fraction often improves in response to exercise after surgery. Similarly, the regional wall motion frequently improves in ischemic zones. Patients undergoing coronary bypass have a markedly improved functional response to exercise compared with patients treated medically. This improvement lasts 10 years and longer in patients receiving mammary grafts.

Arrhythmias and Sudden Death

Arrhythmias usually are little improved in patients with significant preoperative myocardial scarring. In contrast, in patients with ongoing ischemia and good ventricular function arrhythmias may be significantly improved, because ischemia was the basic cause. Effective medical treatment of arrhythmias is significantly improved with widespread use of beta-adrenergic blockers and other drugs such as amiodarone. The more frequent use of 24-h Holter monitoring and electrophysiology studies has improved the effectiveness of antiarrhythmic therapy. Patients with recurrent ventricular tachycardia have been effectively treated with electrical ablation. In refractory cases the implantable defibrillator may be required. Late sudden death primarily from arrhythmias remains a possibility in any patient with coronary artery disease.

The influence of medical and surgical treatment on “sudden death” was reported from results with over 13,000 patients in the CASS study. Over a period of 4 to 5 years sudden death occurred in 452 patients (3.4 percent of the group). This occurred in 6 percent of the medically treated patients but only 2 percent of the surgically treated patients.

Longevity

The influence of coronary bypass on longevity depends on the anatomic severity of the coronary lesions, the degree of reversible ischemia, the underlying cardiac function, and the degree of revascularization. Studies have demonstrated improved survival with surgery compared with medical therapy in patients with double-vessel disease and a tight proximal left anterior descending artery stenosis, in patients with triple-vessel disease and easily inducible ischemia or depressed left ventricular function, and in patients with left main disease. Coronary bypass surgery has had a significant impact on longevity in symptomatic patients and in the anatomic groups listed.

Survival for the first 5 to 7 years after bypass surgery is similar to age- and-sex-matched controls in patients with good left ventricular function. Loop and associates noted 5-year survival rates among different groups of 90 to 93 percent. Kirklin and associates reported a 5-year survival rate after triple bypass of 89 percent. A 10-year survival rate of 75 to 88 percent in several thousand patients was reported by Cosgrove and associates. The 10-year survival rate varied between 84 percent with a normal ventricle and 54 percent with severe cardiac impairment. Survival beyond 10 years may be significantly improved by use of the internal mammary artery, with a 10-year survival rate of nearly 90 percent in those receiving mammary grafts. Late death, like recurrent angina, usually is found to result from stenosis of a previously inserted bypass graft or from progressive disease in an ungrafted vessel.

New Developments

Minimally Invasive Coronary Bypass Surgery

One of the most significant developments in cardiac surgery in the past 20 years has been the introduction of minimally invasive direct coronary artery bypass (MIDCAB). This procedure also has been referred to as the limited anterior small thoracotomy (LAST) bypass operation and “keyhole” bypass surgery. An expanded approach to minimally invasive cardiac surgery has been developed with the use of endocardiopulmonary bypass and balloon aortic occlusion with cardioplegic arrest. This technique has expanded the applicability of minimally invasive bypass surgery, allowing multivessel bypass procedures and improved accuracy.

The initial experience with minimally invasive beating-heart techniques was in Europe, introduced by Calafiore. Initial results were encouraging and the method quickly spread to the United States, with significant work from Subramanian, Fonger, Mack, Magovern, and others, each exploring variations of the beating-heart technique.

MIDCAB Technique

The operative approach uses a small (5 to 7 cm) left anterior thoracotomy incision. The skin incision is beneath and medial to the left breast, and the fourth costal cartilage often is excised for direct exposure to the left internal mammary artery and the anterior surface of the heart. The left internal mammary artery is harvested by direct vision or with a thoracoscope for visual assistance. After the internal mammary artery is harvested the pericardium is opened. The heart rate is slowed with intravenous beta-adrenergic blockers or intermittent asystole is induced with a bolus of intravenous adenosine. Mechanical stabilizers have been developed to decrease the movement of the coronary artery during the anastomosis. Similarly, the coronary artery is temporarily snared or occluded to provide a relatively dry field for the anastomosis.

The worldwide experience with minimally invasive beating-heart bypass procedures exceeds 1,000 patients, with good early clinical results. The early event-free survival rate approaches 90 percent, with an operative mortality rate of 2 percent or less. The advantages of the technique include less pain and a shorter recovery time than with conventional surgery. This approach has numerous potential benefits to the patient.

A significant disadvantage of the beating-heart technique is the need to perform an anastomosis on the moving heart, which results in decreased anastomotic accuracy and a lower graft patency rate than in operations performed on the arrested heart. Early anastomotic failure rates with the beating-heart approach have been as low as 7 percent in experienced hands to a high range of 15 to 20 percent in several series. The overall value of the minimally invasive nature of the procedure may be partially offset by these anastomotic inaccuracies. The beating-heart approach also is only applicable to single-vessel disease, which accounts for only 4 percent of the patients requiring coronary bypass surgery.

Port-Access Technique

An exciting development proposed by Stevens and coworkers is the endovascular cardiopulmonary bypass and cardioplegia delivery system that introduced the concept of minimally invasive cardiac surgery using peripheral cardiopulmonary bypass and endaortic occlusion (Fig. 18-6) for cardioplegic arrest. With newly developed technology for endovascular aortic occlusion and cardioplegia delivery the heart can be stopped, decompressed, and protected without opening the chest. This allows improved anastomotic accuracy and expands the applicability of minimally invasive bypass surgery.

The endovascular cardiopulmonary bypass–cardioplegic arrest system was tested extensively in the experimental laboratory. Reports from Stephens, Schwartz, and associates demonstrated that this method is safe, that it provides effective myocardial protection, and that a high level of anastomotic accuracy could be achieved. These studies provided the basis for expanded clinical applicability of the minimally invasive coronary bypass.

The initial experiences with the port-access system for coronary artery bypass grafting have been positive, and clinical use of the technique has spread rapidly over a relatively short period. Within 4 months of the technique's introduction more than 350 port-access cardiac procedures had been performed, with encouraging results. The technique has been used in patients with multivessel disease, patients with mitral valve disease, and patients requiring combined valve–coronary artery surgery.

The chest incision and mammary artery takedown are identical to those of the beating-heart approach. The mammary artery may be harvested by direct vision or with the aid of a thoracoscope. If multivessel bypass is necessary the radial artery or saphenous vein is harvested, and a end-to- side Y graft is constructed off of the internal mammary artery. This provides inflow for subsequent grafting of the lateral or posterior walls of the heart when the heart is arrested. Peripheral cardiopulmonary bypass is established through the femoral vessels, and the balloon endovascular aortic occluder is positioned and inflated in the ascending aorta. The heart is arrested with cardioplegic solution, which may be delivered into the aortic root (antegrade) or through a specially designed percutaneous coronary sinus catheter (retrograde). Once the heart is stopped and protected, precise distal anastomoses are possible, with the surgeon readily visualizing most areas of the heart for multiple grafts. This approach maintains many of the fundamental principles of conventional coronary bypass surgery, including myocardial protection and anastomotic accuracy, while offering the advantages of minimally invasive surgery.

Transmyocardial Laser Revascularization (TMLR)

Experimental investigations of laser revascularization of the myocardium have been under way since the late 1980s, but clinical feasibility was demonstrated only recently. The technique uses a high-powered carbon dioxide laser to drill multiple holes (30 to 40 per procedure) through the myocardium into the ventricular cavity. The procedure is performed on the beating heart, and the laser pulses are gated to the R-wave on the ECG. The TMLR procedure is used primarily for patients with refractory angina or hibernating myocardium who have documented reversible ischemia but who are unsuitable candidates for standard coronary artery bypass graft, angioplasty, or heart transplantation.

The results of a large multicenter trial with TMLR were reported by Horvath and associates, who analyzed 200 patients from eight centers. Eighty percent of the patients had undergone a prior coronary artery bypass graft operation, and 36 percent had undergone prior angioplasty. The operative mortality rate was 8 percent. Results at 1 year demonstrated a significant improvement in mean angina class from 3.8 to 1.3 and an improvement in the level of perfusion defect measured by nuclear perfusion scan from 5.1 to 2.8. One center demonstrated a significant improvement in subendocardial flow using the PET scan. Hospital admissions for angina decreased from 2.5 to 0.3 per year.

The mechanism of benefit of TMLR remains uncertain. Theoretically, enhanced subendocardial flow comes directly from the ventricle through the laser channel, but evidence on the long-term patency of the subendocardial channels remains equivocal. The TMLR technique may result in the opening of microvascular coronary-coronary collaterals or enhance coronary angiogenesis, resulting in improved blood flow to the ischemic area of myocardium.

Gene Therapy

Significant progress has been made in understanding the cellular and molecular mechanisms of cardiovascular disease, leading to new forms of molecular-genetic therapy. Much of this work has focused on vascular mitogens, on intracellular signaling pathways, and on the underlying genetic functions that control the cellular response. Since the early 1990s new technology has allowed effective gene transfer, opening up a previously impossible field of biomolecular gene therapy.

In the area of coronary artery disease, several gene therapy protocols are now under active investigation. These include: (1) genetic engineering of vein grafts that are resistant to atherosclerosis or restenosis; (2) gene therapy for coronary arteries to prevent restenosis after angioplasty or surgical endarterectomy; (3) genetic manipulation of the coronary and peripheral vascular system in an attempt to prevent lipid accumulation and progression of atherosclerosis; and (4) the biomolecular delivery of growth factors or genetic material into the coronary system in an attempt to enhance coronary collateral growth through therapeutic angiogenesis.

LEFT VENTRICULAR ANEURYSM

Historical Data

Safe excision of a ventricular aneurysm was not possible on a routine basis until the development of a pump oxygenator, although Bailey and colleagues reported successful repair of five cases between 1954 and 1958. Cooley, in 1958, presented one of the first reports of successful excision of an aneurysm with cardiopulmonary bypass. In the next few years excision became a standard procedure in most cardiac clinics. The procedure is common in most cardiac surgical centers, and numerous series of more than 100 aneurysm repairs have been reported. Cooley and colleagues at the Texas Heart Institute reported more than 4,000 ventricular aneurysm repairs over 30 years.

Etiology, Pathology, and Pathogenesis

A left ventricular aneurysm develops over a period of 4 to 8 weeks or longer in 10 to 15 percent of patients who have had a myocardial infarction. It results when a severe transmural infarction destroys virtually all muscular fibers in the area of the infarction and they are replaced by fibrous tissue. It probably does not occur more frequently after transmural infarctions because collateral circulation often is sufficient to maintain the viability of a variable number of muscle fibers in the zone of the infarct.

The classic aneurysm is an avascular thin scar, 4 to 6 mm thick, that bulges outward when the remaining left ventricular muscle contracts in systole (Fig. 18-7 A); hence the term *paradoxical contraction*, more commonly termed *dyskinesis*, is applied rather than *hypokinesis* (impaired contractility) or *akinesis* (absence of contractility). Mural thrombi are found attached to the ventricular surface of the scar in over one-half of patients, but arterial emboli are rare. The aneurysm usually enlarges to a moderate degree and then stabilizes; progressive enlargement and rupture, which usually occurs with atherosclerotic aortic aneurysms, is rare. Spotty calcification eventually develops in the aneurysmal wall in chronic cases. Over 80 percent of aneurysms are in the anteroapical portion of the left ventricle, resulting from occlusion of the left anterior descending artery. This usually involves significant aneurysmal dilatation of the upper part of the ventricular septum. Posterior ventricular aneurysms are less common (15 to 20 percent), and lateral aneurysms are rare. Posterior aneurysms can distort the mitral valve, resulting in concomitant mitral insufficiency.

A “false aneurysm” is a rare finding that differs from a true ventricular aneurysm. A false aneurysm is a contained rupture of the heart resulting from a hematoma that is formed after a rupture from a myocardial infarction has been temporarily supported by adjacent fibrous tissue. Excision should be done promptly because false aneurysms soon expand and rupture.

In 30 to 40 percent of patients with anteroapical aneurysms coronary disease is limited to the anterior descending artery, which is completely occluded or severely stenosed. Multivessel disease is present in the other 60 to 70 percent of patients. Small aneurysms (less than 5 cm diameter) have negligible physiologic significance, except, possibly, as a site of arrhythmias. Larger aneurysms decrease ventricular function by dissipating the energy of ventricular contraction with the ineffective paradoxical expansion of the wall of the aneurysm during systole. With larger aneurysms the left ventricular volume is increased and left ventricular hypertrophy develops. The left ventricular end-diastolic pressure often is markedly elevated. The combination of elevated intracavitary pressure and radius results in a significant elevation in wall tension (by Laplace's law: tension = pressure × radius). The decrease in effective ventricular contraction eventually results in cardiac failure and angina, though angina may be a result of the accompanying coronary disease. Arrhythmias are prominent in 15 to 20 percent of patients. Areas of scar tissue around the edge of the aneurysm frequently serve as foci for the origin of ventricular arrhythmias, and patients with scar tissue often suffer sustained ventricular tachycardia, syncope, or sudden death.

Because the physiologic burden from an aneurysm is related to its size, the degree of improvement after operation to some extent is related to the size of the aneurysm. For this reason it is doubtful that an aneurysm is ever large enough to be truly inoperable because of size. Improvement depends on the amount of functioning myocardium left, and the best results obtain when the other walls of the heart contract normally.

The development of an aneurysm depends on almost total destruction of muscle fibers. A true aneurysm, composed of dyskinetic scar, must be distinguished from a scar that results from an infarction and that may be akinetic but whose wall is composed of varying proportions of fibrous tissue and viable muscle fibers. Excision of akinetic scars has been investigated in detail but has not been determined to be clinically beneficial.

Because of the wide spectrum between a ventricular “scar” and a true “aneurysm,” accurate data to define the course of the disease are almost impossible to obtain. The outcome of a patient with a ventricular aneurysm will be determined by at least four factors: the size of the aneurysm, the residual coronary disease, the function of the remaining viable muscle, and the presence of severe arrhythmias. Five-year survival rates with an untreated aneurysm have ranged from as low as 10 percent to as high as 70 percent in different reports. Brusche and associates reported 5-year survival rates of 70 percent in patients with an akinetic segment, 54 percent in patients with a dyskinetic segment and good residual ventricular function, and 36 percent in patients with a dyskinetic segment and poor ventricular function.

Clinical Manifestations

Dyspnea and angina, alone or in combination, are the two most common symptoms. Arrhythmias are prominent in 15 to 20 percent of patients. Abnormalities on physical examination usually are not diagnostic. The apical impulse may be forceful and diffuse with a “double impulse.”

Diagnostic Studies

The chest x-ray may show a localized enlargement in the anteroapical area of the left ventricle. ECG changes usually show only the signs of the previous infarction. Persistent ST segment elevation in the precordial leads occasionally occurs, but this also can be present with a large infarction without aneurysmal disease. A paradoxical area from the

aneurysm may be demonstrable by echocardiography or gated blood pool scan, and the echocardiogram is useful in detecting intracavitary clot. Most diagnostic information comes from the left ventricular angiogram, outlining an akinetic area bulging paradoxically during systole. Often no clear differentiation can be made between an akinetic scar and a true aneurysm, with the final decision being made at the time of operation. If a discrete scar is found at operation containing few or no muscle fibers, resection is indicated. If a diffuse bulging is present without discrete borders and obviously containing a moderate amount of muscle tissue, resection probably is contraindicated. If symptoms suggestive of sustained ventricular tachycardia are present, electrophysiologic studies should be done. If no known arrhythmias exist, a 24-h Holter study or a signal-averaged ECG should be done to screen for arrhythmias.

Treatment

Operation is indicated for symptomatic aneurysms, and most asymptomatic aneurysms may be simply observed. The operative procedure includes excision of the aneurysm and bypass grafting of the diseased coronary arteries. Grafting of the diseased anterior descending artery, which often supplies principally ventricular scar, is of questionable value, although at one center it is grafted when feasible because of the possibility that the improved blood supply to the ventricular septum might benefit ventricular arrhythmias.

The aneurysm usually is not manipulated until the aorta has been cross-clamped and the heart arrested to prevent dislodgment of mural thrombi. Once the heart has been arrested, the aneurysm is mobilized and freed from the pericardial adhesions. In the classic ventricular aneurysm repair a subtotal excision of the aneurysm is performed, dividing the wall of the aneurysm about 2 cm from its junction with left ventricular muscle, followed by linear closure. The subtotal concept is a crucial one, because the suture line closing the ventriculotomy is inserted through scar rather than through viable muscle surrounding the aneurysm. This precaution also avoids any excessive reduction in size of the ventricular cavity. Many operative deaths from excision of huge aneurysms probably have resulted from excessive excision of the wall of the aneurysm with injury of the surrounding viable ventricular muscle. The classic ventricular aneurysm repair can have a geometrically deforming effect on the remaining left ventricular cavity because of the linear cardiac closure required after aneurysmal excision. Symptoms often improve after standard repair, although an increase in the ejection fraction does not always occur.

A technique of *reconstructive intracavitary aneurysm repair* has been proposed by Jatene and Cooley. Operative repair involves placement of a Dacron patch to obliterate aneurysmal ventricle and septum, reestablishing a Dacron “roof” on the left ventricular cavity (Fig. 18-7 *B, C, D*). This type of repair remodels the ventricular cavity and obliterates the septal component of the aneurysm, neither of which is achievable with classic aneurysm repair. The Dacron patch is sutured circumferentially to the junction of viable and nonviable myocardium and can be combined with subendocardial resection to obliterate conduction of arrhythmias. This technique results in lowering the diastolic volume without deforming the other walls of the heart and provides better improvement in cardiac function.

The wall of the aneurysm usually includes the area of the anterior descending artery with the scar extending into the ventricular septum. Bypass grafting of the anterior descending artery is of uncertain significance, because the muscle supplied by that artery has been infarcted. If significant tributaries to the ventricular septum are patent, the artery should be preserved and a bypass graft attached. Bypass grafts are routinely placed into other areas of viable myocardium if obstructive coronary lesions are present.

The extent of the endocardial scar usually is greater than that of the external aneurysm. Because of the hazard of malignant ventricular arrhythmias, an extensive excision of the subendocardial scar for at least 1 cm around the periphery of the aneurysm is important when arrhythmias are present; this is done easily without significant injury to functioning ventricular muscle. When combined with intracavitary repair and septal obliteration, an encircling excision of subendocardial scar provides reasonably good control of arrhythmias. Electrophysiologic studies have found that trigger zones for arrhythmias usually are located in the scar within 1 to 3 cm of the border of the aneurysm. When severe preoperative ventricular arrhythmias are present, intraoperative electrophysiologic mapping to locate and ablate the irritable foci may be necessary. Otherwise, an implantable defibrillator is placed postoperatively to control the arrhythmias (see Implantable Defibrillators below).

Results

Prognosis is determined principally by the residual ventricular function, which in turn is influenced by the size of the aneurysm and the severity of the coronary disease. If angina was the prominent symptom before operation, 5-year survival rates are 60 to 70 percent or better, but if congestive heart failure was the principal indication for operation, 5-year survival rates are around 50 percent.

Most patients are significantly improved after operation, manifested by relief of angina and improvement in ventricular function. Significant improvement in ventricular function can be demonstrated with hemodynamic studies in some patients, while in others little change is noted. Improvement in ejection fraction may be better after intracavitary repair with reconstructive aneurysmorrhaphy.

Olearchyk and associates described experiences with 244 cases with a 5-year survival rate near 70 percent. Dobell and associates, in a series of 67 patients, found a 5-year survival rate of 84 percent when angina was the prominent symptom and 53 percent when congestive failure was significant.

Akins and associates, in a series of 100 ventricular aneurysms, reported a 2 percent operative mortality rate and a 6-year survival rate of 77 percent. Jatene reported repair in 508 patients from 1977 to 1983 using reconstructive principles for left ventricular aneurysm repair, with an operative mortality rate of 4 percent. Cooley reported repairs in 100 patients using the intracavitary reconstruction technique, demonstrating a significant improvement in left ventricular ejection fraction after this operation, with an operative mortality rate of 4 percent. Sosa and associates reported use of a similar repair in patients with associated sustained ventricular tachycardia, demonstrating an operative mortality rate of 5 percent and freedom from recurrent ventricular tachycardia of 95 percent. Other studies have suggested that aneurysms associated with sustained ventricular tachycardia should be repaired with intraoperative physiologic studies to guide ablation of the arrhythmogenic foci, particularly when sustained ventricular tachycardia is the presenting symptom. Combined aneurysm repair and map-guided ablation can be done with a 5 to 10 percent operative mortality rate.

VALVULAR HEART DISEASE

General Principles

“*When should an operation be performed?*” This basic question must be evaluated periodically during the medical therapy of any patient with valvular disease, because the disease process usually is progressive. Valvular heart disease results in a *pressure load* (valvular stenosis), a *volume load* (valvular insufficiency), or both (mixed stenosis and insufficiency). For example, aortic stenosis increases the afterload of the left ventricle, resulting in left ventricular hypertrophy, while both aortic and mitral insufficiency result in a significant volume overload of the left ventricle with cardiac dilatation. While the heart effectively compensates for these hemodynamic changes for some time, progressive deterioration in cardiac function eventually develops. The goal of the clinician is to decide when progressive deterioration in cardiac function is likely to occur and to intervene before significant irreversible cardiac injury has occurred. A decision for operation often is based on physiologic abnormalities found with diagnostic studies, such as echocardiography, cardiac catheterization, or radionuclide studies, rather than by waiting for severe symptoms to develop. Surgical therapy is recommended at a much earlier stage of the disease today than in earlier years in an attempt to maintain excellent long-term cardiac function after valve replacement.

The importance of this approach is emphasized by the fact that longevity after cardiac valve replacement is strongly influenced by the myocardial function at the time of operation. Patients with early functional disability (NYHA functional class II or early class III) have a 5-year survival rate near 90 percent, but only 60 percent of patients with class IV disability live 5 years. This striking difference is a result of irreversible changes in myocardial function that existed before operation, indicating that operation should not be postponed until symptoms are disabling.

For aortic stenosis, valve replacement is strongly indicated in all symptomatic patients and should be seriously considered in asymptomatic patients if the orifice cross-sectional area has decreased below 1.0 cm². This is especially true if the patient has developed significant left ventricular hypertrophy and is beginning to show signs of systolic dysfunction of the left ventricle. With mitral stenosis the left ventricle is protected from injury, and operation usually is indicated when early symptoms develop or when the left atrium becomes significantly enlarged and atrial fibrillation develops.

With aortic and mitral valve insufficiency, selecting the proper time for operation is more difficult, because it depends on the left ventricular function in response to chronic volume overload. The heart compensates for a significant period of time and the patient remains asymptomatic. The clinician must carefully monitor the patient, looking for signs of decreasing systolic function of the heart or for a rapid enlargement in the size of the heart. The demonstration of a decreased ejection fraction at rest (or a rise in the end-systolic volume by echocardiography) or a fall in the ejection fraction during exercise probably are the best signs that the systolic function of the heart is beginning to deteriorate and that operation should be performed promptly. Cardiac function generally will return to normal if operation is done at this time. Postponing operation until serious enlargement of the left ventricle develops and the systolic function has severely deteriorated is a mistake, because 5-year prognosis after successful operation is greatly decreased because of irreversible ventricular injury.

Even with advanced disease, NYHA class IV disability and pulmonary hypertension, patients with valvular heart disease are rarely inoperable. Valve replacement almost always can be performed with an operative mortality rate of 5 to 10 percent. After the hemodynamic burden on the ventricle has been removed with corrective surgery, the patient is treated with an aggressive medical heart failure regimen (digitalis, diuretics, and afterload reduction), usually with significant improvement. Except in the unusual case of intrinsic myocardial disease with late-stage “cardiomyopathy,” operation should not be denied to patients with advanced valvular heart disease.

Survival after valve repair or replacement is strongly influenced by the left ventricular function beforehand—i.e., the systolic function or ejection fraction—and the clinical functional classification. Other risk factors affecting survival are age, congestive heart failure, pulmonary hypertension, concomitant coronary disease, prior myocardial infarction, concomitant disease in another valve, and prior surgery.

Late complications from valvular surgery include heart failure, endocarditis, thromboembolic and anticoagulant-related complications, prosthetic valve failure, and reoperation.

Surgical Options: Prosthetic Valves, Homografts, Autografts, and Valve Repair

The ideal prosthetic valve does not exist. The two basic types of valves are *mechanical prostheses* and *bioprostheses* (heterografts). Both have advantages and disadvantages, which can be summarized as follows: mechanical prostheses are highly durable but require permanent anticoagulation therapy to minimize the risk of thromboembolic complications; bioprostheses have fewer thromboembolic complications but are more prone to structural failure and to require reoperation.

Mechanical valves (Fig. 18-8) commonly used in the United States include the St. Jude Medical bileaflet prosthesis, the Medtronic-Hall tilting disc valve, the CarboMedics bileaflet prosthesis, and the Omniscience disc valves. The older Starr-Edwards caged ball valve has limited use. The disk prostheses have excellent flow characteristics and durability with a low incidence of late valve-related complications.

With mechanical valves the basic long-term risks are thromboembolism and hemorrhage from anticoagulation therapy with warfarin. With proper anticoagulation, keeping the INR

(international normalized ratio) at 3.0 to 4.0 times normal, the incidence of thromboembolism is low, approximately 1 to 2 percent/patient/year. Antiplatelet therapy with aspirin may additionally lower the risk of thromboembolism, although this may not be necessary if close attention is paid to the INR. Anticoagulant-related hemorrhage resulting from warfarin therapy occurs with a incidence of 1 to 4 percent/patient/year, while combined thromboembolic and anticoagulant-related complications occur in 3 to 6 percent/patient/year. With careful supervision and close attention to INR monitoring of warfarin therapy, significant thromboembolic and anticoagulant complications are becoming progressively less common.

The decision in selecting a mechanical prosthesis depends on the patient's understanding and ability to take anticoagulant therapy safely and indefinitely. Mechanical prostheses are more durable than bioprostheses, with 15-year valve failure rates of approximately 5 percent. Mechanical prostheses usually are preferable in patients with a long life expectancy and in patients who want to minimize the risk of reoperation. The drawbacks of mechanical prostheses include a higher incidence of thromboembolic and anticoagulant-related complications and the need for permanent anticoagulation.

Several types of bioprostheses exist, with similar characteristics (Fig. 18-9 A, B). The glutaraldehyde-preserved stented porcine xenograft valve and the stented bovine pericardial xenograft valve are the two main types. The main advantage of the various bioprostheses is the low incidence thromboembolism, making anticoagulation therapy unnecessary in the majority of patients, but the principal limitation is poor durability because of late valve failure. The late failure rate of bioprostheses is approximately 20 percent at 10 years and over 50 percent at 15 years.

Surgical alternatives to prosthetic valve replacement have been developed in an attempt to utilize the body's natural tissue and lower the incidence of valve-related complications. In the 1960s Ross, in England, and Barrett-Boyes, in New Zealand, described a procedure for aortic valve replacement using antibiotic-preserved aortic homograft valves. Newer methods of homograft preservation that result in significant cellular viability are possible using cryopreservation techniques, widening the availability of homografts and potentially improving the long-term results. Homografts have been used more frequently for aortic and pulmonary valve replacements. Because the homograft valve is natural tissue, the thromboembolic rate is low and long-term anticoagulation therapy is not required. The late durability of homografts remains uncertain. Estimates suggest that the 10- to 15-year durability of aortic homografts may be similar to that of porcine valves, with a freedom from reoperation of approximately 50 percent at 15 years. Some reports suggest better durability when using cryopreserved tissue.

Ross described a potentially more durable, but more complicated, alternative for aortic valve replacement using the patient's own pulmonary valve as an autograft and replacing the pulmonary valve with an aortic or pulmonary homograft (Fig. 18-10). Initially the Ross procedure was not widely accepted, but it has been increasingly used in recent years as operative techniques and myocardial protection have improved and cryopreserved homografts have become more widely available. The Ross procedure has the advantage of placing a natural, autologous pulmonary valve into the aortic position, which should be extremely durable without the need for anticoagulation therapy. The results have been good. Ross reported late follow-up on 339 autograft patients with a rate of freedom from autograft replacement of 85 percent at 20 years and a rate of freedom from all valve-related events of 70 percent at 20 years. Elkins reported similar results with an actuarial freedom from any reoperation of 89 percent at 5 years, 92 percent for the pulmonary autograft, and 95 percent for the homograft in the pulmonary position. Given these excellent results, without the need for long-term anticoagulation, many surgeons recommend the Ross procedure for most younger patients who require aortic valve replacement.

Important alternatives to mitral valve replacement for mitral insufficiency also have also been developed. In the 1960s McGoon, Kay, and Reed each developed separate plication techniques for reconstruction of the mitral valve for mitral insufficiency, but these methods had limited applicability and were used primarily for treatment of isolated chordal rupture or annular dilatation. Renewed interest in surgical reconstruction of the mitral valve resulted from work by Carpentier in the 1970s. Carpentier's system for mitral valve reconstruction was applicable to a wider range of pathologic findings than prior methods, and valve reconstruction has subsequently proved to be highly reproducible. The long-term durability of mitral valve reconstruction has been approximately 90 percent at 10 years for patients with degenerative disease. Valve reconstruction may offer significant advantages over valve replacement in terms of lower thromboembolic and anticoagulant-related complication rates and overall valve-related morbidity and mortality (Fig. 18-11). Mitral valve reconstruction has assumed an important role in the treatment of mitral valve disease, offering an excellent alternative to valve replacement in selected patients.

Recommendations

Before operation the surgeon should give the patient a recommendation on the appropriate prosthesis or procedure. Some patients are capable of making this decision after the various risks and options have been explained, and others are not. The surgeon should attempt to learn from the patient whether there is any strong reason to avoid anticoagulation therapy and how the patient feels about the uncertainty of future reoperation. The surgical recommendation then is based on several factors, including the patient's age, lifestyle, intelligence, reliability, and access to follow-up health care. Socioeconomic factors, the desire to have children in female patients, and associated medical conditions also are considered.

For aortic valve replacement, a mechanical prosthesis or a Ross procedure is recommended for most younger patients, depending on their desire to avoid anticoagulation therapy. An aortic bioprosthesis often is recommended for patients older than 70 to 75 years of age because anticoagulation therapy may be hazardous in the elderly and valve failure is unlikely to occur before death from other causes.

For patients with mitral valve disease, commissurotomy or valve reconstruction may be performed if feasible, as long as a durable result is likely. Reconstructive procedures are not recommended, unless the likelihood of achieving a durable repair is high. Mitral valve replacement is required in 10 to 50 percent of patients, depending on the patient population and the experience of the surgical group. When valve replacement is necessary a mechanical prosthesis is recommended for most patients, and especially for patients in atrial fibrillation, since anticoagulation therapy already is required in this group. Bioprostheses usually are reserved for elderly patients in whom anticoagulation therapy is considered hazardous.

Mitral Valve Disease

Mitral Stenosis Etiology

Mitral stenosis is almost always caused by rheumatic heart disease, although a definite clinical history can be obtained in only 50 percent of the patients. Mixed stenosis and insufficiency also are usually rheumatic in origin, and other causes of mitral stenosis are exceedingly rare. Congenital mitral stenosis can result when a single papillary muscle is present (parachute mitral valve) or when the subvalvular apparatus is fused, producing restricted leaflet motion. Stenosis occasionally occurs from systemic lupus erythematosus, rheumatoid arthritis, mucopolysaccharide disease, or carcinoid.

Pathology

Although the rheumatic inflammatory process is associated with some degree of pancarditis, involving endocardium, myocardium, and pericardium, permanent injury results predominantly from the endocarditis with progressive fibrosis of the cardiac valves. The mitral valve apparently is almost always involved.

Rheumatic valvulitis produces three distinct degrees of pathologic change: fusion of the commissures alone, commissural fusion plus subvalvular shortening of the chordae tendineae, and extensive fixation of the entire valve and subvalvular apparatus, with calcification and scarring of both leaflets and chordae (see Fig. 18-12). The degree of pathology present should be determined preoperatively, because this predicts the suitability of surgical commissurotomy or valve replacement.

Mitral stenosis usually has a prolonged course after the initial rheumatic infection, and symptoms may not appear for 10 to 20 years. The progression to valvular fibrosis and calcification may be related to repeated episodes of rheumatic fever or may be from scarring produced by turbulent blood flow after the initial episode of inflammation. The flow alterations cause repeated trauma to the leaflets, resulting in the deposition of thrombin, platelets, and other blood components.

Mitral stenosis produces a functional narrowing of the valve orifice. This impairment to transvalvular diastolic blood flow results in an end-diastolic pressure gradient across the mitral valve. The most precise determination of the degree of mitral stenosis is the mitral valve area, which can be calculated from the diastolic pressure gradient across the mitral valve and the cardiac output using the formula developed by Gorlin. The normal cross-sectional area of the mitral valve is 4 to 6 cm², varying with body size. Significant hemodynamic changes from mitral stenosis usually do not appear until the cross-sectional area is less than 2 to 2.5 cm², and symptoms progressively increase when the cross-sectional area decreases to less than 1.5 cm². Severe mitral stenosis, producing NYHA functional class III or class IV symptoms, occurs when the mitral valve area is less than 0.8 to 1.0 cm², and an opening of approximately 0.5 cm² is said to be the smallest size compatible with life, producing symptoms at rest.

Pathophysiology

The pathophysiology associated with mitral stenosis results from a chronic elevation in left atrial pressure that produces pulmonary venous congestion and subsequent symptoms. The left ventricular function usually remains normal as the ventricle is protected by the stenotic valve. As the degree of stenosis progresses, the flow of blood into the left ventricle is limited and the cardiac output is reduced, resulting in poor exercise tolerance, fatigue, and muscular wasting. As the left atrium hypertrophies, atrial fibrillation eventually develops, which exacerbates the patient's symptoms and results in an increased likelihood of clot formation and embolization.

Clinical Manifestations

The main symptoms of mitral stenosis are exertional dyspnea and fatigue. Dyspnea occurs when the mean left atrial pressure and pulmonary venous pressure exceed the plasma oncotic pressure, producing interstitial edema and pulmonary congestion. Orthopnea, paroxysmal nocturnal dyspnea, and a cough that worsens when the patient lies down reflect the influence of upright position on pulmonary congestion. Severe pulmonary congestion can produce acute pulmonary edema or hemoptysis. Although hemoptysis often subsides, pulmonary edema may be fatal unless treated promptly. When pulmonary hypertension results in right-sided heart failure, findings such as jugular venous distention, ascites, or ankle edema may be seen.

Atrial fibrillation is present in 30 to 50 percent of the cases, and in some patients arterial embolization is the initial presenting symptom. Atrial thrombi result from stasis and dilatation of the left atrium, with the left atrial appendage being especially susceptible to clot formation. Atrial fibrillation does not need to be present for embolization to occur. Angina is a rare symptom that may result from coronary embolization or from decreased diastolic perfusion of the myocardium.

The characteristic auscultatory findings of mitral stenosis, called the "auscultatory triad," are an increased first heart sound, an opening snap, and an apical diastolic rumble. These findings are pathognomonic. The apical diastolic rumble, produced by blood flowing through the stenotic orifice, may be sharply localized to an area at the apex and usually is heard best when the patient is in the lateral decubitus position. A loud pansystolic murmur transmitted to the axilla usually indicates associated mitral insufficiency. A systolic murmur along the left lower sternal border, loudest near the xiphoid process, commonly occurs with tricuspid insufficiency.

Diagnostic Studies

The ECG may show atrial fibrillation, left atrial enlargement (P mitrale), and right-axis deviation, or it may be normal. The ECG often is an inadequate guide to the severity of the stenosis. In contrast, several abnormalities usually are seen on the chest x-ray. The earliest change is enlargement of the left atrium, typically seen on the posteroanterior film as a

double contour visible behind the right atrial shadow. The overall cardiac size may be normal, but enlargement of the left atrium and the pulmonary artery may obliterate the normal concavity between the aorta and the left ventricle, producing a “straight” left border of the heart. Calcifications of the mitral valve also may be seen. In the lung fields, the typical abnormalities consistent with pulmonary congestion may be present.

Echocardiography is the diagnostic method of choice. Transesophageal echocardiography is a particularly useful test, because it provides enhanced resolution and unobstructed visualization of the mitral valve and the posterior cardiac structures, including the left atrium and the atrial appendage. Echocardiography gives a very accurate measurement of the cross-sectional area of the mitral valve and allows assessment of the degree of leaflet mobility, calcification, and subvalvular fusion, each of which may be important in predicting the feasibility of commissurotomy.

Cardiac catheterization should be performed when the diagnosis is in doubt and in patients in whom concomitant coronary artery disease is likely. Catheterization also is valuable in patients with long-standing disease to assess other factors, such as pulmonary hypertension, the degree of mitral insufficiency, and the presence of associated pathology in another valve.

Operative Indications

Operation is indicated for all symptomatic patients with mitral stenosis and should be considered in patients with minor symptoms whose left atrium is significantly enlarged and in patients who have had recent onset of atrial fibrillation or an embolic event. Exercise studies may be useful in evaluating the need for early operation in minimally symptomatic patients.

In determining the timing of surgery in patients with mitral stenosis, it is important to remember that the disease often progresses insidiously. Patients may be treated medically for years with few symptoms other than a minor limitation of activities and be unaware that progressive destruction of the mitral valve is occurring. Close supervision and periodic echocardiographic evaluation are crucial in choosing the proper time for intervention.

Patients almost never have such advanced disease that operation cannot be done. Even in patients with NYHA functional class IV symptoms with pulmonary hypertension, cardiac cachexia, and ascites, the operative mortality rate is now less than 10 percent, and the 5-year survival rate is over 50 percent. Most patients with class IV symptoms obtain remarkable clinical improvement after operation. Successful operation on the majority of seriously ill patients with mitral stenosis is possible because the stenotic valve has restricted inflow into the ventricular cavity, protecting left ventricular function.

Mitral Insufficiency Etiology

Degenerative disease is the most common cause of mitral insufficiency in the United States, accounting for 50 percent of the patients operated on for it. Other causes include rheumatic fever (20 to 30 percent), ischemic disease (15 to 20 percent), endocarditis, congenital abnormalities, and cardiomyopathy.

Pathology

The four major structural components of the mitral valve are the annulus, leaflets, chordae, and papillary muscles. A defect in any of these components may create mitral insufficiency. A functional classification for mitral insufficiency was proposed by Carpentier, outlining three basic types of functionally diseased valves. Type I insufficiency occurs from annular dilatation or leaflet perforation with normal leaflet motion. Typically, this type is a result of ischemia or endocarditis, although isolated annular dilatation is occasionally seen with rheumatic and degenerative causes. Type II insufficiency occurs secondary to increased leaflet motion with leaflet prolapse. This may be from an elongated or ruptured chorda and is most commonly degenerative or ischemic in origin. Type III insufficiency occurs from restricted leaflet motion, with the involved leaflet not reaching the proper plane of closure during systole; this type is found most commonly in rheumatic patients. Annular dilatation often develops secondary to insufficiency from prolapse or restricted leaflet motion and usually is an additional part of type II or type III insufficiency.

The chordae tendineae are thinned and elongated in patients with degenerative disease. Excessive leaflet tissue usually is present and may be thin, or it may be thickened and whitish in patients with Barlow’s syndrome. The valve usually has a billowing appearance, and the annulus is invariably dilated.

With rheumatic disease the chordae tendineae are thickened and shortened, and leaflet motion is restricted. Varying degrees of commissural fusion, leaflet fibrosis, or calcification may occur, producing mixed stenosis and insufficiency. Asymmetric posterior annular dilatation usually is present.

Pathophysiology

The basic physiologic abnormality in patients with mitral insufficiency is regurgitation of part of the left ventricle stroke volume into the left atrium. This results in decreased forward blood flow and an elevated left atrial pressure, producing pulmonary congestion and volume overload of the left ventricle.

As mitral insufficiency progresses there is a corresponding increase in the size of the left atrium above the normal upper limit of 4 cm in diameter. As this occurs, atrial arrhythmias and eventually atrial fibrillation evolve, particularly after the atrium is dilated to more than 4.5 to 5 cm in diameter. Concurrently, the left ventricle dilates and the stroke volume increases. Eventually, however, this compensatory mechanism fails and the ejection fraction decreases. A decrease in the systolic function of the heart, manifested as a fall in the ejection fraction, is a relatively late finding, because the ventricle is “unloaded” as a result of the valvular insufficiency.

Clinical Manifestations

In patients with acute mitral regurgitation the left atrial pressure rises abruptly and congestive heart failure develops suddenly, while in patients with chronic mitral insufficiency symptoms do not develop until later in the course. As chronic mitral insufficiency progresses, the patient develops exertional dyspnea, orthopnea, easy fatigability, and palpitations. These symptoms arise from the combination of an increased left atrial pressure and a decreased cardiac output. As left ventricular dysfunction progresses, symptoms of pulmonary congestion become more prominent, ultimately producing pulmonary hypertension and right-sided heart failure.

On physical examination the characteristic findings of mitral insufficiency are an apical systolic murmur and a forceful apical impulse. The apical murmur usually is harsh and transmitted to the axilla, although if the left atrial pressure is extremely high, the murmur may not be audible. The severity of the insufficiency may not correlate with the intensity of the murmur.

Diagnostic Studies

The chest x-ray is excellent for assessing cardiac enlargement. Frequently the left atrium and left ventricle are enlarged and the cardiothoracic silhouette is increased.

Echocardiography is considered the most valuable diagnostic test. With echocardiography the severity of insufficiency can be determined accurately and the site of valvular prolapse or restriction identified. An important measurement is the size of the cardiac chambers. The size of the left atrium reflects the chronicity and severity of the insufficiency. The normal left atrium seldom has an internal diameter greater than 4 cm. With severe, chronic mitral insufficiency dilatation of the left atrium to 5 to 6 cm or greater is common. This is important because the propensity for atrial fibrillation is greatly increased when the left atrial size is more than 4.5 to 5 cm. The diastolic dimensions of the left ventricle become enlarged relatively early in patients with mitral insufficiency because of the volume overload inherent in the regurgitant lesion.

Once the echocardiogram demonstrates a decrease in ventricular systolic function, manifested as a rise in the end-systolic dimension of the heart, this is an indication that the left ventricle is no longer able to handle the volume load, and symptoms usually will develop shortly. If there is uncertainty about the physiologic significance of mitral insufficiency, an exercise radionuclide study or a stress-echocardiography study may be used. Normally the ejection fraction rises with exercise, but a fall in ejection fraction with exercise suggests systolic dysfunction in response to stress. If the ejection fraction is diminished at rest, significant systolic dysfunction is already present.

Cardiac catheterization is indicated before operation in patients with advanced mitral insufficiency and cardiac enlargement as well as in patients in whom the diagnosis is uncertain. Coronary angiography is performed in older patients and in patients with a history of angina or myocardial infarction. With catheterization it is important to note the degree of pulmonary hypertension, the left atrial and left ventricular end-diastolic pressures, the ejection fraction, and the presence of associated valvular pathology or coronary artery disease.

Operative Indications

Historically, operation was not recommended for patients with mitral insufficiency until functional disability was present. However, delaying operation until the patient is severely symptomatic and the heart is markedly dilated often results in a certain degree of irreversible ventricular injury. In order to better preserve ventricular function and obtain the best long-term results, a more aggressive approach is recommended today. Operation is recommended *at the first sign of symptoms* and for patients with minimal or no symptoms if there are *signs of diminishing systolic function of the heart*. Operation is not mandatory but should be considered in patients with significant insufficiency when the left atrium is enlarged to more than 4.5 to 5.0 cm and atrial fibrillation develops, particularly if progressive left ventricular enlargement is also occurring.

Recommending operation for minimally symptomatic patients on the basis of hemodynamic abnormalities has been discussed periodically in different reports. Studies of the natural clinical history of mitral insufficiency have found that totally asymptomatic patients with severe mitral insufficiency usually progress to significant disability within 5 years. Similarly, ventricular function appears to be correlated with late results after valve replacement, with the best results obtained in patients with normal ventricular function. Once the ejection fraction has deteriorated, results are significantly worse. These considerations were reviewed in detail by Levine and associates, and by Assey and associates, who proposed parameters of ventricular function to optimize the timing of operation.

Operative Techniques Standard Operative Approach

For mitral valve surgery the traditional operative approach has been through a median sternotomy incision (see Fig. 18-3). This approach has outstanding results providing excellent exposure to the heart and safe access to the great vessels for cannulation, cross-clamping, and administration of cardioplegic solutions. Cardiopulmonary bypass usually is established with cannulation of the ascending aorta and bicaval venous drainage. The aorta is cross-clamped and the heart is arrested with cardioplegic solution given in antegrade fashion into the aortic root or retrogradely into the coronary sinus.

The preferred technique for exposure of the mitral valve is through a left atrial incision, made posterior and parallel to the intraatrial groove. After the left atrial incision is made, self-retaining retractor blades are gently inserted, elevating and rotating the septum superiorly and leftward to expose the mitral valve. In certain patients exposure through the posterior left atrial approach may be not be optimal. This is particularly true in patients with a small left atrium, a deep chest, an aortic prosthesis in place, and in reoperations, in which the tissue is fixed and nonelastic. Alternative incisions for exposing the difficult mitral valve include a transseptal incision, a superior approach through the dome of the atrium, and the biatrial transseptal approach described by Smith.

Open Mitral Commissurotomy

The basic technique for open mitral commissurotomy was first described by Mullin in 1974. If commissural fusion alone is present, excellent results are predictable. In contrast, if the valve leaflets are fibrotic and calcified and the subvalvular apparatus is immobile, restoration of normal mobility usually is impossible, and prosthetic valve replacement usually is required. Shortening and fusion of the underlying chordae tendineae occur in approximately one-third of the patients by the time of surgery. This might explain why surgical commissurotomy may be superior to balloon dilation in many patients. With operation the fused chordae can be surgically divided and mobility restored, but with balloon valvuloplasty this is not feasible.

Once cardiopulmonary bypass has been established and the heart has been arrested, the left atrium is opened and the mitral valve is visualized. Initially the atrial cavity is examined for thrombi, especially within the atrial appendage. If the patient is in atrial fibrillation, the atrial appendage is closed with a continuous suture of 3-0 Prolene to minimize the subsequent risk of emboli.

The mitral valve is assessed by evaluating the leaflet mobility, commissural fusion, and the degree of fibrosis in the subvalvular apparatus. A right- angle clamp often is placed beneath the commissures, gently applying horizontal tension to evaluate commissural fusion. The fused commissure actually is a scar developing at the line of commissural closure of the mitral leaflets. In most patients this can be readily identified as a trench, although if fibrosis of the leaflets is severe, the exact location of the commissure may be difficult to identify. Examining the commissural chordae may provide additional landmarks.

Once the commissure has been accurately identified and the chordae noted, a right-angle clamp is introduced beneath the fused commissure, stretching the adjacent chordae and leaflets, after which the commissure is carefully incised with a No. 11 or No. 15 blade scalpel. The incision is made 2 to 3 mm at a time, serially confirming that the separated margins of the commissural leaflet remain attached to chordae tendineae. The usual commissurotomy curves slightly anteriorly and does not go directly laterally. The incision should stop 1 to 2 mm from the valve annulus where the leaflet tissue becomes thin, indicating the transition from the fused commissure to the normal commissural leaflet of the mitral valve. Once the commissurotomy is completed, the fused papillary muscle often is incised for 5 to 10 mm as necessary to minimize restriction and improve mobility of the attached leaflet.

After separation of the commissure and mobilization of the underlying chordae tendineae and papillary muscle, leaflet mobility is assessed visually. The anterior leaflet is grasped with a forceps and moved throughout the entire range of motion, looking for subvalvular restriction or leaflet rigidity. Movement of the leaflet is assessed by injection of cold saline into the ventricle. In some patients restricted motion may be further improved by dividing secondary chordae or by the selective debridement of calcium. Very thickened chordae can be mobilized by excision of a triangular portion of the fused cords. If extensive debridement and mobilization of the chordal structures is necessary, valve replacement usually is more appropriate. At least 30 percent of patients undergoing commissurotomy require more than simple incision of the commissure to produce an adequate mitral orifice and to restore mobility to the valve.

Mitral Valve Replacement

Mitral valve replacement is necessary when the extent of disease precludes commissurotomy or valve reconstruction (see Fig. 18-12). Valve replacement is most likely in patients with long-standing disease. The techniques of perfusion and the surgical approaches are identical to those described for open mitral commissurotomy.

After the left atrium is opened, the diseased mitral valve is exposed with a self-retaining retractor. If valve replacement is necessary, an incision in the anterior mitral leaflet is made, usually starting at the 12-o'clock position and resecting most of the anterior leaflet and associated chordae. The posterior leaflet and chordal attachments are preserved whenever feasible, although this is not always possible in patients with extensive rheumatic disease, because calcium or extensive valvular thickening is often present.

Although preservation of the subvalvular apparatus and chordae has been demonstrated to be valuable when performing valve replacement for mitral insufficiency, the role of chordal preservation to preserve postoperative left ventricular performance after valve replacement for mitral stenosis remains less certain. Okita compared ventricular functional recovery after mitral valve replacement with and without chordal sparing. Postoperative radionuclide angiography during exercise failed to demonstrate any difference in ejection fraction in the chordal preservation group versus those having chordal resection. Harpole and associates found no decrease in the ejection fraction or in the pressure volume relationship of the left ventricle after mitral valve replacement for mitral stenosis despite the resection of chordae. Posterior chordal preservation during mitral valve replacement does lower the risk of posterior left ventricular free wall rupture, which is a lethal complication of mitral valve replacement.

When the mitral valve is excised, a prosthesis of appropriate size is selected. The valve usually is inserted with 12 to 16 mattress sutures, simple or buttressed with a pledget. The mattress suture technique with pledgeted sutures is recommended because it virtually eliminates perivalvular leakage. The sutures often are inserted from the atrial to the ventricular side when a mechanical prosthesis is being used; it may be desirable to evert the annulus and seat the valve intraannularly (see Fig. 18-12). This technique avoids potential leaflet-annular entrapment.

In patients with friable tissue or a calcified annulus the sutures may be inserted from the ventricular side, through the annulus and sewing ring, seating the valve on top of the annulus. The supraannular technique may be stronger, because it sandwiches the annulus between the pledgets and the sewing ring without everting the annulus. This technique is used frequently for bioprostheses.

Care is taken to insert the sutures precisely into the annular tissue, because excessively deep insertion of sutures may injure critical structures, including the circumflex coronary artery posterolaterally (7 to 8 o'clock), the atrioventricular node anteromedially (1 to 2 o'clock), or the aortic valve anterolaterally (10 to 12 o'clock).

Mitral Valve Reconstruction

The basic techniques of valve reconstruction for mitral insufficiency, described by Carpentier and others, include the use of an annuloplasty ring, quadrangular resection of the posterior leaflet and chordal shortening, chordal transposition, and triangular resection for repair of the anterior leaflet. The remodeling ring annuloplasty concept was based on Carpentier's finding that the deformity resulting in mitral insufficiency was dilatation of the annulus. In association with annular dilatation, other anatomical abnormalities include elongation or rupture of chordae to produce increased leaflet motion, or localized restrictive disease, as described in Carpentier's functional classification of valvular pathology.

The intraoperative assessment of the valvular pathology is the most important step in valve reconstruction. A localized roughened area of atrial endocardium, a "jet lesion," may be present from regurgitant blood striking the endocardium, providing a guide to the location of the most serious insufficiency. The degree of annular enlargement is noted initially. The commissures are then examined, noting whether these are prolapsed, fused, or malformed. The closing plane of the leaflets in the area supported by commissural chordae is determined next, and the anterior and posterior leaflets are then serially examined, noting areas of prolapse or restriction. Abnormalities such as perforation, fibrosis, calcification, or clefts also must be recognized.

Proper evaluation of the degree of leaflet prolapse is critical. The "billowing" mitral valve originally described by Barlow has excessive leaflet tissue, but may remain competent if the chordae are not elongated. In such cases, the rough free edge of the leaflet closes at the proper level even though the midportion of the leaflet may contain excessive tissue. As emphasized by Carpentier, the anterolateral commissural chordae are seldom elongated, so elevating the commissural leaflet with a nerve hook provides a valuable reference point from which the degree of elongation of other chordae may be determined. A total lack of structural integrity from chordal rupture results in a completely flail leaflet.

In patients with rheumatic disease, the chordae may be contracted and foreshortened, producing decreased motion of the associated leaflet. When this finding is present, the leaflet does not reach the proper plane of coaptation during systole.

Posterior Leaflet Procedures

Quadrangular resection of the posterior leaflet has become the mainstay of mitral valve reconstruction (Figs. 18-13 and 18-14). Diseased leaflet tissue in the posterior leaflet is excised with a quadrangular excision, usually removing 2 to 4 cm of tissue and, occasionally, over 50 percent of the leaflet. Strong chordae of proper length are identified on each side of the excised leaflet and encircled with retraction sutures. A rectangular excision is performed, cutting directly down to the mitral annulus, but not excising annulus.

Once the quadrangular excision has been performed, the annulus of the excised segment of leaflet is plicated with several interrupted 2-0 Tevdek sutures placed about 5 mm apart. These are started centrally and extended to include a few millimeters of annulus adjacent to the remaining leaflets. When these annular sutures are tied, the leaflet margins are automatically brought into apposition without any tension. If tension were to exist on the leaflet tissues, there would be a serious hazard of dehiscence of the subsequent leaflet repair. Once the annular sutures have been tied, the leaflet margins are approximated with simple or figure-of-eight sutures, usually 4-0 or 5-0 polypropylene, depending on the thickness of the leaflets.

Often the valve appears quite competent after the leaflet repair has been completed. Gently injecting saline into the ventricle with a bulb syringe and noting both the mobility of the leaflets and their apposition is an excellent visual guide for assessing competency. If localized insufficiency remains in other areas, additional procedures can be done.

Anterior Leaflet Procedures

Different approaches must be used for reconstructing the anterior leaflet. Although the techniques must be well planned and exacting, the results of repair requiring anterior leaflet reconstruction have been excellent. Three primary techniques are used: (1) chordal shortening, (2) chordal transposition from the posterior leaflet, and (3) triangular resection of redundant, prolapsing anterior leaflet tissue.

Shortening of elongated anterior leaflet chordae has been used to correct anterior prolapse in patients with intact chordae, although chordal transposition has been used more frequently and probably is more reliable (Fig. 18-15). A segment of posterior leaflet directly opposite the prolapsed anterior leaflet may be identified for chordal transposition. A small quadrangular excision of the posterior leaflet with the attached chordae is performed, and the mobilized leaflet and chordae then are transposed onto the anterior leaflet to provide structural support. The quadrangular defect in the posterior leaflet then is repaired by the previously described techniques.

An alternative method for treating anterior leaflet prolapse involves triangular resection of the involved area of the anterior leaflet (Fig. 18-16). The adjacent intact chordae are identified, and triangular resection is performed to remove the redundant, flail, or prolapsing segments of the leaflet and any ruptured chordae. The technique seems particularly helpful when a large amount of redundant anterior leaflet tissue is present, and this method of repair may limit the incidence of postoperative systolic anterior motion of the mitral valve after valve repair.

Repair of Leaflet Perforation

Leaflet perforations can be repaired by primary suture closure or by closure with pericardium after debridement of irregular leaflet edges. Extensive leaflet destruction is best managed with mitral valve replacement.

Ring Annuloplasty

Mitral annular dilatation, which often is a significant component of mitral insufficiency, is reliably corrected by ring annuloplasty. The ring acts to remodel the annulus, correcting insufficiency and stabilizing the leaflet and annular repair sites. The size of the mitral orifice is measured with a ring sizer. Once the proper size has been selected, the ring is inserted with a series of 2-0 Tevdek sutures (usually 10 to 14 sutures) carefully placed tangentially in the mitral valve annulus (see Figs. 18-13 and 18-14). Particular care is required in inserting these sutures to be certain that they are in the mitral annulus and not in the leaflet tissue or in the atrial wall and to avoid placing sutures lateral to the annulus, because the aortic valve cusps are only 2 to 3 mm beyond the annulus anterolaterally and the circumflex coronary artery a similar distance posterolaterally.

After the annuloplasty ring has been tied in position, saline is again injected gently into the left ventricle with a bulb syringe to assess leaflet mobility. If focal insufficiency remains after completion of the annuloplasty, several ancillary procedures can be considered. These include leaflet plication with figure-of-eight sutures or triangular excision of small prolapsing segments of leaflet. Elongated chordae may be shortened, and the commissures may be plicated in selected cases after the annuloplasty ring is in place.

Results

After Commissurotomy

The operative mortality rate for open mitral commissurotomy is less than 1 percent. In 1981 Gross reported late results in 202 patients undergoing commissurotomy between 1967 and 1978 with a 98 percent complete follow-up. Five years after operation 87 percent of patients who had no residual valve dysfunction after commissurotomy were free of any complications. The frequency of thromboembolism was 0.3 percent per year in the first 10 years after operation.

Similar results were reported in 1980 by Halseth, who described experiences with 222 patients operated on over a period of 10 years. The operative mortality rate was 1.5 percent, with only 7 percent of the survivors later requiring mitral valve replacement. Open mitral commissurotomy is a well-established standard against which newer and less invasive procedures must be compared. Surgical commissurotomy is a safe procedure, and, by allowing effective correction of both leaflet and subvalvular disease, late results are excellent in 80 to 90 percent of patients at 10 years.

Commissurotomy Versus Balloon Valvuloplasty

Percutaneous mitral balloon valvuloplasty has recently become established as an alternative treatment for mitral stenosis. The choice between surgical commissurotomy and balloon valvuloplasty varies widely among centers. A study by Palacios suggests that in patients with favorable anatomy the immediate outcome after balloon valvuloplasty is similar to short-term results obtained after open commissurotomy. A randomized trial reported by Reyes and associates demonstrated equal immediate and 36-month results with open commissurotomy and balloon valvuloplasty in appropriately selected patients. In this study overall survival, functional capacity, restenosis, and reoperation rates were equivalent at 3 years.

The late results after balloon valvuloplasty are less well established than the results after open commissurotomy. It is well known that open commissurotomy gives a much better late functional result than closed surgical commissurotomy, and balloon valvuloplasty appears to be functionally similar to the older closed surgical commissurotomy technique. Cohen and associates, in a report on 164 consecutive patients undergoing balloon valvuloplasty, open commissurotomy, or mitral valve replacement, obtained significantly better results at 3 years in patients treated with open procedures. The actuarial freedom from subsequent mitral valve procedures at 3 years was 66 percent after balloon valvuloplasty, versus 87 percent after open surgical commissurotomy and 100 percent after valve replacement. The linearized yearly reoperation rates were 12 percent, 4 percent, and 1.2 percent for balloon valvuloplasty, commissurotomy, and valve replacement, respectively.

After Mitral Valve Replacement

The operative mortality rate for mitral valve replacement is 2 to 5 percent, depending on the number of risk factors present. The major predictors of increased operative risk are poor ventricular function, NYHA functional classification, advanced age, previous cardiac surgery, and the presence of associated coronary artery disease or concomitant disease in another valve. Similarly, the major factors influencing long-term survival after mitral valve replacement are age, NYHA functional status, urgency of operation, mitral insufficiency (versus stenosis), ischemic disease, the level of pulmonary hypertension (pulmonary vascular resistance), and the need for concomitant valvular or coronary bypass procedures. Five-year survival rates after mitral valve operation are 60 to 90 percent, and 10-year survival rates are 40 to 75 percent, with late survival varying widely, depending on the number and the severity of the risk factors present.

Improved engineering of mechanical prostheses has produced lower intrinsic thrombogenicity and better durability. These improvements have resulted in fewer late valve-related complications and a lower late incidence of valve-related death after mitral valve replacement in recent years. In 1994 Khan reported late results after 1,000 St. Jude valve implants, with 399 patients undergoing isolated mitral valve replacement. At 10 years 83 percent of the mitral group was free of thromboemboli, 87 percent free of valve-related hemorrhage, and 91 percent free of valve-related death. The study suggests that valve-related factors have significantly less impact on late survival than patient-related factors.

Valve Reconstruction Versus Valve Replacement

In an analysis of 685 patients undergoing Carpentier-type valve repair at NYU between 1979 and 1995, the hospital mortality rate was 2.5 percent for isolated valve reconstruction and 5.9 percent overall. The actuarial freedom from complications at 5 and 10 years, respectively, were as follows: thromboembolic, 92 and 88 percent; anticoagulant-related complications, 98 and 96 percent; endocarditis, 97 and 96 percent; and reoperation, 91 and 84 percent. Postoperative freedom from reoperation was significantly better in nonrheumatic patients (93 percent at 5 years, 88 percent at 10 years) than in rheumatic patients (86 percent at 5 years, 73 percent at 10 years; $p < .005$).

Similar long-term results after mitral reconstruction were reported by DeLoche and Carpentier in 1990. In 206 patients undergoing operative repair between 1972 and 1979 the 15-year actuarial survival was 72 percent, and the 15-year survival from valve-related death was 83 percent. At 15 years, 94 percent of patients were free from thromboembolism, and 97 percent were free from endocarditis. Freedom from reoperation was better in patients with degenerative disease than in those with rheumatic disease (93 percent versus 76 percent).

In 1991 Yun and Miller extensively reviewed published data comparing mitral valve repair with replacement, analyzing reports from several large series. They found that long-term freedom from late valve-related morbidity generally was better after valve repair than after valve replacement.

Theoretically, the long-term survival after valve repair also could be better than after valve replacement because of the lower risk of valve-related complications and because of better preservation of left ventricular function as a result of chordal preservation. A review of all mitral valve patients operated on between 1980 and 1995 at NYU demonstrated better late survival in nonrheumatic patients undergoing isolated mitral valve repair than in patients undergoing valve replacement. In contrast, in rheumatic patients and in patients requiring double- or triple-valve procedures, late results in terms of freedom from late cardiac death, reoperation, and all valve-related complications were better after valve replacement using the St. Jude mechanical prosthesis. These findings suggest that while isolated mitral valve repair may offer improved late results in patients with degenerative, single-valve involvement, patients with rheumatic pathology and those with multivalvular involvement have better long-term results if valve replacement is performed.

The data suggest that mitral valve reconstruction is a durable and reproducible procedure in patients with degenerative disease, producing excellent long-term results with a low risk of valve-related complications. Patients with degenerative disease undergoing valve repair may have a better survival rate and a lower risk of late complications than those undergoing valve replacement. Valve reconstruction may be the procedure of choice for many patients with degenerative disease. Valve replacement is preferable if a durable repair cannot be achieved because of advanced rheumatic disease, extensive valvular deformity, or surgical inexperience with valvular reconstruction. Mechanical valve replacement gives improved durability and improved freedom from late valve-related events in patients with rheumatic or multivalve disease.

Minimally Invasive Mitral Valve Surgery

Because of advances in technology and instrumentation, such as the development of an endovascular perfusion and cardioplegic arrest balloon catheter system by Stevens and coworkers, minimally invasive surgery can be applied in an expanding number of complex heart operations, including mitral valve surgery. Extensive experimental studies on the feasibility, safety, and reproducibility of minimally invasive mitral valve surgery formed the basis for subsequent clinical trials, which established the feasibility and reproducibility of minimally invasive mitral surgery, with experimental results equivalent to those obtained with standard open-chest surgery. The port-access method of minimally invasive mitral valve surgery was subsequently applied clinically with excellent initial results.

The operative approach is through a right anterior minithoracotomy with a 5- to 8-cm skin incision made in the inframammary skin fold. The technique uses femoral cannulation and a balloon endoaortic occlusion system for cardioplegia (Fig. [18-17](#)). This approach provides excellent exposure of the mitral valve, and valve repair or replacement are readily achievable.

The initial experience with minimally invasive mitral surgery has been promising. Over 100 minimally invasive mitral procedures were performed at NYU within 6 months of the technique's introduction with no operative deaths and with excellent results. The advantages of the minimally invasive approach are less pain, smaller scar, improved cosmetic result, and shorter recovery time.

Aortic Valve Disease

Effective surgical treatment of aortic valve disease became possible in 1960 with the development of satisfactory prosthetic valves by Starr and Edwards and by Harken and associates. Earlier attempts to correct aortic valvular disease by cusp replacement with prosthetic cusps of Teflon cloth or by extensive debridement of calcific material from calcified valve cusps initially gave satisfactory results in some patients, but a high failure rate within 1 to 2 years led to abandonment of these techniques as soon as satisfactory prosthetic valves became available.

Several modifications of valvular prostheses have been proposed over the years, and numerous effective mechanical and tissue valves have been developed. Thromboembolic events occur with a frequency of 1 to 2 percent per year after mechanical aortic valve replacement. Bioprostheses (stented glutaraldehyde-preserved xenografts), which were developed to minimize the risk of thromboembolism, do not require permanent anticoagulation therapy when used in the aortic position, but they undergo progressive deterioration, with an increasing incidence of valve failure between 5 and 15 years. The failure rate for bioprostheses is approximately 5 percent at 5 years, 20 percent at 10 years, and 50 percent at 15 years.

The Ross procedure (pulmonary autograft) has a low risk of thromboembolism and does not require anticoagulation therapy. The risk of reoperation after the Ross procedure lies between those achieved with mechanical and with tissue prostheses, approximately 20 percent at 15 years and 30 percent at 20 years.

Aortic Stenosis Etiology

The three main causes of aortic stenosis in the adult population are congenital malformation, rheumatic disease, and acquired calcific disease. Congenital aortic stenosis is discussed in detail in Chap [20](#) but, in general, about 50 percent of adults undergoing operation have a congenitally malformed valve, usually a bicuspid valve. These patients frequently have minimal disability for decades until the valve calcifies, usually in the fourth or fifth decade of life. Rheumatic fever is the primary cause in 30 to 40 percent of patients. With rheumatic disease the degree of stenosis progresses with time, and concomitant mitral valve disease is almost always present, although not always clinically significant. The third major cause of aortic stenosis is acquired calcific stenosis, which is the most frequent cause in older patients, occurring in the seventh or eighth decade of life. Calcific stenosis appears to be a part of the aging process, with valve damage and calcification developing from years of flow and turbulence.

Pathophysiology

A normal aortic valve has a cross-sectional area of 2.5 to 3.5 cm², depending on body size. Moderate stenosis is present when the valve orifice has narrowed to less than 1 to 1.2 cm², and the patient often becomes symptomatic once the valve area is less than 0.8 cm². Cross-sectional areas of less than 0.5 cm² may be found in advanced disease, often with a systolic gradient of 100 mmHg or greater across the valve. In most patients with significant aortic stenosis the gradient is at least 50 mmHg, although the gradient may be misleading when the cardiac output is low. The valve area should always be calculated using the Gorlin formula. Nevertheless, gradients greater than 60 to 70 mmHg are almost always significant.

The increased workload on the myocardium imposed by aortic stenosis results in progressive concentric ventricular hypertrophy, but little ventricular dilatation. Left ventricular hypertrophy results in a thick, noncompliant ventricle that develops early diastolic dysfunction. The systolic function of the ventricle remains well-preserved early, decreasing later from “afterload mismatch” once the thickened ventricle cannot produce the tension required to effectively eject blood through the stenotic valve. Once systolic dysfunction occurs, the patient usually develops symptoms within 12 to 24 months, with congestive heart failure progressing thereafter.

Myocardial ischemia develops in some patients with severe aortic stenosis, usually in response to exercise. The left ventricular mass and left ventricular systolic wall tension are increased, resulting in increased oxygen demand. Simultaneously, the cardiac output often is low and does not increase in response to the demands of physical activity, while the end-diastolic pressure of the ventricle is high, resulting in poor perfusion of the subendocardium. This results in an imbalance between oxygen supply and demand. Symptoms include angina and arrhythmias, and sudden death can occur.

Clinical Manifestations

Characteristically, patients with aortic stenosis have a long, asymptomatic, latent period, sometimes for 10 to 20 years. A patient with moderate aortic stenosis with classic physical findings may exhibit only slight dyspnea or no symptoms at all for many years. Once the ventricle develops systolic dysfunction and begins to deteriorate, three classic symptoms may occur: exertional dyspnea (or heart failure), angina, and syncope. Once these symptoms develop, the risk of death exceeds 30 to 50 percent over the next 5 years, and operation is urgently indicated. Sudden death, which accounts for 15 to 20 percent of fatalities from aortic stenosis, becomes much more of a threat once these symptoms are present.

The most common symptom is exertional dyspnea with decreased exercise capacity and easy fatigability. True left ventricular failure, manifested as severe congestive heart failure with pulmonary edema, is a more ominous finding. The risk of death is high once heart failure is present, approximately 40 percent over the next 2 to 3 years. Atrial fibrillation, a consequence of prolonged elevation of left atrial pressure, is also a significant finding, because it can indicate an advanced left ventricular failure unless mitral valve disease is present.

Angina pectoris develops in 30 to 40 percent of the patients, a manifestation of myocardial ischemia. Many ischemic episodes are associated with “silent” muscle necrosis, because some patients with surprisingly few symptoms are found to have large amounts of myocardium replaced by scar tissue. Associated coronary artery disease should always be excluded when angina is present. The average life expectancy once angina or syncope has appeared is about 3 years.

Syncope develops in about 10 percent of the patients, apparently from decreased cerebral blood flow. In some patients it may occur after minimal effort and with little warning. More often syncope develops in response to exercise or increased physical activity because the cardiac output cannot respond appropriately. In a small proportion of patients it results from a conduction abnormality, apparently an intermittent heart block from involvement of the atrioventricular node by calcium arising from the stenotic valve.

The principal physical finding is a harsh, systolic murmur at the base of the heart (right second interspace) with radiation to the carotid arteries. The pulse pressure is narrow and sustained (pulsus parvus et tardus). The apical impulse has been described as a “prolonged heave,” not a “forceful thrust” that is found with ventricular dilatation from aortic or mitral insufficiency.

Diagnostic Studies

The heart size usually is normal or only slightly enlarged on chest x-ray, and calcification of the valve often is visible in older patients. The ECG is not reliable, because of the wide variation of findings. In some patients left ventricular hypertrophy is evident, but in some seriously ill patients with severe aortic stenosis the ECG is virtually normal. Conduction abnormalities are common, apparently from spicules of calcium projecting into the conduction bundle located just beneath the base of the noncoronary sinus. Some patients develop complete heart block. Atrial fibrillation generally indicates the presence of mitral stenosis or advanced disease with a prolonged elevation of intracardiac pressures.

The diagnosis of aortic stenosis can be made by echocardiography, which: (1) demonstrates the presence of calcium in the valve and demonstrates leaflet mobility; (2) provides an estimate the peak and mean transvalvular systolic gradients; (3) documents the ventricular wall thickness and the degree of left ventricular hypertrophy; and (4) measures the end-systolic and end-diastolic dimensions of the left ventricular cavity. The Doppler echocardiogram measures flow velocity to determine the peak instantaneous pressure gradient, but it may overestimate the peak transvalvular gradient. By echocardiography the mean gradient usually is a more accurate measure of the true transvalvular gradient and a better predictor of the degree of stenosis.

Cardiac catheterization readily confirms the diagnosis by measuring the transvalvular gradient and permitting calculation of the cross-sectional area of the valve. Operation usually is indicated when the cross-sectional area is less than 0.8 cm² and the gradient exceeds 50 mmHg. At catheterization coronary arteriography should be done in patients over 55 to 60 years of age and in patients with angina or a strong family history of coronary disease. Concomitant coronary artery disease is found in 30 to 50 percent of adult patients undergoing aortic valve surgery, with the frequency increasing with age. The mitral and tricuspid valves should be assessed for stenosis or insufficiency, particularly when rheumatic disease is present or when the patient has significant heart failure and pulmonary hypertension. The left ventricular function, left ventricular end-diastolic pressure, and the pulmonary artery pressure should be measured in patients with heart failure. Catheterization is not always necessary in younger patients.

Treatment

Operation is recommended for all symptomatic patients with aortic stenosis. For asymptomatic patients, periodic echocardiographic studies are done to assess the transvalvular gradient, the cardiac size, and the ventricular function. If a patient with a significant aortic gradient develops left ventricular hypertrophy and a drop in the ejection fraction (or a rise in the end-systolic volume by echocardiography), operation usually is indicated. Similarly, operation is recommended once the cross-sectional area is less than 0.8 cm², especially if significant left ventricular hypertrophy is present. Sudden death remains a small but definite hazard in such patients, and progressive clinical deterioration is likely to occur soon once this degree of stenosis is reached.

Aortic Insufficiency

Etiology and Pathology A variety of diseases can produce aortic insufficiency, including endocarditis, rheumatic fever, degenerative valvular disease, congenital disease, aortoannular ectasia, aortic aneurysm, and aortic dissection. Mixed disease, with stenosis and insufficiency, can develop in any patient with aortic stenosis.

Inflammatory diseases are the most common causes of aortic insufficiency. Perhaps the most frequent cause is bacterial endocarditis, occurring from infections with streptococci, staphylococci, or enterococci, in decreasing order of frequency. Rheumatic fever is another common cause of aortic insufficiency, while other inflammatory diseases such as syphilis are increasingly rare causes.

One variant of degenerative valvular disease is the so-called floppy valve, a type of myxomatous degeneration of the valve that produces thin and elongated tissue. The aortic leaflets sag into the ventricular lumen, often with no other histologic abnormality. The gross and histologic appearances suggest that this is a variant of the more common mitral valve prolapse.

Congenital aortic insufficiency rarely is present at birth, but it may develop in older patients if stiffening and calcification of the malformed bicuspid valve produces an insufficient rather than a stenotic valve. This accounts for 10 to 25 percent of the patients operated on for aortic insufficiency. Aortic insufficiency also occurs in association with subaortic ventricular septal defects from a venturi effect that results in prolapse of the aortic leaflet into the septal defect.

Aortoannular ectasia is an unusual type of connective tissue disease seen with increasing frequency as the average age of the population increases. It is often of unknown cause. Aortoannular ectasia occurs in its most extreme form with connective tissue disorders, such as Ehlers-Danlos syndrome and Marfan's syndrome. These diseases involve defective collagen synthesis or cross-linking that results in extensive cystic medial necrosis throughout the aorta, with particular involvement of the aortic root. These patients have a greatly increased risk of aortic dissection. The aortic root gradually enlarges, starting in the sinuses of Valsalva and progressing to a discrete aneurysm in the ascending aorta. The pathologic process is unusual because dilatation decreases and almost stops at the level of the innominate artery. The size and shape of the aneurysm is quite characteristic, resembling a truncated cone with the narrow apex near the level of the innominate artery. Aortic insufficiency results from dilatation of the aortic annulus.

In less severe forms of aortic degenerative disease there may be a localized aneurysm in the ascending aorta, with or without aortic insufficiency. Often no other signs of connective tissue disease are present, although histologic examination of the excised aneurysm usually demonstrates characteristic cystic medial necrosis. Atherosclerotic aneurysms also may produce aortic insufficiency by dilatation of the annulus, although aortic insufficiency is less common in patients with pure atherosclerotic disease. Aortic dissection produces insufficiency by dissection of the aortic wall with detachment and prolapse of the valve cusps, usually the noncoronary cusp. Aortic dissections and aneurysms are discussed in more detail in Chap. [19](#).

Pathophysiology

Surprisingly large volumes of blood regurgitate into the ventricle with severe aortic insufficiency. This results in an increased ventricular end-diastolic volume and a compensatory increase in the left ventricular stroke volume that may be two or three times greater than the normal stroke volume of 60 to 75 mL. As the ventricular diastolic volume increases

(increased preload), dilatation and eccentric hypertrophy develop to maintain the ratio of wall thickness cavity radius at normal levels. The diastolic pressure may not increase until later in the clinical course, so symptoms of pulmonary congestion appear only with advanced disease. The process of volume overload and ventricular dilatation contrasts with aortic stenosis, in which systolic pressure overload and concentric ventricular hypertrophy develop early, without dilatation. With a continued volume overload the left ventricular end-diastolic pressure rises to 20 to 30 mmHg. Eventually the ratio of wall thickness to cavity radius decreases as cardiac dilatation continues, the increased systolic wall tension exceeds the ability of the ventricular muscle to eject, resulting in “afterload mismatch,” and the systolic function of the ventricle begins to deteriorate.

With marked dilatation of the left ventricle and increased intracardiac pressures mitral insufficiency may begin to develop. When a rheumatic history is present, it may be impossible to determine preoperatively whether the mitral insufficiency represents dilatation with secondary insufficiency or rheumatic disease. Secondary mitral insufficiency usually regresses satisfactorily after replacement of the aortic valve.

Clinical Manifestations

Symptoms develop at a variable rate in patients with aortic insufficiency, depending on the acuity and severity of the insufficiency and the characteristics of the heart muscle. Frequently the patient who gradually develops moderate to severe insufficiency remains asymptomatic for many years, often ten or more. Once symptoms appear, however, the ventricular function usually is significantly depressed and rapid clinical deterioration occurs over the next 4 to 5 years. In the presurgical era, about 40 percent of patients died within 10 years and 90 percent within 20 years after the onset of aortic insufficiency. The terminal illness usually is progressive cardiac failure; sudden death is much less common than with aortic stenosis.

The most common symptom is dyspnea on exertion and a decreased exercise capacity, gradually increasing in severity as the ventricle deteriorates. Palpitations also are common, apparently arising from forceful contraction of the dilated left ventricle. Biventricular heart failure and angina pectoris occur with advanced disease, usually with severe aortic incompetence in which the regurgitant flow exceeds 50 percent of forward flow.

Palpation readily discloses an enlarged heart and a prominent cardiac impulse, located inferiorly and to the left of the normal location. The hallmark of aortic insufficiency is a high-pitched decrescendo diastolic murmur along the left sternal border, starting immediately after the second sound. The length of the murmur may correspond with the severity of the insufficiency, but the intensity does not. If the murmur is loudest to the right of the sternum, dilatation of the aortic ring, as in Marfan's syndrome, is likely. An ejection systolic murmur of moderate intensity is frequent even in the absence of aortic stenosis because of increased flow. An S₃ gallop indicative of heart failure may be present. In some patients a middiastolic rumble is noted in the mitral valve area—the Austin Flint murmur that simulates mitral stenosis but is produced by the diastolic flow of blood from the aortic insufficiency and impedes opening of the mitral valve during diastole.

Examination of the peripheral arterial circulation usually reveals several abnormalities. The pulse pressure is widened, partly from an increase in systolic pressure, but principally from a decrease in diastolic pressure, which may be in the range of 30 to 40 mmHg. The true diastolic pressure, measured by direct arterial puncture, is never less than 30 to 35 mmHg, even though on auscultation a diastolic pressure of zero may be obtained in some patients. The exact level of diastolic pressure is not closely correlated with the severity of the aortic insufficiency, because of the influence of peripheral resistance. The peripheral pulses usually are visible, forceful, and bounding. The pulse is described as “water-hammer,” or quickly collapsing, referred to as a Corrigan's pulse. “Pistol shot” sounds are readily heard with the stethoscope over peripheral arteries. A wide variety of other auscultatory phenomena have been described, some over a century ago, all indicating vasodilatation and a hyperactive peripheral circulation.

Diagnostic Studies

The chest x-ray usually shows impressive cardiac enlargement, with the apex displaced downward and to the left. If the cardiothoracic ratio is 0.5 or less, asymptomatic patients may be monitored periodically with biannual x-rays as long as the heart size is normal. The ECG is normal early in the disease, but with cardiac enlargement signs of left ventricular hypertrophy become prominent. The cardiac rhythm remains sinus early in the disease, although atrial fibrillation is common after the onset of advanced disease and has an ominous prognosis, usually representing chronic severe volume overload with severely elevated intracardiac pressures.

The degree of the aortic insufficiency and the size and function of the left ventricle can be evaluated more precisely with echocardiography, which measures the degree of valvular insufficiency, the end-systolic and end- diastolic ventricular dimensions, the left atrial size, and the ejection fraction. The echocardiogram also can assess the degree of mitral or tricuspid insufficiency, rule out associated valvular stenosis, and estimate the pulmonary artery pressure.

The classic finding on cardiac catheterization is the visible reflux of dye from the aortic root into the ventricle with angiography, graded from 1+ to 4+. In patients with chronic disease or cardiac failure the left ventricular end- diastolic pressure usually is elevated to 15 to 20 mmHg and sometimes higher, often with an associated rise in the pulmonary artery pressure. The aortic root should be assessed for aneurysmal disease, and coronary angiography should be performed to rule out coronary artery disease.

Operative Indications

While surgery is indicated in all symptomatic patients with aortic insufficiency, it has long been recognized that postponing operation until symptoms are disabling is not satisfactory. Many patients already will have developed substantial ventricular enlargement and cardiac dysfunction by that time. Clinical investigation has sought a noninvasive measurement that would identify the proper time for operative intervention. This is best done by periodic echocardiography.

Operation is recommended for asymptomatic patients with aortic insufficiency at the first sign of deteriorating systolic cardiac function, manifested as a rise in the end-systolic dimension of the ventricle echocardiographically or by a drop in the ejection fraction measured by radionuclide studies. All indications suggest that cardiac function will return to normal and long-term survival will be improved significantly if an operation is done at this stage. Intervention should be performed before the ventricular function severely deteriorates, usually when the end-systolic dimension of the left ventricle exceeds 45 to 50 mmHg or when the resting ejection fraction drops below 50 percent. Similarly, a rapid increase in cardiac size or a progressive increase in the diastolic volume of the heart over a 6- to 12-month interval is an indication for operative intervention before systolic dysfunction develops.

The development of dyspnea or other symptoms of congestive heart failure are clear indications for operation. In some NYHA functional class IV patients with advanced left ventricular dysfunction, how much improvement can be expected from valve replacement is uncertain; the principal symptoms may be from progressive cardiomyopathy. Available studies do not permit a precise scientific decision in this regard. In the authors' experience, valve replacement can be performed even in the most advanced patients with an operative mortality rate of less than 10 percent. Many of these patients will improve significantly after surgery, although the degree of improvement may be uncertain for 6 to 12 months. Postoperative medical therapy with afterload reduction, digoxin, and diuretics reduction is beneficial in this group of patients after valve replacement to control heart failure and to help remodel the ventricle.

Operative Techniques

Aortic Valve Replacement At NYU The St. Jude Medical bileaflet mechanical valve is the most widely used prosthesis in younger patients, although the Medtronic-Hall, the CarboMedics, and the Omniscience valves are equally efficacious. While the flow characteristics are excellent with all of the mechanical valves, new designs that allow supraannular rather than intraannular placement (St. Jude HP valve and CarboMedics “Top Hat”) have allowed better flow when the aortic annulus is small. Bioprostheses (the Carpentier-Edwards porcine valve, the Carpentier-Edwards pericardial valve, or the Hancock porcine valve) are used primarily in older patients with acquired calcific stenosis.

Aortic valve replacement is performed through a median sternotomy, using cardiopulmonary bypass for perfusion and cardioplegia for myocardial protection. This technique has been firmly established for over 20 years with a high degree of safety and reproducibility. After cardiopulmonary bypass and moderate systemic hypothermia have been initiated, the aorta is cross-clamped and cardioplegic solution is delivered directly into the coronary ostia or retrogradely through the coronary sinus venous system. Topical hypothermia is used routinely to prevent cardiac rewarming, wrapping the heart with a cold gauze pad or cooling device. This technique results in total recovery of cardiac function postoperatively in most patients. The heart usually is vented with a catheter placed through the right superior pulmonary vein or through the apex of the left ventricle.

After the heart has been arrested, an oblique aortotomy incision is made, beginning approximately 1 cm above the right coronary artery and extending medially toward the pulmonary artery and inferiorly into the noncoronary sinus of Valsalva. The aortic valve is excised totally (Fig. 18-18), with care being taken to avoid losing any calcific fragments detached during removal of the valve. After the valve is excised with a scissors or a knife, calcium in the annulus is debrided as necessary to achieve a smooth annular surface for suture placement. A gauze pack is placed routinely in the ventricle before removal of the valve is begun to minimize the risk of embolism.

A pledgeted horizontal mattress suture technique is used almost exclusively at NYU (see Fig. 18-18); other techniques include figure-of-eight sutures, simple interrupted sutures, and continuous sutures. The pledgeted mattress suture technique probably is unnecessary in many patients, but it virtually eliminates the hazard of periprosthetic leaks. Care is taken to avoid damage to the coronary ostia, to the conduction bundle (which is adjacent to the membranous septum between the right and the noncoronary valve cusps), and to the mitral valve posteriorly.

Most mechanical valves are placed in the intraannular position, and the sutures are placed from above downward, everting the annulus. When the sutures are tied the pledgets remain visible in the aorta and the valve sits completely intraannularly. This technique avoids tissue overhang, which could interfere with leaflet movement, but it requires placing a slightly smaller valve size.

The supraannular technique is used for most bioprostheses and for newer supraannular mechanical valves, designed for the small annulus. The sutures are placed from below the annulus upward, passing the needles through the annulus and then through the valve sewing ring. The valve is seated on the top of the annulus, allowing placement of a slightly larger prosthesis, which is important if the annulus is small (Fig. 18-19).

Coronary bypass with the internal mammary artery or saphenous vein graft is performed in standard fashion whenever associated coronary disease is present.

Aortic Valve Repair

Though aortic valve repair was one of the first attempted cardiac operations, it had only limited success, and these procedures were infrequently used once prosthetic valves became available. Surgeons have occasionally proposed newer techniques of aortic valve repair in an effort to avoid the long-term complications inherent with valvular prostheses, but most of these techniques have been abandoned because of the high incidence of late failure. The various treatments of aortic stenosis involving debridement of the aortic valve resulted in a high incidence of progressive valvular restenosis or insufficiency, and these techniques are now seldom used. Two newer techniques of valve repair for pure aortic insufficiency have achieved some success and deserve mention.

Fraser and associates reported results with repair of insufficient bicuspid aortic valves in 72 patients. The operative technique involves a triangular resection of the redundant

segment of the involved valve cusp in an attempt to achieve cusp symmetry, followed by annular plication of one or both commissures in an attempt to achieve greater leaflet coaptation. Short-term results have been good, with approximately 90 percent of patients remaining free from reoperation at 2 years.

David and associates proposed a different but similarly innovative technique for repair of insufficient aortic valves in patients with aortic root aneurysms. This technique is based on the principle that aortic insufficiency in patients with aortoannular ectasia is from annular dilatation or distortion of the sinotubular ridge or both. Patients with annular dilatation and sinotubular distortion were treated with aortic annuloplasty and tubular graft placement, with reimplantation of the native aortic valve into the graft. Patients without annular dilatation were treated by sinotubular remodeling. Early results have been good in the initial 45 patients reported by David, with only two patients requiring reoperation.

Ross Procedure

The Ross procedure involves removal of the aortic valve and replacement of the valve (free-hand technique) or removal of the entire aortic root (cylinder root replacement technique) (see Fig. 18-10) and replacement with a pulmonary valve autograft transplanted from the native pulmonary position; the pulmonary valve and main pulmonary artery are replaced with a pulmonary homograft.

The cylinder root replacement technique, which is the most reproducible, will be described briefly. The native aorta is transected 5 mm above the sinotubular ridge. The aortic valve and sinuses of Valsalva are removed totally, preserving the left main and right coronary arteries on buttons of aortic tissue. The main pulmonary artery is transected at the bifurcation, and a separate incision is made below the pulmonary valve in the right ventricular outflow tract. The pulmonary valve and artery are enucleated en bloc from the outflow tract bed, with care being taken to avoid injury to the first septal perforator as the valve is removed from the septum medially. The pulmonary autograft annulus is sutured to the aortic annulus with continuous or interrupted sutures, and the coronary arteries are reimplanted into the autograft. The pulmonary valve and right ventricular outflow are reconstructed in standard fashion with a homograft.

The operative risk and perioperative complications with the Ross procedure have been similar to those with standard valve replacement. These patients do not require long-term anticoagulation therapy, and the risk of thromboembolism is negligible. The late durability is better than that achieved with bioprostheses. The Ross procedure has become an attractive option for many young patients requiring aortic valve replacement.

Minimally Invasive Aortic Valve Surgery

Recent attempts have been successful at using a “minimal incision” for aortic valve replacement. While these methods are still under development, most have involved femoral cannulation for perfusion and the use of a small transverse or vertical incision in the right third costal interspace. The small incision limits pain and potentially shortens the recovery time.

Postoperative Care

Postoperative care usually is uneventful after aortic valve replacement. Arrhythmias are relatively common, so ECG monitoring is routine for 24 to 48 h. Anticoagulation therapy is started 2 to 3 days after mechanical valve replacement, targeting an INR (international normalized ratio) of approximately 3 to 3.5 times normal. Antiplatelet therapy with aspirin is used with bioprostheses and for 3 to 6 months after homografts or the Ross procedure. The hospital stay usually is 5 to 7 days, depending on the patient's age and overall physical condition.

Except for patients with severe ventricular dysfunction, patients usually become asymptomatic and regain a normal range of physical activity within 2 to 3 months after operation. Periodic medical supervision should be instituted for all patients because of the problems inherent with any prosthetic valve. The patient should have long-term monitoring for proper anticoagulation therapy (with the INR followed in patients on warfarin), and the valve function should be periodically assessed by echocardiography. In patients with homografts or the Ross procedure, yearly echocardiographic evaluation is recommended to assure continued proper valve function. Thromboembolism, anticoagulant-related hemorrhage, endocarditis, and prosthetic valve failure are the principal late complications that require periodic monitoring. With good anticoagulation therapy, thromboembolism occurs with an incidence of 1 to 2 percent per year after mechanical valve replacement and 0.5 to 1 percent per year after bioprosthetic valve replacement. The risk of thromboembolism approaches zero after the Ross procedure. Endocarditis remains an infrequent but serious late hazard after valve replacement, and routine antibiotic prophylaxis is recommended lifelong for any invasive procedure that might produce a transient bacteremia.

Results

The operative mortality rate for aortic valve replacement is 1 to 2 percent in uncomplicated patients and seldom exceeds 10 percent even with advanced disease and pulmonary hypertension. In patients over 70 years of age the operative risk is approximately 5 percent for isolated aortic valve replacement and 10 to 15 percent when associated coronary artery disease is present. Christakis and associates, Kirklin and Barrett-Boyes, and the Society of Thoracic Surgeons National Database have each reported the clinical variables affecting the operative risk for aortic valve replacement. The major risk factors are age, NYHA functional status, congestive heart failure, ventricular function (ventricular ejection fraction), cardiomegaly, pulmonary artery pressure, unstable hemodynamics, angina or associated coronary disease, concomitant mitral or tricuspid valve disease, aortic insufficiency (as opposed to stenosis), preoperative renal insufficiency, and reoperation. The mode of perioperative death usually is stroke, operative hemorrhage, or arrhythmia. Heart block has become an uncommon complication.

The 10-year survival rate after aortic valve replacement exceeds 80 percent for most patient groups, but it is significantly worse in patients with severely impaired ventricular function, NYHA class IV symptoms, and pulmonary hypertension, emphasizing the need for early operation when signs of deteriorating ventricular function are found in diagnostic studies.

Tricuspid Stenosis and Insufficiency

Etiology

Organic disease of the tricuspid valve is almost always a result of rheumatic fever. With the exception of septic endocarditis, usually in intravenous drug abusers, it virtually never occurs as an isolated lesion, but only in association with extensive disease of the mitral valve. With mitral disease the frequency of associated tricuspid disease is 10 to 15 percent, although an incidence as high as 30 percent has been reported. Rarely, blunt trauma produces rupture of a papillary muscle or chordae tendineae with resulting tricuspid insufficiency.

Tricuspid insufficiency is the more common lesion encountered; pure stenosis is infrequent, because stenotic lesions usually have concomitant insufficiency. Functional tricuspid insufficiency is much more common than insufficiency from organic disease. It develops from dilatation of the tricuspid annulus and right ventricle as a result of pulmonary hypertension and right ventricular failure. These abnormalities result from left ventricular failure and chronic elevation of left atrial pressure.

Pathology

With tricuspid stenosis, the pathologic changes are similar to those found with the more familiar mitral stenosis. There is fusion of the commissures to form a small central opening 1 to 1.5 cm in diameter. As right atrial pressure is normally only 4 to 5 mmHg, significant tricuspid stenosis may be present with a valve orifice considerably larger than that seen with mitral stenosis. With rheumatic disease, combined stenosis and insufficiency or pure insufficiency results from fibrosis and contraction of the valve leaflets, often in association with shortening and fusion of chordae tendineae. Calcification is rare. More commonly functional dilatation of the tricuspid annulus results in tricuspid insufficiency. The valve leaflets appear stretched but otherwise are pliable and seemingly normal even though serious regurgitation is present. The dilatation and deformity of the annulus are irreversible. Valves with severe functional insufficiency usually do not regain competency, even though the mitral valve disease is corrected and pulmonary artery systolic pressure returns to normal.

Pathophysiology

With tricuspid stenosis or severe insufficiency the mean right atrial pressure becomes elevated to 10 to 20 mmHg and sometimes higher. The higher pressures are found with a tricuspid valve orifice smaller than 1.5 cm² and a mean diastolic gradient between the atrium and ventricle of 5 to 15 mmHg or in patients with pulmonary hypertension and severe insufficiency. When the mean right atrial pressure remains above 15 mmHg, hepatomegaly, ascites, and leg edema usually appear.

A moderate degree of tricuspid insufficiency may be tolerated with little adverse influence on the circulation except for a decrease in cardiac output. This is in striking contrast to mitral insufficiency, in which the regurgitating blood and elevation of left atrial pressure produce pulmonary congestion. The unusual patient with isolated tricuspid insufficiency produced by a traumatic injury may do well for years, as the only physiologic disturbance is elevation of venous pressure and a decrease in cardiac output. The purest example of the surprising tolerance for tricuspid insufficiency is seen in the intravenous drug abuser with septic endocarditis who has been treated by total excision of the tricuspid valve. Some but not all patients tolerate absence of the tricuspid valve with total tricuspid insufficiency for months or years. In most patients chronic, severe tricuspid insufficiency eventually produces signs of right heart congestion.

Clinical Manifestations

The symptoms and signs of tricuspid valve disease are similar to those of right heart failure resulting from mitral valve disease. These result from chronic elevation of right atrial pressure above the range of 15 to 20 mmHg. The most familiar ones are edema, ascites, jugulovenous distention, and hepatomegaly. Characteristic murmurs are present and may be associated with hepatic pulsations. With long-standing severe tricuspid insufficiency hepatic dysfunction and clotting abnormalities may develop. As similar findings result from right heart failure without tricuspid disease, the concomitant presence of tricuspid disease in the patient in heart failure with mitral valve disease may be easily overlooked.

The characteristic murmur of tricuspid stenosis is best heard as a diastolic murmur at the lower end of the sternum. It is a low-pitched murmur of medium intensity and can easily be overlooked, because it is well localized at the lower end of the sternum. During inspiration the intensity of the murmur increases as the volume of blood returning to the heart is temporarily raised by an increase in intrathoracic negative pressure. Tricuspid insufficiency produces a prominent systolic murmur at the lower end of the sternum and also at the cardiac apex, where it may be confused with the systolic murmur of mitral insufficiency. The murmur often is found in association with an enlarged, pulsating liver and prominent, engorged peripheral veins. A prominent jugular pulse, especially when the cardiac rhythm is sinus, may be the best clue to unsuspected tricuspid disease. The liver often is enlarged and pulsatile, and a hepatojugular reflex may be noted.

Diagnostic Studies

The x-ray shows enlargement of the right atrium and right ventricle. Prominent P waves may be visible on the ECG if a sinus rhythm is present. Echocardiography confirms enlargement of the right atrium and ventricle and readily detects tricuspid stenosis or insufficiency, although it may overestimate the degree of insufficiency. Cardiac catheterization frequently is required to confirm the diagnosis.

If the blood volume and cardiac output are adequate, intraoperative palpation has been useful in helping to determine the significance of tricuspid insufficiency, correlating this

information with clinical, physical, and echocardiographic findings.

Treatment

Usually the surgical decision in tricuspid insufficiency is a tentative one until the valve is examined at operation. Mild degrees of tricuspid insufficiency usually are left alone, especially in the absence of pulmonary hypertension. The degree of hypertrophy of the right atrial wall is a helpful guide, because the absence of significant right atrial hypertrophy indicates that chronic severe elevation of right atrial pressure has not been present.

With significant tricuspid insufficiency, annuloplasty or tricuspid replacement usually should be done. In some cases this must be performed as an isolated procedure, often as a reoperation for persistent right heart failure after previous surgery on the other valves. Accordingly, the authors prefer to perform concomitant tricuspid valve repair when severe tricuspid insufficiency accompanies mitral disease or multiple valve disease. Effective tricuspid valve repair in these circumstances minimizes the risk of late right-sided heart failure and reoperation.

In the majority of patients tricuspid disease is from dilatation of the annulus, which is evidenced not only by the large annulus, but also by the absence of fibrotic changes in the leaflets. Typically the leaflets appear entirely normal. Virtually all such patients can be treated by annuloplasty. Data on more than 300 patients from our institution show that the posterior leaflet annuloplasty is simple, safe, and reproducible in the absence of significant intrinsic leaflet disease. In our experience, tricuspid valve repair was 98 percent durable at 7-year follow-up using this technique. The Carpentier ring annuloplasty may be used if the annulus is extremely distorted and the right heart pressures are expected to remain chronically elevated. Excellent results with tricuspid repair using the Carpentier technique have been reported.

In the minority of patients whose tricuspid stenosis is from commissural fusion, a commissurotomy may be performed. This often is combined with the Carpentier annuloplasty. More commonly valve replacement is performed when stenosis is present.

Valve replacement is seldom necessary for pure tricuspid insufficiency, except in patients with significant pulmonary hypertension and leaflet disease precluding annuloplasty. In a 1986 report of experiences with 151 valve replacements and 63 valve repairs, the prosthetic valve subsequently had to be replaced in 20 patients, principally because of progressive thrombosis. The 10-year durability of tricuspid bioprostheses is higher than the 80 percent 10-year durability with mitral or aortic bioprostheses, in which higher pressures are present. The choice of optimal prosthesis in the tricuspid position is uncertain.

When the prosthetic valve is inserted, care is required in suture placement along the septal leaflet, where the conduction bundle is located. In this area sutures should be placed more superficially, through the base of the septal leaflet, to avoid injury to the conduction bundle. Because of the proximity of the conduction tissue to the tricuspid annulus in this area, heart block is more frequent than after replacement of other valves.

In the patient with tricuspid endocarditis, Arbulu demonstrated that total excision of the tricuspid valve without replacement could be tolerated. This approach permitted removal of all infected tissue without insertion of a foreign body, increasing the likelihood of cure of the endocarditis with antibiotics. Of the 50 long-term survivors, 11 subsequently required prosthetic replacement.

Some have questioned this approach, because there are few data to indicate that insertion of a prosthetic valve is associated with higher frequency of recurrent endocarditis if the proper antibiotics are given, yet the overall hemodynamic response is better when valve replacement is performed. Our experience with tricuspid endocarditis supports the use of valve replacement at the initial operation.

The operative mortality rate for isolated tricuspid valve replacement is 1 to 2 percent. In earlier years the reported mortality rate for patients undergoing tricuspid surgery in conjunction with aortic or mitral surgery was high, running from 25 to 40 percent, primarily because the presence of tricuspid disease represented far advanced cardiac failure. An additional cause of high mortality was probably inadequate myocardial preservation of the hypertrophied right ventricle. With present techniques, however, tricuspid surgery seems to add only a small additional risk to aortic or mitral surgery. A study from our institution with data from 1976 to 1985 noted an operative risk of 6.3 percent for combined mitral and tricuspid surgery.

Multivalvular Disease

Disease involving multiple valves is relatively common, particularly in patients with rheumatic disease. Prominent signs in one valve can readily mask disease in others. With aortic valve disease, functional mitral insufficiency can result from a progressive rise in the left ventricular end-diastolic pressure and volume. Similarly, mitral valve disease may result in pulmonary hypertension, right heart failure, and functional tricuspid insufficiency. Often these secondary functional changes resolve without treatment if the primary pathology is corrected. Multiple-valve surgery has a higher operative risk than single-valve procedures, because the condition often represents more advanced disease or is associated with significant cardiac dysfunction.

In a 1992 report by Galloway and colleagues, 513 patients with multiple-valve disease treated surgically between 1976 and 1985 were followed to assess factors influencing operative risk and long-term survival. Three groups accounted for the majority of the cases: 58 percent had aortic and mitral valve disease (AV + MV), 29 percent had mitral and tricuspid valve disease (MV + TV), and 12 percent had triple-valve disease (AV + MV + TV). Preoperative congestive heart failure was present in 91 percent, 41 percent were NYHA class III, and 54 percent were NYHA class IV. The average pulmonary artery systolic pressure was 60 mmHg. Despite chronic symptoms and severe disease the overall operative mortality rate was 12.5 percent and the 5-year survival rate was 67 percent. The variables predicting decreased survival time were systolic pulmonary artery pressure, age, triple-valve procedure, concomitant coronary disease requiring bypass operation, previous heart surgery, and diabetes. After operation 80 percent of the patients improved to NYHA class I or class II, demonstrating that most patients had significant clinical improvement despite advanced disease. The 5-year freedom from late cardiac-related complications or death was 82 percent.

AV + MV

Nine combinations of valvular pathology can produce AV + MV, because each valve can be stenotic, insufficient, or both. Stenosis in both valves may lead to underestimation of the degree of aortic stenosis, because return of blood to the left ventricle is limited as a result of mitral stenosis. Aortic insufficiency, which produces the Austin Flint murmur, might overshadow and mask true mitral stenosis. With functional mitral insufficiency resulting from severe aortic disease, aortic valve replacement can lead to resolution of insufficiency in some patients, but patients with more severe mitral insufficiency may require mitral annuloplasty or valve replacement. Each patient should be examined closely for these and other considerations, and cardiac catheterization usually should be performed before operation. The operative mortality rate for isolated AV + MV replacement is 4 to 5 percent.

MV + TV

Nine combinations of valvular pathology are possible with mitral and tricuspid disease, but mitral disease with functional tricuspid insufficiency is the common scenario, resulting from chronic pulmonary hypertension and right heart failure. The operative mortality rate for isolated MV + TV replacement is approximately 6 percent.

Triple-Valve Disease

Triple-valve surgery can be challenging, because the clinical condition usually is a result of chronic aortic and mitral disease with severe pulmonary hypertension, biventricular failure, and functional tricuspid insufficiency. Occasionally rheumatic disease affects all three valves. The degree of pulmonary hypertension is the most significant predictor of survival with triple-valve disease. The overall operative mortality for 61 triple-valve procedures in the above-cited NYU report (Galloway et al.) was 23 percent, but only 5.6 percent when the pulmonary artery systolic pressure was less than 60 mmHg. This emphasizes the value of early operation, before the development of irreversible ventricular dysfunction and chronic pulmonary hypertension.

CARDIAC TUMORS

General Considerations

Primary cardiac neoplasms are rare, reported to occur with incidences ranging from 0.001 to 0.3 percent in autopsy series. Benign tumors account for 75 percent of primary neoplasms, and malignant tumors account for 25 percent. The most frequent primary cardiac neoplasm is myxoma, comprising 30 to 50 percent. Other benign neoplasms, in decreasing order of occurrence, include lipoma, papillary fibroelastoma, rhabdomyoma, fibroma, hemangioma, teratoma, lymphangioma, and others. Most primary malignant neoplasms are sarcomas (angiosarcoma, rhabdomyosarcoma, fibrosarcoma, leiomyosarcoma, liposarcoma), with malignant lymphomas accounting for 1 to 2 percent. Metastatic cardiac neoplasms are more common than primary neoplasms, occurring in 4 to 12 percent of patients dying of cancer.

Symptoms include dyspnea, fever, malaise, weight loss, arthralgias, and dizziness. Clinical findings may include murmurs of mitral stenosis or insufficiency, heart failure, pulmonary hypertension, and systemic embolization.

The diagnosis usually is readily established by 2-D echocardiography. Transesophageal echocardiography may be useful when transthoracic findings are equivocal or confusing. MRI has been of value in diagnosis, providing excellent cardiac definition. Cardiac catheterization is not necessary in the majority of cases but may be necessary when other cardiac disease is suspected or if other diagnostic studies are equivocal.

Excision is the treatment of choice and is possible for most benign tumors. Care is taken to avoid deformity or destruction of adjacent cardiac structures, and reconstruction of the involved cardiac chamber occasionally is necessary. Total excision of metastatic or primary malignant neoplasms is less frequently possible but should be attempted. Otherwise incisional diagnostic biopsy is performed. Multimodality therapy with excision, chemotherapy, and radiotherapy is indicated for most malignant cardiac neoplasms.

Myxoma

Sixty to 75 percent of cardiac myxomas develop in the left atrium, almost always from the atrial septum near the fossa ovalis. Most other myxomas develop in the right atrium. Fewer than 20 have been reported in the right or left ventricle. The curious predilection for a myxoma to develop from the rim of the fossa ovalis in the left atrium has been studied, but no satisfactory explanation has been found.

Myxomas are true neoplasms, although their similarity to an organized atrial thrombus has led to considerable debate. The occurrence of myxomas in the absence of other organic heart disease, histochemical studies demonstrating mucopolysaccharide and glycoprotein, and a distinct histologic appearance indicate that myxomas are true neoplasms. The tumors recur locally, but they do not invade or metastasize and are considered benign.

Pathology

The tumors usually are polypoid, projecting into the atrial cavity from a 1- to 2-cm stalk attached to the atrial septum. The size ranges from 0.5 cm to larger than 10.0 cm. Only the superficial layer of the septum is involved; invasion of the septum does not occur. Some myxomas grow slowly; a few patients have symptoms for many years. There is no tendency to invade other areas of the heart; distant metastases are rarely reported. The friable consistency of a myxoma is of particular significance, because fatal emboli have occurred after digital manipulation of the tumor at operation.

Histologically, a myxoma is covered with endothelium and composed of a myxomatous stroma with large stellate cells mixed with fusiform or multinucleated cells. Mitoses are infrequent. Lymphocytes and plasmacytes are regularly found. Hemosiderin, a result of hemorrhage into the tumor, also is common.

Sporadic myxomas usually present in the fifth or sixth decade of life but have been described in younger and older patients. Autosomal dominant genetically transmitted familial myxomas can occur, usually presenting before 30 years of age. Familial “myxoma syndrome” includes myxomas, freckles, pigmented nevi, nodular adrenal cortical disease, and mammary myomatous fibroadenomas. Testicular tumors and pituitary adenomas with two or more components are required for diagnosis.

Pathophysiology

A myxoma might cause no difficulty until it grows large enough to obstruct the flow of blood through the mitral or tricuspid valve or fragments to produce peripheral emboli. The frequency of embolization, previously estimated to occur in 40 to 50 percent of patients, is not surprising, for an astonishing degree of to-and-fro motion of a myxoma, swinging on a small pedicle with each cardiac contraction, may be seen with echocardiography or angiography. Intermittent acute obstruction of the mitral orifice has been reported to produce syncope or even sudden death. Some myxomas produce generalized symptoms resembling an autoimmune disorder, including fever, weight loss, digital clubbing, myalgia, and arthralgia. These patients may have an immune reaction to the neoplasm, as elevated levels of interleukin-6 and elevated levels of antimyocardial antibodies have been described.

Clinical Manifestations

Symptoms may be those of mitral valve obstruction, resembling mitral stenosis, except for acute exacerbations, presumably because of transient lodging of the myxoma in the mitral orifice, peripheral embolization, or generalized autoimmune symptoms. The diagnosis often is made after an embolic episode, from histologic examination of the surgically removed embolus or as a result of subsequent diagnostic studies to determine the reason for embolism. The precision and reliability of 2-D echocardiography has greatly simplified diagnosis. Angiography is optional unless additional disease is suspected. CT has been reported to be helpful with small tumors, but MRI is more definitive. Abnormalities usually are found on examination of the heart and also on the electrocardiogram, but these are not diagnostic.

Treatment

Operation should be performed as soon as possible after the diagnosis has been established, because a disabling or fatal cerebral embolus is an ever-present hazard. A sternotomy incision is used. Once extracorporeal circulation has been established, the aorta is clamped to avoid embolism. Palpation is avoided. The right atrium is opened and the fossa ovalis incised to expose the stalk of the myxoma. The left atrium is then opened in the interatrial groove. With the tumor visualized, the segment of atrial septum from which the tumor arises is excised, after which the tumor is removed through the incision in the left atrium (Fig. 18-20). The defect in the atrial septum is closed primarily or with a small patch. The technique is simple and permits exploration of atria and ventricles.

A few cases of recurrent myxoma have been reported, some of which have been successfully operated on. These were thought to have resulted from inadequate excision of the site of origin, but some have recurred at more remote sites in the atrium, indicating the multipotential source of these unusual neoplasms. It seems prudent to perform periodic echocardiography routinely for several years after operation.

Larrieu and associates described experiences with 18 myxomas in a series of 25 cardiac tumors over a period of 24 years. Fyke and associates treated 21 patients with mitral myxoma in the first 7 years after the introduction of 2-D echocardiography. The operative mortality rate today is 1 to 2 percent.

Metastatic Neoplasms

Cardiac metastases have been found in 4 to 12 percent of autopsies performed for neoplastic disease. Although they have occurred from primary neoplasms developing in almost every known site of the body, the most frequent have been carcinoma of the lung or breast, melanoma, and lymphoma. Cardiac metastases involving only the heart are very unusual. Similarly, a solitary cardiac metastasis is infrequent; usually there are multiple areas of involvement. Cardiac involvement is common with leukemia or lymphoma, developing in 25 to 40 percent of patients. All areas of the heart are involved with equal frequency except the cardiac valves, perhaps because lymphatics are absent in valves.

The diagnosis of a primary cardiac malignant tumor may be suspected in a patient in whom an unexplained hemorrhagic pericardial effusion develops, especially in association with a bizarre cardiac shadow on the radiograph. Echocardiography should confirm the presence of an abnormal cardiac mass. Thoracotomy or sternotomy usually is required to establish the diagnosis. Combined chemotherapy and radiation is indicated, but only rarely is effective therapy possible.

Rhabdomyoma

A cardiac rhabdomyoma probably is not a true tumor but a hamartoma, representing a focal arrest and maturation of cardiac muscle. The nodules have also been termed *nodular glycogenic degeneration*, thought to be a manifestation of glycogen storage disease. About one-half of the patients have tuberous sclerosis of the brain. On histologic examination cells with large vacuoles are found in which the nuclei appear suspended by threads of cytoplasm, giving origin to the term “spider cell.” Associated adenoma sebaceum and benign kidney tumors occasionally are noted.

Although rhabdomyoma is said to be the most common cardiac tumor in children, it is a rare lesion. Reece and associates found that only about 110 cases were reported in the literature before 1984. The cardiac lesions may be solitary or multiple nodules or may present a diffuse infiltration of the cardiac muscle. The lesions do not grow.

Most rhabdomyomas on record were recognized in infancy, at an average age of 5 months. The disease is fatal, but whether the death is from the tumor or from associated disease is uncertain. Symptoms may result from obstruction of a ventricular chamber or from arrhythmias, such as recurrent ventricular tachycardia. Complete excision has been accomplished in a few patients. If tuberous sclerosis of the brain is not present, some infants may be operated on successfully and cured of potentially fatal arrhythmias.

Miscellaneous Tumors

Unusual benign lesions of the heart include fibromas, lipomas, angiomas, teratomas, and cysts. Fewer than 50 of each of these types of lesion have been reported. Fibromas have been found most frequently in the left ventricle, often as 2- to 5-cm nodules within the muscle. Sudden death, probably from a cardiac arrhythmia, has been reported with these tumors and may be the reason that only 18 percent of the reported tumors have been found in adults.

Lipomas are rare asymptomatic tumors found projecting from the epicardial or endocardial surface of the heart in older patients. Angiomas are small, focal, vascular malformations of no clinical significance, although in the literature four were reported to have been associated with a heart block. Pericardial teratomas and bronchogenic cysts are rare lesions that can cause symptoms from compression of the right atrium and obstruction of venous return. Most of these occur in children. Some of the larger cysts, up to 10 cm in diameter, may produce grotesque deformities from extensive invagination of the right atrial wall. Myxomas are by far the most common benign tumor in adults; they are seldom found in children except as part of the familial syndrome described in the previous section.

PERICARDITIS

Acute Pericarditis

Pericarditis results from acute inflammation of the pericardial space, resulting in substernal chest pain, ECG changes, and a pericardial friction rub. The pain often is inspiratory, worse in the supine position, and relieved by leaning forward. Associated ECG changes frequently occur, most commonly sinus tachycardia with concave upward ST segment elevation throughout the precordium. The ECG typically progresses to T-wave inversion, followed by the total resolution of all changes. The cause of acute pericarditis is variable, including infection, myocardial infarction, trauma, neoplasm, radiation, autoimmune diseases, drugs, nonspecific causes, and others (Table 18-3). Untreated pericarditis may result in progressive development of a pericardial effusion with subsequent cardiac tamponade. Infectious causes may result in septic complications. Chronic constrictive pericarditis may develop after resolution of the acute process.

Diagnosis

The diagnostic work-up should attempt to determine the underlying cause of the pericarditis. Blood tests should include erythrocyte sedimentation rate, hematocrit level, white blood cell count, bacterial cultures, viral titers, heterophile antibody, blood urea nitrogen, T₃, T₄, thyroid-stimulating hormone, antinuclear antibody, rheumatoid factor, and myocardial enzyme levels. The ECG may be typical or nonspecific. The chest x-ray may be normal or may demonstrate an enlarged cardiac silhouette or a pleural effusion. An echocardiogram to evaluate the degree of pericardial effusion is essential. A pericardiocentesis or pericardial biopsy may be necessary when the diagnosis is uncertain.

Treatment

The preferred treatment depends on the underlying cause. Purulent pyogenic pericarditis requires drainage and prolonged intravenous antibiotic therapy. Postpericardiotomy syndrome, post-myocardial infarction syndrome, viral pericarditis, and idiopathic pericarditis often are self-limiting but can require a short course of treatment with nonsteroidal anti-inflammatory agents. If a significant pericardial effusion is present, surgical drainage is indicated if signs of tamponade are present or if resolution is not prompt with anti-inflammatory agents. A 5- to 7-day course of steroids occasionally is necessary. Follow-up studies should be done to document resolution of pericardial effusion or to assess for late constrictive pericarditis.

Chronic Constrictive Pericarditis

Etiology

In the majority of patients, the cause of chronic constrictive pericarditis is unknown and probably is the end stage of an undiagnosed viral pericarditis. Tuberculosis is a rarity. Intensive radiation is a significant cause in some series. Constrictive pericarditis may develop after an open-heart operation. Previous cardiac surgery was reported in one study to be the cause in 39 percent of the patients treated surgically for constrictive pericarditis at NYU.

Pathology and Pathophysiology

The pericardial cavity is obliterated by fusion of the parietal pericardium to the epicardium, forming dense scar tissue that encases and constricts the heart. In chronic cases, areas of calcification develop, adding an additional element of constriction.

The physiologic handicap is limitation of diastolic filling of the ventricles. This results in a decrease in cardiac output from a decrease in stroke volume. The right ventricular diastolic pressure is increased, with a corresponding increase in right atrial and central venous pressure, ranging from 10 to 30 mmHg. The venous hypertension produces hepatomegaly, ascites, peripheral edema, and a generalized increase in blood volume.

Clinical Manifestations

The disease is slowly progressive with increasing ascites and edema. Fatigability and dyspnea on exertion are common, but dyspnea at rest is unusual. The ascites often is severe, and the diagnosis is easily confused with cirrhosis.

Hepatomegaly and ascites often are the most prominent physical abnormalities. Peripheral edema is moderate in some patients, but severe in others. These findings are manifestations of advanced congestive failure from any form of heart disease. With constrictive pericarditis, however, the usual cardiac findings are a heart of normal size without murmurs or abnormal sounds. Atrial fibrillation is present in about one-third of the patients, and a pleural effusion is common in more severe cases. A paradoxical pulse is found in a small proportion of patients.

Laboratory Findings

Venous pressure is elevated, often to 15 to 20 mmHg or higher. The ECG, though not diagnostic, usually is abnormal, with a low voltage and inverted T waves. The chest x-ray usually shows a heart of normal size, but pericardial calcification may be seen in a significant proportion of cases and often is the first clue to the diagnosis. Echocardiogram, MRI, or CT scan may demonstrate a thickened pericardium.

Findings on cardiac catheterization are highly characteristic. There is elevation of the right ventricular diastolic pressure with a change in contour, showing an early filling with a subsequent plateau, the “square root” sign. There also is “equalization” of pressures in the different cardiac chambers, because right atrial pressure, right ventricular diastolic pressure, pulmonary artery diastolic pressure, pulmonary wedge pressure, and left atrial pressure are similar. The one condition that cannot be excluded without myocardial biopsy is a restrictive cardiomyopathy.

Treatment

When the diagnosis has been made, pericardiectomy should be done promptly, because the disease relentlessly progresses. Operation can be done through a sternotomy incision or a long left anterolateral thoracotomy. The constricting pericardium should be removed from all surfaces of the ventricle, mobilizing the heart to where it can be held freely upward in the hand. Removal of the pericardium over the atria and the venae cavae is considered optional, although this usually is done as well. The heart-lung machine is kept on a standby basis in the event of significant hemorrhage. If this occurs, the patient can be heparinized and the blood aspirated and returned to the patient until the laceration is repaired. The pericardium is removed from the pulmonary veins on the right to the pulmonary veins on the left. Both phrenic nerves are mobilized and protected. Particular care is taken to remove pericardium over the pulmonary artery, where residual constriction can seriously impair the operative result.

As the constricting scar develops from organization of an exudate between the pericardium and the epicardium, the plane of dissection may be external to the epicardium, which will greatly decrease operative hemorrhage. If the epicardium is thickened, it must be removed from the underlying myocardium, though this is tedious and results in diffuse bleeding.

Intracardiac pressures should be measured by direct needle puncture before and after pericardiectomy. Often with a complete pericardiectomy the characteristic pressure abnormalities are eliminated or greatly improved. If significant abnormalities remain, the operative field should be carefully checked for any residual sites of constriction. In the past, slow recovery over many months probably was a result of inadequate pericardiectomy, not underlying “ventricular atrophy.”

Results

After a radical pericardiectomy that corrects the hemodynamic abnormalities, patients improve promptly with a massive diuresis. The risk of operation varies with the age of the patient and the severity of the disease; the mortality rate usually is less than 5 percent. A good result can be anticipated for more than 95 percent of the patients.

Culliford reported 62 patients treated surgically with total pericardiectomy. The majority of patients were NYHA class III or class IV preoperatively. Sixteen percent required cardiopulmonary bypass for treatment of associated pathology, usually tricuspid insufficiency. The operative mortality rate was 3 percent. After operation hemodynamic abnormalities promptly corrected, ascites and peripheral edema resolved, and functional status improved dramatically.

ARRHYTHMIA SURGERY

Surgical treatment of cardiac arrhythmias began in 1968 when Sealy first successfully interrupted the bundle of Kent in a patient with Wolff- Parkinson-White (WPW) syndrome. This was possible because of the newly developed electrophysiologic studies and mapping techniques described by Durrer, of Amsterdam, who mapped a patient with WPW syndrome in 1967, demonstrating electrical conduction through an accessory pathway in the area of ventricular preexcitation. Daniel and associates and Kaiser and associates independently reported intraoperative mapping for ischemic ventricular arrhythmias in 1969, but advances in surgical treatment of ventricular tachycardia did not occur until the late 1970s, when Guiraudon described the encircling endocardial ventriculotomy and Josephson and associates proposed map-guided subendocardial resection for ablation of recurrent ventricular tachycardia.

Subsequently, surgical methods for treatment of arrhythmias were advanced by Cox and others. The development of multipoint (160 to 256 channel) computerized cardiac mapping systems greatly improved the speed and efficiency of arrhythmia mapping, and better operative skills and adjuvant cryoablation techniques improved the efficacy of surgical methods. The development of radiofrequency catheter ablation allows treatment of cardiac arrhythmias in the cardiac catheterization laboratory.

Most ablative therapy for arrhythmias, surgical or nonsurgical, is done for one of four entities: (1) WPW syndrome with preexcitation; (2) paroxysmal supraventricular tachycardia (PSVT) from (a) atrioventricular (AV) node reentry or (b) concealed AV pathways; (3) sustained ventricular tachycardia; and (4) chronic atrial fibrillation. Patients with cardiac arrhythmias, with the exception of atrial fibrillation, require electrophysiologic studies before treatment, and additional intraoperative mapping is done at the time of surgery. Catheter ablation methods, when appropriate, can be applied in the catheterization laboratory after electrophysiologic studies are completed.

An epicardial and an endocardial approach have been used for surgical treatment of WPW syndrome and for paroxysmal supraventricular tachycardia, frequently using operative cryoablation as an adjunct. Both operative approaches have been highly successful. The majority of patients with WPW syndrome or PSVT are now treated nonoperatively with less morbidity using radiofrequency catheter ablation techniques. Mapping of the slow posterior pathway has allowed successful catheter treatment of PSVT associated with AV node reentry tachycardia without heart block, and radiofrequency ablation has been successful for WPW syndrome.

Implantable cardioverter defibrillators (ICD) are used for ventricular tachycardia unless it is sustained and unresponsive to medical therapy. A small but significant number ventricular tachycardias can be treated with catheter ablation. These arrhythmias often are life threatening. The ventricular arrhythmia is induced by electrophysiologic studies and attempts are made to suppress the arrhythmia with pharmaceutical agents. If the arrhythmia remains nonsuppressible, surgery is indicated.

Operative map-guided methods have been highly effective for the treatment of sustained ventricular tachycardia associated with left ventricular aneurysms. While results have been encouraging using “blind” (non–map-guided) endocardial resection and remodeling endoaneurysmorrhaphy for treatment of this combination of diseases (see Left Ventricular Aneurysm, above), most reports note lower arrhythmia recurrence rates when mapping methods are used.

Nonsuppressible ischemia-related sustained ventricular tachycardia without aneurysmal disease also may be treated by definitive map-guided operative ablation or by placement of the implantable defibrillator. Coronary bypass is performed concomitantly if reversible myocardial ischemia is present. Although the operative mortality rate is lower with placement of the implantable defibrillator than with open ablative surgery (3 percent versus 8 to 10 percent), the incidence of late sudden death is lower after operative ablation, and the choice of appropriate treatment is controversial. When ventricular fibrillation and not ventricular tachycardia is the primary event, the implantable defibrillator becomes the treatment of choice. Ventricular fibrillation cannot be mapped, and electrophysiologic studies cannot be used to follow the response to medications. Nonoperative radiofrequency ablation has not been effective in the treatment of sustained ventricular tachycardia, and neither operative nor radiofrequency ablation methods have been effective for ventricular fibrillation.

Chronic atrial fibrillation is the most common cardiac arrhythmia. The incidence in the general population is 0.4 to 2 percent, and 10 percent for those older than 60 years of age. Sequelae of chronic atrial fibrillation include: (1) stasis of flow in the left atrium, which may result in thromboembolism; (2) loss of atrioventricular synchrony, which causes a decrease in cardiac output that may be significant; and (3) an irregularly irregular heartbeat that causes discomfort for many patients. Atrial fibrillation is considered *chronic* when the fibrillating atria cannot be converted to and maintained in sinus rhythm or maintained in sinus rhythm by electrical or pharmacologic means.

Medical treatment of chronic atrial fibrillation is focused on ventricular rate control and anticoagulation therapy. Digitalis, beta blockers, and calcium- channel antagonists are first-line drugs for controlling ventricular rate by slowing atrioventricular conduction. Warfarin is used for long-term anticoagulation therapy to prevent thromboembolism. Despite these measures, patients may suffer congestive heart failure from loss of atrioventricular synchrony, thromboembolism from inadequate anticoagulation, bleeding complications from over-anticoagulation, and a sense of anxiety and discomfort from an irregular heartbeat.

Because of the suboptimal results of medical therapy, surgical investigators sought to develop a surgical technique to restore sinus rhythm to chronically fibrillating atria. Using electrophysiologic mapping of the atria, Cox and colleagues determined that atrial fibrillation was caused by macroreentrant circuits of electrical activity that required a large area of atrium in order to form. They also determined that atrial automaticity functioned independently from the macroreentrant circuits. On the basis of these studies they concluded that (1) surgical interruption of the reentrant circuits would abolish the ability of the atria to fibrillate, and (2) automaticity should be preserved to restore sinus rhythm.

Cox then developed a surgical procedure based on strategically placed full- thickness incisions in both atria. Dividing atrial wall and sewing it back together interrupts the macroreentrant circuits and eliminates the atrial fibrillation. With strategically placing the incisions, “corridors” are created for the propagation of depolarization and contraction. The configuration of the corridors results in a single pathway from the SA node to the AV node, which restores AV synchrony. From this “true pathway,” other pathways direct depolarization into “blind alleys” configured to cover nearly all remaining areas of the atria, resulting in widespread atrial contraction. The configuration of a true pathway giving rise to multiple blind pathways resembles a maze. By restoring sinus rhythm and atrial contractility, the maze procedure results in active transport of blood through the atrium and into the ventricles. This improves cardiac output and eliminates the stasis of blood flow, thereby reducing the risk of thromboembolism and eliminating the need for permanent anticoagulation therapy.

The maze procedure has been used for nearly 10 years and has been modified twice. A report on long-term follow-up has been published. The report includes 164 patients followed for at least 3 months (100 percent follow-up) and includes maze-I, maze-II, and maze-III procedures. Sinus rhythm was restored in 100 percent of patients. Recurrence of

atrial fibrillation or flutter occurred in 12 patients (7 percent) but was converted back to sinus rhythm and maintained medically in all 12 patients. At 6 months, atrial function was evaluated in 125 patients using transesophageal echocardiography or dynamic MRI. Right atrial function was preserved in 98 percent of patients, and left atrial function in 86 percent. Follow-up in patients undergoing the maze-III modification revealed right and left atrial function preservation of 98 and 94 percent, respectively. There have been no strokes, and two patients reported transient ischemic attacks. No patients in the series are receiving permanent anticoagulation therapy.

PACEMAKERS/IMPLANTABLE DEFIBRILLATORS/INTRAAORTIC BALLOON PUMP/ASSIST DEVICES

Pacemakers

Indications

Permanent pacemakers initially were used for patients with complete (third- degree) AV heart block that developed spontaneously in older patients or that occurred secondary to operative trauma. Pacemakers have been used for a variety of other arrhythmias, including the sick sinus syndrome and for any second-degree, bifascicular, or trifascicular heart block associated with intermittent bradyarrhythmias or symptoms. Asymptomatic patients with Mobitz II second-degree block or with Mobitz I second-degree block at the level of the bundle of His also are considered by most authorities to be candidates for a pacemaker. The most common indication for permanent pacemaker implantation is sick sinus syndrome, accounting for 50 percent. Temporary pacemakers are used for transient heart block associated with myocardial infarction or cardiac surgery or in symptomatic patients awaiting a permanent pacemaker.

Pathophysiology of Heart Block

In normal cardiac conduction tissue the cardiac impulse originates in the sinoatrial node near the junction of the superior vena cava and the right atrium. The impulse is propagated through the right atrium to the AV node, which lies medial to the ostium of the coronary sinus beneath the septal portion of the tricuspid valve at the apex of the triangle of Koch. From the AV node, conduction travels near the annulus of the tricuspid valve and along the bundle of His to pass through the central fibrous body of the ventricular septum, coursing slightly leftward on the crest of the muscular component of the ventricular septum. Here the bundle divides into the left and right bundles that travel to the left and right ventricles, respectively.

The most common surgical trauma producing complete heart block is valve surgery, but the incidence is the highest during the repair of a ventricular septal defect or an ostium primum atrial septal defect. Complete heart block may rarely follow prosthetic replacement of the aortic, mitral, or tricuspid valves, either from direct injury to conduction tissue or from traction with subsequent fibrosis. Endocarditis can result in complete heart block from an annular abscess. Intrinsic disease may develop in the SA node and the AV node in the aging population, and it can develop as a result of ischemic disease.

Symptoms attributed to first-degree heart block (PR interval > 0.2 s) are rare. With second-degree heart block (intermittent lack of AV conduction), symptoms become apparent if the bradycardia is severe or persistent. Two types of second-degree heart block are described: Mobitz I (Wenckebach) typically has progressive prolongation of the PR interval followed by a nonconducted P wave. This usually is benign unless it occurs at the His- Purkinje conduction level. Mobitz II second-degree block is more ominous, presenting with normal PR intervals, but with sporadic nonconduction or third-degree block. Mobitz II often progresses to complete third-degree block with associated symptoms.

Third-degree (complete) heart block seriously impairs cardiac output in several ways. The resulting bradycardia varies from 25 to 60 beats/min, which may compromise the coronary and the cerebral circulation. Refractory congestive failure may exist with heart rates of 45 beats/min or less. Patients with complete heart block frequently have extreme exercise intolerance, and dangerous symptoms of cerebrovascular insufficiency can occur, such as syncope and convulsions (Adams-Stokes syndrome).

Once complete AV dissociation and third-degree heart block occurs, patients often develop a slow ventricular escape rhythm, typically with heart rates of 25 to 60 beats/min. Cardiac arrest and death can occur. Others may develop ventricular tachycardia or ventricular fibrillation instead of a stable ventricular escape mechanism. Although a few patients remain asymptomatic with a rate as low as 35 beats/min, most have symptoms once the heart rate is less than 45 beats/min. With Mobitz II second- degree block the heart rate may be normal most of the time, but can abruptly change into complete AV disassociation.

Diagnosis

Milder symptoms of light-headedness or near-syncope may be caused intermittent bradycardia or heart block. The differential diagnosis for syncope or near-syncope includes second- or third-degree heart block, sick sinus syndrome, paroxysmal atrial tachycardia, sustained ventricular tachycardia, spontaneous ventricular fibrillation, vasovagal reaction, aortic stenosis, carotid sinus syndrome, occlusive arterial disease of the carotid or cerebral circulation, epilepsy, and idiopathic syncope. The diagnosis of complete heart block can be established with an ECG, but the diagnosis of intermittent heart block, sick sinus syndrome (tachy-brady arrhythmias), or paroxysmal atrial tachycardia requires serial ECGs or a 24-h Holter monitor.

Pacemaker Physiology

The efficacy of cardiac pacing depends on the ability of the heart to respond to short bursts (2 ms) of electrical stimulation, ideally with less than 1.5 to 2 mA of current. There is a direct linear relationship between stimulation threshold and the electrode surface area, with more concentrated charge present in smaller electrodes. Characteristics of modern pacemaker generators include a voltage ranging from 2½ to 7½ V, delivering a current of 3.5 to 15 mA. The pulse width of delivered charge can be adjusted from 0.15 to 2.0 ms. External programming capabilities usually are present.

The pacing threshold determination is particularly important with intravenous implantations to ensure that the pacing lead is in the proper position. With satisfactory location of the intravenous intracardiac electrode determined by fluoroscopy, an optimal stimulation threshold for pacing is 0.4 to 1.0 mA at 0.2 to 0.5 V with a pulse width of 0.5 ms. The resistance of the pacing electrode is calculated from the voltage and current threshold required to achieve cardiac pacing, with 500 to 1,000 ohms considered acceptable.

Cardiac pacing may be done with unipolar or bipolar electrodes. Today most pacing is done with bipolar leads. In a bipolar system the positive and negative electrodes are in contact in the heart. When unipolar pacing is used, the tip of the electrode is the stimulating pole, and the ground is the metal of the generator. This is the most common method, although sensing occasionally is improved by switching to bipolar leads.

Types of Pacemakers

Demand pacemakers are now used almost exclusively. A widely used type of pacemaker is the atrial-ventricular pacemaker, or dual-chamber pacemaker, which requires electrodes in both the atrium and the ventricle. Dual-chamber units allow AV sequential pacing (Fig. 18-21) by sensing both chambers and pacing as necessary. Newer pacemakers have rate-responsive capabilities, increasing their rate in response to the patient's bodily activity. Almost all pacemakers are now externally programmable.

A standardized code to describe pacemakers has been developed. It usually includes three to five letters that describe the functions of the pacemaker. The first letter indicates the chamber(s) paced (V = ventricle, A = atrium, D = dual-chamber pacing). The second letter indicates the chamber(s) sensed (V = ventricle, A = atrium, D = dual-chamber sensing, 0 = none). The third letter describes the response of the pacemaker to a sensed beat (T = triggered, I = inhibited, D = dual-chamber inhibition, 0 = not applicable). For example, a DDD pacemaker has dual-chamber pacing, sensing, and inhibition. Occasionally a fourth letter is used to indicate programmability or rate modulation (P = simple programmable, M = multiprogrammable, C = communicating, R = rate modulation), and a fifth letter may be used if antitachycardia or defibrillation functions are available (P = antitachycardia pacing, S = shock, D = dual function). These later designs often are combined in the automatic implantable defibrillator.

Operative Technique

For transient heart block after myocardial infarction a temporary pacing electrode is percutaneously introduced through the subclavian or femoral vein and advanced into the right ventricle. Fluoroscopy may be helpful but usually is not necessary. Temporary pacemaker wires are also commonly placed on the epicardial surface of the heart after cardiac surgical procedures. Temporary transvenous or epicardial pacemaker wires are easily removed before hospital discharge.

Most permanent pacemakers are inserted by the transvenous route. The cephalic vein, the external jugular vein, or the internal jugular vein can be used, but more commonly a direct sterile subclavian puncture is used for venous access. When the needle is in the subclavian vein, a dilator and sheath are passed over a guide-wire, and the pacing electrode is advanced through the sheath. The transvenous electrode can be advanced into the appropriate chamber of the heart, guided by fluoroscopic control. Pacing threshold and P-wave or R-wave sensitivity are determined. Once the electrode or electrodes have been positioned, the pacemaker is implanted in a subcutaneous pocket on the anterior chest wall.

Open surgical approaches use one of three routes: left intercostal, left subcostal, or subxiphoid incision. Because the morbidity is greater with the placement of epicardial leads, this method is reserved for special circumstances, such as in patients with prosthetic tricuspid valves or in neonates.

Postoperative Considerations

The morbidity with transvenous pacemaker implantation is small. Migration of the pacing electrode is the most common complication. Perforation of the ventricle can occur, resulting in diaphragmatic pacing or even cardiac tamponade. Infection is surprisingly rare. Recovery after pacemaker placement usually is uneventful. Antibiotics are given for 24 h, but there are no data to support their use. Difficulties with the subcutaneous implantation of the generator are rare with the small generators now available.

After discharge from the hospital, the patient should be seen in 2 to 3 weeks to assess for a rise in the pacing threshold. Telephonic electrocardiographic surveillance has been a significant advance. Data indicate that this type of periodic monitoring is mandatory for good care. As the battery is wearing down, the pacemaker's output changes, switching to a fixed mode; this can be determined by telephonic monitoring. When generator failure begins to occur, the pacemaker is electively replaced. Continuous follow-up is essential.

Special problems may occur in pacemaker patients requiring other surgical procedures in which the electrocautery is needed. Electromagnetic fields as high as 60 V/m are commonly induced with the electrocautery. This far exceeds the energy level required to activate the sensing circuit in most pacemakers. As a result this electrical signal may inhibit the pulse generator, damage the circuitry, or reset the pacing programs. A variety of arrhythmias have been observed as a result of subsequent pacemaker malfunction, such as ventricular asystole, multiple premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation. Total destruction of some pacemakers has occurred. In patients for whom use of the electrocautery is necessary, brief bursts of cautery should be used, keeping as far from the generator as possible. A bipolar cautery probably is safest. A pacemaker programming system should be available, and the pacemaker should be interrogated and reprogrammed after use of electrocautery. For patients who are totally pacemaker dependent, a backup transvenous wire and external pacemaker should be available before the electrocautery is used.

Implantable Defibrillators

More than 500,000 deaths occur in the United States each year from sudden cardiac arrest; the majority of these are a consequence of ventricular fibrillation and ventricular

tachycardia. Less than 10 percent of these deaths occur in the setting of acute myocardial infarction. The survival rate for an out-of-hospital cardiac arrest not associated with myocardial infarction is less than 25 percent.

Spontaneous ventricular tachycardia and ventricular fibrillation commonly are a result of underlying structural heart disease, such as coronary artery disease, ventricular aneurysm, or cardiomyopathy. Long-term survival in these patients is poor and their risk for sudden death can be stratified by ejection fraction and electrophysiologic studies. For patients with inducible ventricular arrhythmias that are not suppressed with medication, the 2-year survival rate is less than 40 percent. These patients are candidates for arrhythmia surgery or for placement of the internal cardioverter defibrillator.

Internal Cardioverter Defibrillator (ICD) Devices

The early development of the implantable defibrillator was achieved by Mirowski, with the first human implantation being performed in 1980. In early 1982 a second-generation device, the automatic internal cardioverter defibrillator, became available. Third- and fourth-generation ICD devices are in clinical trials (Fig. 18-22). These units allow programmability, backup bradycardia pacing, antitachycardia pacing, and standard cardioversion. Until recently ICD placement required open implantation, but totally transvenous systems are available now.

Indications

The indications for ICD therapy are similar to those for arrhythmia surgery:

- (1) One or more episodes of spontaneous sustained ventricular tachycardia (VT) or ventricular fibrillation (VF) in a patient in whom electrophysiologic testing or spontaneous ventricular arrhythmias cannot be used accurately to predict the efficacy of other therapies.
- (2) Recurrent episodes of spontaneous sustained VT or VF in a patient despite antiarrhythmia drug therapy (guided by electrophysiologic testing or noninvasive methods).
- (3) Spontaneous sustained VT or VF in a patient in whom antiarrhythmia drug therapy is limited by intolerance or noncompliance.
- (4) Persistent inducibility of clinically relevant sustained VT or VF on electrophysiologic studies on the best available drug therapy or despite surgical/catheter ablation in a patient with spontaneous sustained VT or VF.

Results

Several reports have documented the efficacy of ICD therapy. In a large series by Winkle the rate of freedom from sudden death after 5 years with use of the ICD was 96 percent. Although the risk of sudden cardiac death is substantially reduced by ICD therapy, overall survival rates are eroded by congestive heart failure, with a 5-year survival rate of 70 to 75 percent. Similar results are obtainable with arrhythmia surgery, and the appropriate treatment of these patients is controversial.

Intraaortic Balloon Pump

The intraaortic balloon pump (IABP) is the most common and effective technique for assisted circulation. Approximately 70,000 are inserted annually in the United States. The technique was developed by Alstin and associates. A balloon catheter is inserted through the femoral artery and advanced into the thoracic aorta. Insertion of the balloon may be done by direct arteriotomy or with a percutaneous insertion kit. With electronic synchronization, the balloon is alternately inflated during diastole and deflated during systole. Coronary blood flow is increased by improved diastolic perfusion, and afterload is reduced. The cardiac index typically improves after insertion, and the preload decreases. Total myocardial oxygen consumption is diminished by approximately 15 percent.

The IABP can be used for several days or weeks with minimal morbidity. Ischemia of the extremity through which the IABP is inserted is the most serious complication, and the extremity must be examined frequently for viability. Platelet consumption also may occur.

Assist Devices

Temporary assisted circulation is a valuable clinical modality in the treatment of transient cardiac injury. The most common indication for temporary assisted circulation is cardiac failure after cardiac surgery, manifested by a cardiac index of less than 1.5 L/min/m² despite inotropic support. Often an IABP has been used without success. In such instances, mechanical cardiac assistance for 24 to 48 h or longer may permit recovery of cardiac function, probably by minimizing reperfusion injury and from resolution of myocardial edema. Some patients who are dying while awaiting heart transplantation may benefit from circulatory support with a cardiac assist device.

Several types of ventricular assist devices (VAD) are available, including temporary extracorporeal centrifugal pumps, implantable left ventricular assist systems (LVAS), external heterotopic pulsatile ventricular assist devices, and total artificial hearts (TAH). The most commonly used devices are simple pumps (DeBakey roller pump or BioMedicus centrifugal pump) connected to the left atrium and the aorta. These devices can provide effective support for 5 to 7 days, and, in rare cases, up to 2 weeks. External pulsatile assist devices deliver blood flow in synchrony with the native heart and are used for short-term support after cardiac surgery or primarily as a bridge to cardiac transplantation. Attempts at total cardiac replacement with an artificial heart, such as the Symbion Jarvik-7 TAH, have been largely unsuccessful because of long-term thromboembolic complications, infection, and trauma to blood elements.

Results

At NYU over 100 temporary ventricular assist devices have been used for postcardiotomy shock in the past 15 years, with an overall survival rate of approximately 30 percent. Prompt insertion is necessary before irreversible myocardial damage has occurred. The authors currently use the centrifugal pump with heparin-bonded tubing for short-term cardiac assistance. Similar results were reported by Pae and associates from a combined registry experience of 965 cases, with a hospital survival rate of 25 percent. Eighty-six percent of the surviving patients were subsequently NYHA functional class I or class II. The survival rate was equivalent to those obtained with the use of pulsatile pumps or nonpulsatile centrifugal devices. All ventricular assist devices are associated with a significant risk of thromboembolism and infection.

Data are available from the registry of the International Society of Heart Transplantation on the use of ventricular assist devices in 291 patients as a bridge to cardiac transplantation, 213 patients (73 percent) of whom survived transplantation. Pretransplant cardiac support ranged from 19 to 159 days. Data from St. Louis University indicate a survival rate of 48 percent when assist devices were used as a bridge to transplantation. All patients undergoing cardiac support, either after cardiac surgery or as a bridge to transplantation, would have died had ventricular assist devices not been available. With steady improvements in technology, long-term cardiac assistance or totally artificial hearts may have an expanded role in the future.

CHAPTER 19 - Thoracic Aneurysms and Aortic Dissection

Aubrey C. Galloway
Jeffrey S. Miller
Frank C. Spencer
Stephen B. Colvin

THORACIC ANEURYSMS

General Considerations

Modern surgical treatment of arterial aneurysms was introduced nearly a century ago by Rudolf Matas, who described a method of internal repair of aneurysms termed *reconstructive endoaneurysmorrhaphy*. Nearly fifty years later, in 1952, notable work by Cooley and DeBakey demonstrated the feasibility of repairing aneurysms involving the thoracic aorta. Subsequently, *excisional therapy* became the mainstay of the modern surgical approach to aneurysm disease, with resection of the aneurysmal aortic segment followed by restoration of blood flow through the placement of an interposition Dacron graft.

More recently excisional therapy and endoaneurysmorrhaphy with internal graft placement have been used for repair of thoracic aortic aneurysms. When the aneurysm is well localized, total excision of the diseased aorta usually is feasible, and the involved area is replaced with an end-to-end Dacron graft (*graft interposition technique*). Many surgeons prefer this technique for aneurysms involving the aortic root or the ascending aorta, because the excisional method is associated with a lower risk of subsequent reoperation for pseudoaneurysm. By contrast, in patients with more extensive aneurysmal disease, i.e., aneurysms that involve a long segment of aorta or invade adjacent structures, excisional therapy is unnecessary and may be hazardous. In these patients a simpler and equally effective method is replacement of the diseased segment of aorta from within by placing a Dacron graft, without excising the aorta itself. An end-to-end anastomosis between the graft and the aorta is performed, working from within the open aneurysm. The wall of the aneurysm subsequently is wrapped around the graft for tissue coverage. This technique, termed the *graft inclusion method*, has the advantage of limited operative dissection and is associated with less risk of bleeding or injury to adjacent structures.

Etiology and Pathogenesis

An aortic aneurysm can be defined as a localized or diffuse aortic dilatation, usually exceeding 5 to 6 cm in diameter. Aneurysms develop from a weakness or defect in the aortic wall, which has a tendency to dilate progressively. This is to some extent a self-perpetuating process, because the lateral wall tension of a vascular tube is related to the radius by Laplace's law (tension = pressure × radius). The larger the aneurysm, the greater the wall tension. Past concepts of the pathogenesis of aneurysm formation were oversimplified and inaccurate. Aneurysms do not form simply from tension related to passive dilation but are a result of a complex remodeling process involving the vessel wall, as was recently outlined in a review by Halloran and Baxter. This remodeling process involves a change in the structure of collagen and elastin within the vessel wall with an increased proteolytic enzyme activity that changes the balance between proteases and protease inhibitors (Table 19-1). Serine protease, metalloprotease, and neutrophil elastase activity are increased in the aneurysmal vessel, resulting in a net degradation of elastin and collagen. Protease inhibitor activity is simultaneously decreased, leading to an additional imbalance in the ratio of protease to protease inhibitor. These biochemical changes produce progressive dilation of the vessel wall. Inflammatory mediators also are activated, especially in patients with atherosclerotic, infectious, or autoimmune diseases, additionally enhancing the proteolytic process. The net effect is vascular remodeling with dilation of the vessel wall. Initially there is a loss of elastin in the media with compensatory thickening of the adventitia, which maintains vessel wall integrity despite increased wall tension. Later in the process, increased collagenase activity leads to degradation of the adventitial layer with additional dilation or rupture of the aneurysm.

The main causative factors associated with aortic aneurysms are age, hypertension, smoking, atherosclerosis, aortic dissection, and connective tissue disorders. Although atherosclerosis has long been thought to be a primary cause of aneurysmal formation, this may be an oversimplification. While atherosclerosis is associated with aneurysmal disease, the presence of atherosclerosis alone probably is not sufficient for an aneurysm to develop. Chronic atherosclerosis results more often in a proliferative, obstructive vascular disease, with aneurysmal dilatation occurring in a minority of individuals. The available data suggest that other factors, such as inflammation or a genetic tendency for increased proteolytic activity, also must be present for an aneurysm to develop in atherosclerotic patients.

Aortic dissection may result in acute or chronic aneurysmal dilatation. This is discussed in detail later in this chapter. The most common connective tissue disorder associated with aneurysm formation is Erdheim's cystic medial necrosis, in which the underlying defect is idiopathic degeneration of the media with progressive aneurysmal dilation. Marfan syndrome and Ehlers-Danlos syndrome, both with identifiable genetic defects, are well-defined connective tissue diseases associated with aortic aneurysms. In Marfan syndrome, the defect is in the gene coding for fibrillin, which is a major structural component of the microfibrils in connective tissue. Marfan syndrome patients have a well-described phenotype that includes a tall stature, high palate, joint hypermobility, lens disorders, mitral valve prolapse, and aneurysms involving the aortic root or other parts of the aorta. Patients with Marfan syndrome have a significantly increased risk of aortic valvular insufficiency, aortic rupture, and aortic dissection. A similar but less common defect is Ehlers-Danlos syndrome, which is a consequence of a group of genetic mutations leading to defective collagen synthesis, resulting in aneurysm formation in multiple locations throughout the body. Similar to Marfan patients, these patients develop aneurysms of the aortic root with an increased risk of spontaneous aortic rupture. The surgeon should be familiar with the various genetic defects associated with aneurysmal disease, because identification of a genetic disorder can lead to earlier and more effective operative treatment of these high-risk patients.

Less common causes of thoracic aneurysms include trauma, infection (syphilitic or other mycotic), inflammatory diseases (granulomatous and Takayasu's arteritis), and autoimmune diseases.

Classification

Aneurysms of the thoracic aorta are best classified in terms of anatomic location; the clinical significance and the surgical approach vary widely with the location of the aneurysm. The four major locations are (1) the aortic root and ascending aorta, (2) the transverse aortic arch, (3) the descending thoracic aorta, and (4) the thoracoabdominal aorta. Aneurysms of the aortic root or ascending aorta are the most common, representing over 40 percent of thoracic aneurysms in a large series. The descending aorta is involved in about 35 percent of thoracic aneurysms, and the transverse arch and the thoracoabdominal aorta are involved in 10 to 15 percent each. Localizing aneurysms to a specific location may be misleading, because the entire aorta may be diseased and the most obvious location might be only a portion of a more diffuse disease process.

Other descriptive terms have been helpful in identifying specific areas of aortic involvement. *Aortoannular ectasia* is a descriptive term for a degenerative dilatation of the aortic annulus and the sinuses of Valsalva, producing aortic insufficiency and a localized aneurysm involving the aortic root. This lesion often is associated with connective tissue diseases such as Marfan syndrome or Ehlers-Danlos syndrome. *Traumatic aneurysms* may occur after blunt trauma to the chest. They are located just distal to the subclavian artery at the site of insertion of the ligamentum arteriosum. While the management of acute traumatic aortic transection is discussed in Chap 6 (Trauma), the surgical management of elective repair of a traumatic aneurysm is similar to that of all other descending thoracic aneurysms. The term *dissecting aneurysm* is a misnomer, usually meaning *aortic dissection*, which results from an intimal tear in the aortic wall with subsequent disruption of the media, producing a true and a false lumen throughout the dissected aorta. When a dissected aorta dilates to over 5 to 6 cm in diameter, it is appropriately termed an *aortic aneurysm secondary to aortic dissection*. These may be acute or chronic.

Clinical Manifestations

The classic symptom associated with a large or an expanding aneurysm is pain, which may be excruciating and severe. With chronic aneurysms the symptoms may be more subtle, such as chronic pressure or a low-grade aching pain. Because symptomatic patients have an increased risk of rupture, pain possibly related to aneurysmal expansion must be thoroughly investigated. New onset of pain in a patient with a known aneurysm is highly significant and may indicate rapid expansion, leakage, or impending rupture.

Large aneurysms may produce symptoms from compression of adjacent structures, such as the trachea, mainstem bronchus, superior vena cava, pulmonary artery, recurrent laryngeal nerve, or vertebral bodies. Syphilitic aneurysms, seen less now than in the past, were known for their tendency to invade bone, producing back pain from erosion of the thoracic spine, which occurs less frequently with other aneurysms. The most common symptoms in patients with thoracic aneurysms are, in decreasing order of frequency, pain, pulmonary symptoms, and hoarseness.

The majority of patients with moderate-sized thoracic aneurysms are asymptomatic unless significant enlargement has occurred. These aneurysms usually are discovered incidentally in a routine chest radiograph or during catheterization or imaging studies performed for other reasons. Usually there are no physical abnormalities or hemodynamic disturbances, except in aneurysms of the aortic root, which may be associated with aortic valvular insufficiency.

Diagnostic Studies

Once an abnormal shadow has been identified on chest x-ray, an attempt to establish the diagnosis of an aneurysm is made with magnetic resonance imaging (MRI), computed tomography (CT), or echocardiography. Aortography, previously the primary diagnostic tool, is seldom necessary because of newer imaging techniques. The full extent of aneurysmal involvement can be well demonstrated with MRI, CT, or MR angiography. Echocardiography is used to determine the size of the ascending aorta and aortic root and is especially helpful in detecting any associated valvular insufficiency. When surgery involving the aortic root is necessary, cardiac catheterization usually is indicated to additionally define the degree of aortoannular ectasia and the degree of coronary artery displacement. An aortic root angiogram with runoff images of the aortic arch is recommended, evaluating the involvement of the sinuses of Valsalva, the degree of aortic insufficiency, the amount of coronary artery displacement, and the degree of aneurysmal involvement of the aortic arch distally.

Patients with thoracic aneurysms have a high incidence of associated coronary artery disease. These patients should have screening studies or coronary angiography before aneurysm repair.

Natural History and Operative Indications

The natural history of aortic aneurysms is one of progressive enlargement with eventual rupture. Factors related to the risk of rupture include aneurysmal size, change in size, age of the patient, pain, symptoms of aneurysmal expansion, smoking, and chronic obstructive pulmonary disease (COPD). Juvonen and associates analyzed multiple risk factors to develop a multivariate equation to calculate the probability of rupture for thoracic aneurysms. Patients with large aneurysms (more than 6 to 7 cm in diameter) with rapid aneurysm expansion or with pain generally underwent elective repair, while others with aneurysms of moderate size were monitored with serial CT scans over approximately 5 years. The risk of rupture for aneurysms of various sizes was as follows: less than 3 cm, 0 percent; 3–4 cm, 6 percent; 4–5 cm, 12 percent; 5–6 cm, 36 percent; 6–7 cm, 50 percent; and 7–8 cm, 100 percent. Age and COPD were factors other than aneurysm size that independently increased the risk of rupture. The approximate risk of rupture for an individual patient with a thoracic aneurysm can be estimated on the basis of clinical variables and compared with the estimated operative risk. Although the majority of aortic aneurysms steadily enlarge and elective surgery can be planned, sudden rupture occurs in a small proportion of patients with smaller aneurysms that were not progressively enlarging. Patients treated nonoperatively should be warned of this possibility.

Other clinical trials have demonstrated a similar risk of rupture for thoracic aneurysms. In a large series reported by Bickerstaff and associates in which patients were treated nonoperatively, the 1-year survival rate was 60 percent, and the 5-year survival rate was 13 percent. Over 70 percent of the deaths were caused by rupture of the aneurysm. Pressler and McNamara reported observations in 260 patients with thoracic aneurysms, 126 of whom were treated surgically. The 5-year survival rate in the patients treated nonoperatively was only 21 percent, with high rupture rates noted for atherosclerotic and dissecting aneurysms. Similarly, Finkelmeier demonstrated that 41 percent of patients with chronic traumatic thoracic aneurysms died or developed symptoms from the aneurysm within 5 years.

Data support elective operative treatment for most thoracic aneurysms larger than 5 to 6 cm in diameter, because of the significant risk of rupture and death within 5 years. Operation should be strongly considered in patients with saccular aneurysms or connective tissue diseases once the aneurysm exceeds 4.5 to 5 cm, depending on the estimated operative risk, because the rupture rate is higher in these patients.

Aortic Root and Ascending Aortic Aneurysms

General Considerations

Aneurysms localized to the aortic root are often a result of cystic medial necrosis or connective tissue disease involving the aortic wall. Atherosclerotic aneurysms occur in the ascending aorta but are seldom limited to this area. Aortic dissection, inflammatory diseases (syphilis, autoimmune diseases, and aortitis), and congenital defects (bicuspid aortic valve and aortic coarctation) are other causes of ascending aortic aneurysms. In a series of 165 ascending aortic and aortic arch aneurysms reported from New York University (NYU), 29 percent were from aortic dissection, 22 percent from atherosclerosis, 22 percent from cystic medial necrosis or connective tissue diseases, and 27 percent from other causes.

Aneurysms involving the ascending aorta (Fig. 19-1) may be isolated to the supracoronary position, may extend distally to involve the aortic arch, or may extend proximally with involvement of the aortic root and sinuses of Valsalva. With aneurysms originating in the supracoronary part of the ascending aorta (i.e., not involving the sinuses of Valsalva), the aortic valve usually is normal and uninvolved, unless separate pathology such as congenital aortic stenosis is present. In contrast, aneurysms originating in the aortic root by definition involve the sinuses of Valsalva, causing distortion of the sinotubular ridge (the point where the commissures of the aortic valve attach to the ascending aorta). The process of aortoannular ectasia stretches and distorts the valvular commissures and cusps, producing central aortic insufficiency. In these patients the annulus, the sinuses of Valsalva, and the sinotubular junction are all dilated, and the coronary ostia usually are displaced superiorly by 2 to 3 cm. In some patients aortic insufficiency is severe, and cardiac failure may be the initial clinical finding. Chronic ascending aneurysms from aortic dissection often produce a similar finding, because the dissection process may distort the commissural attachments of the aortic valve at the sinotubular ridge, producing aortic insufficiency.

Before surgical therapy was available, most patients with Marfan syndrome died in the third decade of life from aortic dissections or rupture. Early surgical intervention for aortic root aneurysms is therefore recommended in patients with Marfan syndrome or Ehlers-Danlos syndrome, usually when the diameter of the aortic root exceeds 4.5 to 5 cm.

Operative Treatment

The standard operative approach for aneurysms involving the aortic root or ascending aorta is through a median sternotomy incision, using cardiopulmonary bypass and cardioplegia. When the aneurysm is confined to the ascending aorta without involvement of the aortic root, the ascending aorta is replaced with a woven Dacron graft, beginning just distal to the sinotubular ridge and ending proximal to the innominate artery (Fig. 19-2). Concomitant valve replacement is performed if aortic valve disease is present.

Replacement of the aortic root is performed when the aortic root is aneurysmal (aortoannular ectasia). The operation most commonly used for root replacement is the composite valve graft procedure, which involves replacement of the aortic valve and aortic root with an aortic valve–Dacron graft conduit, placed from the aortic annulus to the distal aorta beyond the aneurysm. This technique necessitates reimplantation of the coronary arteries into the composite graft. The need for aortic root replacement often can be determined preoperatively by MRI, CT, or echocardiographic studies, or by an angiogram of the aortic root during cardiac catheterization. The final decision often is made at operation; if the sinuses of Valsalva and the aortic annulus are dilated and the ostia of the coronary arteries are displaced more than 2 cm from the annulus, then the aortic root should be replaced.

The technique for aortic root replacement initially was described by Bentall and Debono. With the Bentall method, the composite valve graft is placed from within the aorta without cutting out the aneurysm, reimplanting the coronary arteries into the graft. The aneurysmal sac is closed around the composite graft as part of a graft inclusion technique (Fig. 19-3). This classic Bentall method is used less frequently today because of a significant incidence of late false aneurysm formation within the aneurysmal wrap. The most widely used technique for root replacement is a modification of the Bentall procedure in which the aortic root is totally excised, leaving “buttons” of aortic tissue around each coronary ostium for subsequent direct reimplantation into the composite graft (Fig. 19-4). Cabrol described an alternative method for coronary artery reimplantation during aortic root replacement using a Dacron tube 10 mm in diameter to connect the left and right coronary arteries, subsequently performing a side-to-side anastomosis between the small tube graft and the composite valve graft to reestablish coronary flow (Fig. 19-5). Aortic root replacement also can be performed using a cryopreserved homograft or a pulmonary autograft.

Results

Aortic root replacement with a composite graft can be safely performed, with excellent long-term results. The operative mortality rate is 2 to 5 percent, depending on the number of associated risk factors, such as coronary artery disease, reoperation, New York Heart Association (NYHA) class IV functional status, Marfan or Ehlers-Danlos syndrome, aneurysm rupture, or superimposed acute aortic dissection. The operative risk is less for isolated ascending aneurysm repair without root involvement. Because the operative risk is markedly increased once rupture or dissection has occurred, elective operation should be recommended whenever an aneurysm larger than 4.5 to 5.5 cm in diameter is identified.

Aortic Arch Aneurysms

Aortic arch aneurysms may be isolated or may be part of a continuous aneurysmal process involving the ascending and descending aorta. The most common causes are atherosclerosis, aortic dissection, and connective tissue disorders. The diagnosis usually is suspected after identification of an abnormality on a chest radiograph and confirmed by MRI, CT, or aortography. The innominate, carotid, or subclavian arteries also may be aneurysmal. The proximal and distal extent of disease and the degree of great-vessel involvement should be clearly defined preoperatively, because these characteristics strongly influence the operative approach.

Treatment

The operative procedure for arch replacement is complex, involving issues of surgical technique and cerebral protection. Depending on the extent of arch involvement, it may be necessary to perform *total arch replacement* (Fig. 19-6) with reimplantation of the arch vessels into the graft, or *partial hemi-arch replacement* (Fig. 19-7), with placement of a beveled graft leaving the arch vessels to arise from the native aortic arch superiorly. The hemi-arch repair has been used with increasing frequency at NYU over the past several years. This technique, initially described by Cooley, is simpler to perform and allows the surgeon the freedom to tailor the repair as necessary, replacing anywhere from 25 to 85 percent of the aortic arch. A third technique of arch replacement, the *elephant trunk technique* described by Borst and associates, is used in a small number of patients who will require a subsequent operation for a descending aneurysm. The elephant trunk technique is similar to standard total arch replacement, but the distal graft is invaginated into itself while the anastomosis is constructed, and the invaginated portion is subsequently unfolded so that it lies free in the descending aorta. This allows the surgeon easier access to the distal graft, or elephant trunk, during the subsequent descending aneurysm repair, which usually is performed several weeks later via a left thoracotomy.

In various large clinical trials reported by Coselli, Svensson, Ergin, and Galloway the overall operative risk for arch aneurysm surgery has ranged from 6 to 15 percent, depending on the number of risk factors present. The risk factors for poor outcome have been identified as advanced age, emergency surgery, acute dissection, aneurysm rupture, cardiac tamponade, Marfan syndrome or other connective tissue diseases, previous aortic surgery, and presence of a second aneurysm in the descending thoracic aorta. Other operative variables influencing survival include cardiopulmonary bypass time, operative bleeding, renal failure, and stroke.

Before the introduction of deep hypothermia and circulatory arrest, arch aneurysm repair had one of the highest operative risks of any surgical procedure, with mortality rates exceeding 75 percent. The demonstration that the brain could safely tolerate circulatory arrest for periods of up to 45 min if the temperature was carefully lowered to 15 to 17°C formed the basis for an improved surgical approach. This technique, termed deep hypothermia and circulatory arrest, was first applied by Griep and associates in 1975. The hypothermic circulatory arrest technique involves core cooling of the blood to 10 to 15°C while the head is packed in ice and the body is cooled externally with a cooling blanket. The patient is cooled until the tympanic membrane temperature is 15 to 17°C or until electroencephalogram (EEG) silence is achieved, after which cardiopulmonary bypass is stopped. Use of hypothermic circulatory arrest for cerebral protection allows the surgeon to stop all blood flow during arch repair so that a precise, sound technical arch anastomosis can be performed. The technique has the added advantage of avoiding clamping and manipulation of the diseased aorta, which lessens the risk of aortic injury or embolization. The circulatory arrest technique has resulted in a dramatically lower mortality rate.

The incidence of permanent neurologic injury (stroke) after circulatory arrest is low if the cerebral ischemic time does not exceed 45 min. A report by Galloway in 1989 described repair of 165 arch aneurysms over 10 years using hypothermia and circulatory arrest in the majority of cases; 85 percent of the arch repairs had circulatory arrest times of less than 45 min. The operative mortality rate was approximately 10 percent, and the frequency of stroke was less than 2 percent.

Ergin and associates analyzed neurologic outcome in patients undergoing hypothermic circulatory arrest for arch repair and demonstrated a correlation between the risk of temporary neurologic dysfunction (transient confusion, agitation, or obtundation) and the circulatory arrest interval. Temporary neurologic dysfunction occurred in 20 to 30 percent of the patients in whom the circulatory arrest interval had exceeded 50 min. The most common cause of permanent neurologic injury in the patients was embolic events, not ischemia from the circulatory arrest.

The incidence of neurologic injury after aortic arch repair varies from 0 to 15 percent in different series. The risk factors for stroke are age, complexity of the arch repair, circulatory arrest time, and the amount of clot or atheromatous debris in the arch.

A new technique of cerebral protection involving retrograde cerebral perfusion (through the superior vena cava) has been used to minimize the risk of cerebral ischemia during arch aneurysm surgery. Retrograde perfusion uses venous perfusion of the brain with blood that has been cooled to 7 to 12°C. Flow rates usually are 200 to 500 mL/min during the period of systemic circulatory arrest, maintaining a cerebral venous perfusion pressure at 30 to 40 mmHg. Reports by Bavaria, Ergin, Lytle, and Coselli have shown a diminished risk of stroke with the use of retrograde cerebral perfusion. The technique is of most importance in cases in which the circulatory arrest time is expected to exceed 45 min.

Descending Thoracic Aortic Aneurysms

General Considerations

Descending aneurysms may result from atherosclerosis, cystic medial necrosis, connective tissue diseases, aortic dissection, infection, inflammation, or prior trauma.

Atherosclerosis and degenerative diseases probably are the most common causes of descending aneurysms. The majority of aneurysms begin in the proximal descending aorta and extend for varying distances, often involving the entire descending thoracic aorta. Atherosclerotic aneurysms generally are fusiform, but some are localized and saccular. Concomitant abdominal aortic aneurysms occur in 25 to 30 percent of the patients, and the entire thoracoabdominal aorta may be involved in 10 percent. The aneurysmal disease may extend proximally to involve the aortic arch. Traumatic aneurysms arise from prior aortic transection after blunt trauma to the chest, developing in those few patients who survived the initial injury. While acute traumatic aortic transection usually follows trauma, a chronic aneurysm can develop after acute traumatic aortic injury, usually occurring immediately distal to the left subclavian artery, where the aorta is fixed by the ligamentum arteriosum. A chronic traumatic aneurysm of the descending aorta generally is repaired with a prosthetic graft and reconstruction techniques identical to those used for other forms of chronic descending aortic aneurysms.

Clinical Manifestations

Most patients with descending aortic aneurysms are asymptomatic, and the diagnosis is made after a chest radiograph, usually performed for other reasons. Symptoms, when present, usually result from aneurysmal enlargement or compression of adjacent structures. Large aneurysms may compress the left main bronchus, resulting in cough and dyspnea, or erode into the lung parenchyma, producing hemoptysis. Enlarging aneurysms near the left recurrent laryngeal nerve may produce vocal cord paralysis and hoarseness. Pain is the most common and concerning symptom, because it usually suggests significant compression of an adjacent vital structure or aneurysmal expansion with impending rupture.

The physical examination usually is normal. Rarely a bruit is audible in the left paravertebral area. Peripheral pulses usually are normal, although a large aneurysm compressing the left subclavian artery may result in diminished pulses in the left arm. A chronic dissection may shear off the origin of the subclavian or iliac vessels, resulting in diminished or unequal pulses in the arms or legs.

Diagnostic Studies

The diagnosis of a thoracic aneurysm usually is suspected after identification of a mass in the region of the descending aorta on a chest radiograph. The differential diagnosis includes bronchogenic carcinoma, metastatic carcinoma, or mediastinal tumors. Laminar calcifications may be visible in the wall of the aorta.

The diagnosis is confirmed by standard CT or MRI (Fig. 19-8), which readily demonstrate the size and extent of aortic aneurysmal involvement. These studies also are especially useful to evaluate aneurysms periodically for progressive enlargement so that the proper timing of surgery can be determined. Aortography may be used to confirm the diagnosis and further delineate the precise extent of the aneurysmal involvement before surgery. Today standard aortography is seldom necessary, however, because newer forms of enhanced MR or CT angiography are available. These imaging studies allow three-dimensional reconstruction of the aorta with scan times of less than 3 min and have largely replaced conventional aortography in the evaluation of thoracic aortic aneurysms.

Because concomitant atherosclerosis often is present in the coronary, renal, or carotid arteries, a thorough preoperative evaluation should be undertaken. Provocative stress testing, coronary arteriography, and carotid studies should be performed as indicated to determine whether concomitant cardiovascular disease requires treatment before thoracic aneurysm repair. Patients with symptomatic coronary artery disease or with a positive stress test should undergo cardiac catheterization and revascularization before aneurysm repair.

Operative Indications

In patients with descending aneurysms larger than 5 to 6 cm in diameter elective operative repair is recommended. This is especially important because of the high risk of subsequent rupture in these patients and because emergency surgery has mortality rates four to five times higher than elective surgery. In patients with aneurysms less than 5 cm in diameter, a policy of observation may be used, but these patients require frequent follow-up imaging studies, and operation is indicated if the aneurysm expands or if the patient becomes symptomatic.

Operative Technique

A variety of techniques have been used for repair of descending aortic aneurysms, with technical advances resulting in a marked reduction in the operative mortality over the past 10 to 15 years. Two major operative techniques are in use. *Unprotected cross-clamping* is performed with cross-clamps placed proximally and distally without distal perfusion, or with a single proximal cross-clamp with controlled distal exsanguination. In *perfusion or shunting techniques* bypass or passive shunts are used to maintain distal aortic perfusion during the cross-clamp time. Perfusion may be done with left atriofemoral bypass, with femoral–femoral bypass with an oxygenator, or with a Gott shunt from the proximal to the distal aorta. Perfusion and shunting techniques were introduced to limit spinal cord ischemia during the cross-clamp time.

Operative exposure is achieved with a left posterolateral thoracotomy through an appropriate interspace, usually the fourth, fifth, or sixth. For most mid–descending aortic aneurysms a fifth interspace incision is used, although the sixth rib may be resected if more extensive exposure is required. Initially the aorta is mobilized and encircled proximal and distal to the aneurysm. In some cases the aorta is controlled proximally between the left carotid and left subclavian arteries; approximately 25 percent of descending aneurysms require placement of the cross-clamp proximal to the left subclavian artery. Operative dissection in this area is facilitated by opening the pericardium to expose the intrapericardial portion of the transverse aortic arch. The vagus nerve and recurrent laryngeal nerve should be mobilized and protected.

The technique for graft placement is standard. An initial dissection is performed to isolate the aorta proximally and distally. The aorta must be sufficiently mobilized to allow precise placement of the cross-clamps, with proximal control usually obtained first. The surgeon must then decide whether a simple cross-clamp technique or a perfusion technique is to be used.

When the aorta is clamped and opened widely, thrombus is removed from the lumen. Ostia of intercostal vessels are oversewn from within the aneurysm unless they are to be reimplanted into the side of the graft. In most patients with descending aortic aneurysms the aneurysm is not resected, but rather the graft is placed internally after the aneurysmal contents are evacuated. A woven Dacron graft is inserted, and end-to-end anastomoses are performed proximally and distally with continuous vascular suture. Rarely, an interrupted or felt-reinforced suture technique is used if the aorta is especially friable. After the graft is placed the clamps are temporarily opened to remove air or thrombus, after which the suture lines are securely tied. The cross-clamps are removed slowly, and the distal body is perfused through the graft. Reperfusion often is accompanied by transient hypotension, which is corrected by volume infusion and sodium bicarbonate to correct reperfusion-related acidosis. Once hemostasis is obtained the aneurysmal sac usually is wrapped around the graft to provide additional hemostasis and tissue coverage.

The most dreaded complication after repair of descending thoracic aneurysms is paraplegia, which continues to occur in a small proportion of patients despite numerous technical efforts to minimize the risk. Simple cross-clamping without distal perfusion can be performed relatively safely if occlusion lasts less than 20 min, but longer unprotected cross-clamp periods are associated with an increased risk of paraplegia. If the cross-clamp period exceeds 40 to 45 min, the risk of paraplegia is over 20 percent, and it approaches 100 percent once the cross-clamp time exceeds 60 min. Research suggests that when the cross-clamp time exceeds 30 to 40 min, perfusion of the distal aorta reduces the risk of paraplegia, renal insufficiency, intestinal ischemia, and reperfusion-related white blood cell activation with multiorgan dysfunction.

Perfusion Technique with Spinal Cord Monitoring

For over 15 years at NYU, a distal perfusion bypass technique with femoral–femoral or atriofemoral bypass (Fig. 19-9) has been used for most patients undergoing elective repair of descending aneurysms. The technique initially was proposed by Cunningham and associates in 1982. Perfusion options include using femoral vein–femoral artery perfusion with an oxygenator, or left atriofemoral artery bypass using heparin-bonded circuits, no oxygenator, minimal heparin, and a cell-saver–rapid infuser. The left atriofemoral bypass technique minimizes the use of heparin and allows better control of the proximal blood pressure, because the left heart is unloaded by the left heart bypass, minimizing the need for nitroprusside. Left atriofemoral bypass is preferred for most patients.

In addition to distal perfusion, a key component of this approach has been the use of *somatosensory evoked potential (SEP)* monitoring to evaluate spinal cord ischemia or the adequacy of perfusion while the aorta is occluded. Research indicates that paraplegia usually results from spinal cord ischemia because of low aortic perfusion pressure or from the direct interruption of critical segmental blood supply to the spinal cord. Diminution of spinal cord SEPs during the cross-clamp time suggests that spinal cord perfusion pressure is inadequate or critical intercostal arteries have been interrupted. If the distal perfusion pressure is low and the SEPs become abnormal, the flow rate is increased until the distal pressure exceeds 55 mmHg. This often results in a return of the SEP amplitude to normal. In patients with refractory shock it is often impossible to achieve an adequate distal perfusion pressure. In a small number of patients the SEPs are lost despite an adequate distal perfusion pressure. In this situation intercostal arteries arising from the aneurysmal segment of aorta should be reimplanted into the Dacron graft. In these patients the loss of SEPs suggests that the blood supply to the distal spinal cord is dependent on critical intercostal arteries arising from the aneurysmal segment of aorta. In approximately one-third of the population the anterior spinal artery is inadequate to supply the distal spinal cord, which receives its major blood supply from segmental arteries arising between T8 and L2. Whether this is because of a true *arteria radicularis magna* (artery of Adamkiewicz), or whether the segmental blood supply is from a cluster of intercostal arteries is debatable. The majority of available data support the idea that several segmental arteries usually are present.

The NYU experience with 78 patients undergoing descending aneurysm repair was reported by Galloway and associates in 1996. A selective operative approach was used in these patients, using bypass with distal perfusion and SEP monitoring for most elective cases and simple cross-clamp with controlled distal exsanguination for others. With this technique, the incidence of paraplegia was low, and it was zero in patients undergoing elective repair. In perfused patients, paraplegia did not occur as long as the perfusion pressure was above 55 mmHg and the SEPs remained intact. The flow rate required to maintain an adequate distal pressure and spinal cord perfusion varied from 3 L/min to as high as 6 L/min.

Many surgical groups recommend the use of a distal perfusion method routinely, especially when the cross-clamp time is expected to exceed 30 to 40 min. Borst recommended the routine use of left atriofemoral bypass for descending aneurysm repair to minimize the risk of paraplegia, renal insufficiency, and death. Lawrie and colleagues reviewed 659 patients who underwent descending thoracic aortic aneurysm resection from 1953 to 1993 at Baylor College of Medicine. The incidence of neurologic injury was reduced by the use of a bypass technique, which they recommend whenever the cross-clamp time is likely to exceed 30 min. The routine use of distal perfusion and SEP monitoring is controversial. Crawford and associates reported no difference in the incidence of paraplegia when using distal perfusion and SEP monitoring compared to the simple cross-clamp method.

Single Cross-clamping with Controlled Distal Exsanguination

The technique of single proximal cross-clamping with controlled distal exsanguination (Fig. 19-10) was popularized by Cooley and Crawford. Theoretically, controlled distal exsanguination reduces venous distention and lowers cerebrospinal fluid pressure, improving cord perfusion during the cross-clamp period and limiting spinal cord ischemia and edema. Experimentally this has been shown to provide some measure of spinal cord protection and to lengthen the amount of time that cross-clamping can be maintained safely, without neurologic injury. Published clinical data are encouraging, showing an acceptably low risk of paraplegia with this approach as long as the cross-clamp period does not exceed 30 to 40 min. In reports from Galloway, Coselli, Crawford, and Cooley the risk of paraplegia was less than 2 percent in selected patients undergoing isolated descending

aneurysm repair with use of the simple cross-clamp with controlled distal exsanguination method. Since no bypass circuit for distal perfusion is required and no heparin is used, the risk of bleeding and coagulopathy may be lower.

Results

Mortality rates are 3 to 6 percent for elective descending aneurysm repair, and 20 percent for emergency surgery in patients with rupture, hypotension, or shock. Variables associated with an increased risk of death include emergent operation, acute rupture, shock, age, and untreated concomitant coronary artery disease.

The most common perioperative complications in descending aneurysm repair are bleeding, renal failure, stroke, myocardial infarction, respiratory failure, and paraplegia. In the NYU analysis of descending thoracic aortic aneurysm repair, the factors most highly associated with an increased risk of paraplegia were emergency presentation and preoperative shock. In patients in whom a repair technique using distal perfusion and SEP monitoring was performed, paraplegia was related to the inability to maintain an adequate distal perfusion pressure above 55 mmHg and to the loss of SEPs. In patients undergoing repair with a nonperfused single- cross-clamp technique, paraplegia was primarily related to the length of the cross-clamp time.

Both perfusion techniques and single-cross-clamping methods are viable options for descending aortic aneurysm repair. The authors recommend using a selective operative strategy that includes both options but prefer a bypass technique with distal perfusion for most patients undergoing elective repair. The risk of paraplegia is exceedingly low with this approach as long as distal perfusion is adequate (above 55 to 60 mmHg) and the SEPs remain intact. The single-cross-clamp technique is particularly useful in selected patients with acute rupture, bleeding, aneurysmal erosion into the lung, or anatomically complicated aneurysms.

The long-term prognosis after aneurysm repair depends on the presence of concomitant coronary artery or cerebrovascular disease and on the presence of aneurysmal disease in other parts of the aorta. Approximately 30 percent of patients with descending thoracic aneurysms develop aneurysmal disease elsewhere, so follow-up imaging studies on a yearly basis are strongly recommended.

New Developments

A technique using endovascular stented grafts for the treatment of descending thoracic aortic aneurysms has been described. A report by Mitchell and associates from Stanford University demonstrated successful results in 44 patients with three deaths (7 percent). Expandable stented grafts are placed percutaneously to exclude the aneurysmal segment of aorta. Further long-term follow-up is necessary to evaluate the effectiveness of this procedure.

Thoracoabdominal Aneurysms

Etiology and Classification

Thoracoabdominal aneurysms usually are associated with atherosclerosis, connective tissue disease, or aortic dissection. Crawford classified thoracoabdominal aneurysms on the basis of the anatomic extent of aortic involvement as follows:

Type I—proximal descending to upper abdominal aorta

Type II—proximal descending aorta to below the renal arteries

Type III—distal descending and abdominal aorta

Type IV—suprarenal and infrarenal abdominal aorta

Physiology of Repair

Thoracoabdominal aneurysms typically involve the segment of aorta where the celiac axis, superior mesenteric artery, and renal arteries arise. Surgical repair of these aneurysms is challenging and may result in transient spinal cord, renal, and visceral organ ischemia, with subsequent ischemic reperfusion-related white blood cell activation, leading to multiorgan injury. The risks of postoperative renal insufficiency and multiple organ failure are higher in repair of thoracoabdominal aortic aneurysms than of other aneurysms. Coagulopathy and bleeding may be significant in these patients. If massive transfusion is required, the risk of multiple organ failure is increased.

The blood supply to the lower spinal cord is segmental and arises from the aorta between T8 and L2 in approximately one-third of the population. Understanding spinal cord ischemia during aortic cross-clamping is particularly important in patients with thoracoabdominal aneurysms, because these aneurysms involve the aortic segment in which the blood supply to the lower spinal cord most commonly arises. Replacement of the thoracoabdominal aorta is associated with the highest risk of paraplegia of any aneurysmal surgery, with a risk ranging from 5 to 40 percent, depending on the extent of aortic involvement and the cross-clamp time.

Operative Treatment

Etheredge and DeBakey described the first surgical approach for thoracoabdominal aneurysms in 1955, which involved replacement of the aorta with a homograft. The DeBakey technique subsequently evolved into reconstruction of the aorta with a long tube graft, from which smaller grafts were individually attached to the celiac, superior mesenteric, and renal arteries. The operative mortality was high, exceeding 50 percent for many years.

In 1965 Crawford described the basic repair technique for thoracoabdominal aortic aneurysms that is still used today. This technique uses the graft inclusion method, with reimplantation of the ostia of the visceral vessels as an island into the side of the aortic Dacron graft (Fig. [19-11](#)). Crawford summarized a 20-year experience with 605 such operations in 1986, with an operative mortality of approximately 9 percent.

The operative exposure requires a large thoracoabdominal incision. The sixth or seventh intercostal space of the left chest is entered, the costal cartilage is divided, and the incision is extended below the umbilicus. The diaphragm is divided circumferentially along the periphery, preserving the central innervation. In the left chest the descending thoracic aorta is isolated proximal to the aneurysm. The spleen, left colon, and kidney are reflected medially, and the retroperitoneum is entered to expose the aorta distally to the bifurcation. The retroperitoneal lymphatics often are tied in continuity.

Once the aneurysm has been exposed the aorta is clamped proximally. Distally the aorta is left open or clamped and perfused. The aneurysm is incised, and an anastomosis is performed between the graft and proximal aorta. Segmental intercostal arteries or clusters of arteries above and below the diaphragm are reimplanted into the graft. The cross-clamp is sequentially moved distally beyond the reimplanted intercostal arteries. The visceral vessels are reimplanted and perfused in a similar fashion. After reimplantation of the visceral vessels an anastomosis between the graft and the distal aorta is performed. This may be done immediately adjacent to the superior mesenteric and renal arteries, immediately below the renal arteries, or at the aortic bifurcation.

Crawford found that the risk of paraplegia could be significantly reduced by reimplanting large intercostal vessels, or clusters of vessels, into the aortic graft. With Crawford's technique intercostal arteries are reimplanted and perfused within 20 to 30 min.

Additional techniques for spinal cord protection include sequential reimplantation of intercostal arteries, bypass methods to increase spinal cord blood flow, the use of intrathecal vasodilators such as papaverine, systemic steroids, intravenous lidocaine for membrane stabilization, systemic hypothermia, barbiturate administration to lower neurometabolism, calcium-channel blockers and oxygen radical scavengers to minimize reperfusion injury, and cerebrospinal fluid (CSF) drainage to decrease spinal cord pressure.

The bypass techniques and the single-cross-clamp technique with controlled distal exsanguination have been used to minimize the risk of paraplegia. Distal perfusion methods, however, are used less frequently with thoracoabdominal aneurysms. The technique is cumbersome because the aorta is clamped above and below the area from which the cord segmental blood supply arises. Separate perfusion must be provided to the visceral vessels, or the cross-clamp must be sequentially moved so that the intercostal vessels are intermittently perfused before reimplantation. Nevertheless, some surgeons advocate perfusion of the aorta whenever feasible.

The single cross-clamp with controlled distal exsanguination is used more commonly. By emptying blood from the lower body (distal exsanguination), the CSF pressure is lowered significantly, which maximizes cord perfusion and increases the safe ischemic interval. For thoracoabdominal aneurysm repair the controlled distal exsanguination method is often combined with the techniques of CSF drainage to lower CSF pressure and administration of intrathecal papaverine to increase blood supply to the spinal cord by a factor of five. With single cross-clamping and controlled distal exsanguination, CSF drainage, and intrathecal papaverine, the incidence of paraplegia has been as low as 0 to 5 percent in some reports. Despite these advances and the variety of technical options available, the optimal method of spinal cord protection during thoracoabdominal aneurysm repair is controversial.

Results

In 1993 Svensson and associates reported the cumulative Baylor College of Medicine experience with 1,509 patients undergoing thoracoabdominal aneurysm repair over 30 years. The operative mortality rate was 8 percent, and the incidence of paraplegia was 16 percent. The other major complications included renal insufficiency (18 percent), gastrointestinal complications (7 percent), and myocardial infarction. Variables associated with increased operative risk were age, preoperative creatinine level, concurrent proximal aortic aneurysm, concomitant coronary artery or pulmonary disease, and aortic cross-clamp time. Variables associated with an increased risk of paraplegia were cross-clamp time, extent of the aneurysmal involvement (Crawford types I and II), aortic rupture, age, proximal aortic aneurysm, and a history of preoperative renal insufficiency.

The extent of aneurysmal involvement is strongly associated with the risk of paraplegia. In Svensson's report the incidence of paraplegia was 31 percent in patients with Crawford type II thoracoabdominal aortic aneurysms. Similarly, in a report by Griep and colleagues the incidence of paraplegia was 30 percent in patients with Crawford type I or type II aneurysms. In large aneurysms with involvement of more than 10 intersegmental arteries, the risk of paraplegia increased by a factor of 29.

AORTIC DISSECTION

Etiology

Aortic dissection begins as a tear in the intima, with entry of blood and separation of the media for a variable distance, resulting in blood flow down a “false lumen.” A localized aneurysm may develop immediately, or months or years later where the aortic wall has become weakened and enlarged from the original dissection. The disease is 3 to 4 times more common in males than in females and occurs predominantly in older patients. Dissection may occur in any age group, but with certain cases occurring in childhood, usually secondary to coarctation of the aorta.

Aortic dissection usually results from a combination of hypertension and degenerative connective tissue disease. Roberts has emphasized that a history of hypertension is obtainable in 60 to 75 percent of patients, with hypertrophy of the left ventricle present in approximately 90 percent. Roberts determined that hypertension frequently is the precipitating factor in patients with Marfan syndrome who develop aortic dissection and predicted that proper control of hypertension would significantly lower the risk of dissection in all patients.

The strongest predisposing factor to aortic dissection is cystic medial necrosis, which may be idiopathic (Erdheim's cystic medial necrosis) or secondary to a known connective tissue disease, such as Marfan syndrome or Ehlers-Danlos syndrome (see above, Thoracic Aneurysms, subsection Etiology and Pathogenesis). Other factors associated with aortic dissection include aortic coarctation and congenital bicuspid aortic valve. Rarely, an atherosclerotic plaque or traumatic injury serves as the initiating tear site for aortic dissection.

Aortic dissection usually is not caused by atherosclerosis. Atherosclerosis is a proliferative disease of the intima and media, occurring most frequently in the abdominal aorta. Aortic dissection is a disease of the media, almost always originating in the thoracic aorta, although the dissection may continue distally to the aortic bifurcation. Although aortic dissection and atherosclerosis occur in older patients, they are distinctly different and unique disease processes. Rarely, an atherosclerotic plaque serves as a lead site for aortic dissection.

Pathology

The major initiating pathologic event is a tear in the intima and media, usually involving half the circumference of the aorta. The intimal tear permits blood to enter the media and dissect distally. The aortic wall progressively separates ("dissects") with an inner lumen composed of intima and an outer false lumen composed of the media and adventitia. In the classic pathologic analysis published by Roberts, the intimal tear was located in the ascending aorta in about 70 percent of patients, in the aortic arch in 10 percent, in the upper descending thoracic aorta near the ligamentum arteriosum in 20 percent, and in the abdominal aorta in about 2 percent. In a study by Miller and associates the intimal tear was found to be in the ascending aorta in 60 percent of patients, in the aortic arch in 10 percent, and in the descending aorta in 30 percent.

Once the dissection begins, it usually extends rapidly through the thoracic and abdominal aorta into the peripheral arteries. The dissection process extends into a peripheral artery in more than 50 percent of patients. Roberts has estimated that the entire aorta will dissect within minutes unless some structural abnormality that has disrupted continuity of the aortic wall, such as atherosclerosis or coarctation, halts the dissection. If this theory is correct, younger patients with less atherosclerosis would more frequently have dissection involving the entire aorta. A "reentry" tear can be identified in most patients, located in the aorta in about one-half of the patients, and in a peripheral artery in the others.

As the dissection progresses, branch vessels are sheared off and obliterated unless a communication with the false lumen is established. Proximally, the coronary arteries may be involved. Often one or more aortic valve commissures are detached, creating aortic insufficiency. The commissure between the right sinus and the noncoronary sinus is most commonly involved. Distally, any vessel may be involved. Innominate or carotid artery involvement may produce neurologic injury. Obstruction of a subclavian artery may produce arm ischemia and a differential pressure between the two arms. Occlusion of intercostal arteries may cause spinal cord injury with paraparesis or paraplegia. Dissection of renal arteries may produce renal insufficiency, hematuria, oliguria, or anuria. Distally, acute obstruction of the iliac or femoral arteries may cause leg ischemia, manifested with pain, sensory loss, or even gangrene. Overall, approximately 5 percent of patients with aortic dissection have some degree of visceral ischemia, peripheral neurologic injury, or paraplegia on admission.

The dissection may result in a fatal complication at any time. Rupture into the pericardial cavity with cardiac tamponade is the most common fatal complication, probably because the velocity of blood flow and aortic diameter are greatest in the ascending aorta. Rupture into the left pleural cavity or the retroperitoneum occurs less commonly.

Clinical Manifestations

The abrupt onset of excruciating pain, almost immediately reaching its peak intensity, is characteristic of aortic dissection. A patient with a myocardial infarction, by contrast, may gradually develop pain of increasing severity. Sutton and associates reported that chest pain, usually in the anterior chest, occurred in nearly 80 percent of 113 patients with aortic dissection. Back pain occurred in about one-third of the patients, suggesting that absence of back pain does not rule out a dissection of the thoracic aorta. Another characteristic is the tendency for the pain to migrate into different areas as the dissection extends distally. Many different pain syndromes can occur. The pain may radiate to the neck, the arms, the epigastrium, or the legs. It might mimic myocardial infarction or pulmonary embolus. The diagnosis of aortic dissection must be considered in patients with suspected myocardial infarction or pulmonary embolus in order to avoid a fatal treatment error. Pain is seldom completely absent in a patient with acute aortic dissection, although Spittell and coworkers reported that 15 percent of 236 patients presented with painless dissection.

Other presenting symptoms include congestive heart failure, tamponade, syncope, stroke, peripheral neurologic injury, leg or arm ischemia, paraplegia, gastrointestinal hemorrhage, hematuria or anuria, hoarseness, dysphagia, superior vena cava syndrome, and aortic insufficiency. In the Spittell study the initial clinical impression was a diagnosis other than aortic dissection in 38 percent of the patients. An awareness of the variety of symptoms associated with aortic dissection is essential if the diagnosis is to be made promptly.

Classification

DeBakey classified aortic dissections into types I, II, and III (Fig. 19-12). In the DeBakey type I dissection the tear site originates in the ascending aorta, usually just above the left main coronary artery, and the dissection continues distally into the descending or abdominal aorta. In the type II dissection the tear site is in a similar location in the ascending aorta, but the dissection stops distally at the innominate artery. In the type III dissection the tear site originates in the upper descending thoracic aorta, just distal to the subclavian artery; in type IIIA the dissection is localized in the thoracic aorta, and in type IIIB the dissection proceeds into the abdominal aorta.

The Stanford classification proposed by Miller is based on the clinical course and the surgical significance of the dissection (see Fig. 19-12). Stanford type A dissection includes any dissection involving the ascending aorta (DeBakey types I and II), and Stanford type B dissection involves only the descending aorta (DeBakey type III). Overall, approximately two-thirds of patients with acute dissection have Stanford type A, and one-third have Stanford type B. This is significant, because the prognosis without treatment is much worse for Stanford type A dissections.

Diagnostic Studies

On the chest radiograph a widened mediastinum or a left pleural effusion from extravasation of blood frequently is seen. In some patients the chest radiograph is completely normal. The electrocardiogram (ECG) is of value in distinguishing a dissection from a myocardial infarction, but there are no characteristic features of aortic dissection. Occasionally the ECG is misinterpreted because of the presence of ST-segment elevation secondary to hypertension and ventricular strain. If patients are treated for myocardial infarction with thrombolytic therapy on the basis of this misinterpretation, catastrophic exsanguination may occur. The most common abnormalities on the ECG are sinus tachycardia or left ventricular hypertrophy from the antecedent hypertension.

Transesophageal echocardiography (TEE) is the initial diagnostic procedure of choice for most patients with suspected aortic dissection (Fig. 19-13). The examination can be performed in the emergency department immediately whenever a diagnosis of aortic dissection is considered. TEE is sensitive and specific, establishing the diagnosis with a 99 percent accuracy. The tear site usually can be located, and the ascending aorta and aortic arch can be assessed and potential complications such as aortic valvular insufficiency and cardiac tamponade identified.

If the cardiology team is not equipped to make the diagnosis promptly by TEE, other valuable tests include a rapid-sequence CT scan with contrast, MRI, or enhanced MR angiography (Fig. 19-14). Aortography is highly accurate, but it is seldom necessary.

Medical Treatment

Once the diagnosis of aortic dissection is established, immediate drug therapy to control the blood pressure and decrease the forceful contractility of the left ventricle (dp/dt) is initiated. Antihypertensive therapy should be started when the diagnosis is suspected because lowering the blood pressure may stop the dissection process and prevent exsanguination. Various pharmacologic regimens are available, using combination drug therapy to achieve beta-adrenergic blockade and afterload reduction. The primary goal of medical therapy is to reduce shear stress by reducing left ventricular dp/dt. The systolic blood pressure should be kept below 110 to 120 mmHg.

Natural History and Operative Indications

Patients with acute Stanford type A dissection are at risk for early death because of aortic rupture or cardiac and neurologic complications. These patients have an extremely poor prognosis with medical therapy, and they should be operated on emergently. In contrast, patients with acute Stanford type B dissection have a relatively good prognosis, and early operation in this group generally is recommended only for patients with complications.

The high mortality rate for unoperated patients with Stanford type A dissection is documented in virtually every report. Thirty to 50 percent of these patients die within 24 h, 50 to 75 percent within 1 to 2 weeks, and 90 percent within 3 months. In a classic review of 425 cases by Hirst, 74 percent of patients with type A dissection died within 2 weeks and 91 percent within 6 months. Of the 62 patients reported by Lindsay and Hurst, almost all of the untreated type A patients died within 1 month.

The survival rate for patients receiving nonoperative therapy for Stanford type B dissection is much better, with a 1-month survival rate of 85 to 90 percent. Consequently, most patients with type B dissections are treated medically unless a complication develops. Complications requiring immediate operative treatment are rupture, hemodynamic compromise, prolonged pain, aneurysm expansion, visceral or limb ischemia, and new neurologic signs. Close observation is mandatory in patients receiving medical therapy. This includes serial hematocrit determinations, chest x-rays, and follow-up imaging studies during the initial hospital stay. Approximately 10 percent of patients with acute type B dissection treated medically develop a serious complication within 2 weeks, and prompt surgery is indicated for these patients.

In patients who survive acute aortic dissection a chronic aneurysm may develop, usually with a double lumen in the distal aorta. Blood flow often is present in both lumens, although the false lumen clots and heals in approximately 20 percent of the patients. When flow is present in both aortic lumens, the visceral blood supply may arise from the true lumen or the false lumen. For example, one renal artery may arise from the false lumen and the other from the true lumen, or both renal arteries may arise from the false lumen while all other vessels arise from the true lumen. Frequently, the aorta gradually becomes aneurysmal, especially if hypertension is poorly controlled. For patients with chronic aneurysms secondary to dissection, surgical intervention is recommended when the aorta grows larger than 5 to 6 cm in diameter, similar to the recommendations for other patients with chronic aneurysms. Patients with chronic aortic dissection must be monitored closely with yearly imaging studies; approximately 30 to 40 percent of these patients require surgery within 5 years.

Operative Treatment of Stanford Type A Dissection

Modern surgical treatment of ascending aortic dissection evolved from the work of DeBakey and Cooley, who reported successful excision and grafting of a chronic ascending dissection in 1955. In the early years the operative mortality exceeded 50 percent. Today the mortality rate for repair of acute type A dissection is less than 10 percent, which

compares favorably to the poor prognosis with medical therapy. Prompt operation is recommended for almost every patient with acute Stanford type A aortic dissection.

The main objectives of operation are to remove the intimal tear site, to replace diseased or dilated aorta as necessary, to obliterate the false lumen and redirect blood flow into the true lumen, and to correct associated valvular insufficiency or coronary ischemia. These goals usually are best accomplished with use of deep hypothermia and circulatory arrest (described above for arch aneurysm repair). Use of circulatory arrest allows the surgeon to avoid clamping and potentially injuring the diseased aorta and allows performance of the distal anastomosis “open,” under direct vision. At NYU a variation of the hemi-arch replacement technique (Fig. 19-15) is used almost exclusively for repair of acute type A dissections. The technique includes internal replacement of the dissected aortic segment with a Dacron graft.

The most frequent cause of operative death is hemorrhage. Performing the distal arch anastomosis with an “open” technique during circulatory arrest permits precise inclusion of all layers of the dissected aorta. The anastomoses usually are performed with a continuous suture of 4-0 polypropylene; excessive tension on the suture line, which may lacerate the friable intima, is avoided. Once the distal anastomosis is completed, the prosthetic graft is occluded and flow to the brain is restored while the proximal anastomosis is performed. The aortic wall is closed around the graft to complete the graft inclusion technique. This technique limits the risk of operative exsanguination.

Alternatively, the aorta may be excised totally, with removal of the tear site and any aneurysmal segments. The intima and adventitia are reapproximated proximally and distally with Teflon felt reinforcement, obliterating the false lumen. An end-to-end interposition Dacron graft is then inserted proximally and distally. This method may be associated with fewer late false aneurysms, but the risk of early bleeding may be increased.

Miller reported that excision of the intimal tear site does not influence late survival. In contrast, the NYU experience suggests that removal of the tear site from the circulation is a basic principle in the treatment of aortic dissection and should be done whenever possible.

When the aortic valve is involved with aortic dissection, resulting in aortic insufficiency, resuspension of the valve has been highly effective. Fann and associates reported satisfactory durability after aortic valve resuspension. In the NYU experience reported by Galloway, patients with severe valvular insufficiency underwent successful valve repair using valve reconstruction techniques adopted from the homograft experience. If a competent valve cannot be assured, however, aortic valve replacement should be performed; the long-term results are excellent after valve replacement under these circumstances. Overall, the risk in acute type A aortic dissection repair is relatively low, with an operative mortality rate of 5 to 10 percent in most major medical centers. Factors that increase operative risk are rupture, shock, and visceral organ ischemia.

Operative Treatment of Stanford Type B Dissection

With Stanford type B dissections originating in the descending thoracic aorta, most groups advocate initial medical therapy. In 10 to 15 percent of these patients urgent operation is indicated for complications such as recurrent pain, progressive mediastinal hematoma, leakage, acute expansion, rupture, visceral organ ischemia, extremity ischemia, progressive neurologic dysfunction, and retrograde dissection with aortic valve involvement.

The operation for repair of type B dissection is performed through a left thoracotomy. The goals of therapy are to exclude the tear site from the circulation, to obliterate the false lumen, and to redirect blood flow through the graft into the true lumen of the aorta distally. The operative techniques used to replace the descending aorta for a Stanford type B dissection are identical to those described previously for aneurysms of the descending thoracic aorta.

The operative mortality rate for repair of acute type B dissection is 10 to 15 percent, primarily because most type B repairs are done emergently. If initial medical therapy is successful and urgent surgery is not necessary, the patient is reevaluated in 1 to 2 months and yearly thereafter. Elective repair is recommended if the patient develops symptoms or progressive aneurysmal disease.

Prognosis

Aortic dissection usually occurs in patients with chronic hypertension and in those with chronic degenerative disease of the aorta. Aggressive treatment of hypertension and careful follow-up for the remainder of the patient's life is mandatory. The residual false lumen beyond the site of repair may gradually enlarge and become aneurysmal within several years. In the series reported by Miller and associates the 5-year and 10-year survival rates were 76 and 37 percent, respectively. Late rupture in another segment of the aorta accounted for 30 percent of the late deaths.

Tight control of hypertension is essential. More than one fatal aortic rupture has resulted from inadvertent cessation of antihypertensive therapy years after recovery from surgical treatment of aortic dissection. Late aneurysm formation in another part of the aorta occurs in at least 30 percent of patients with aortic dissection within 5 years. Therefore, patients with aortic dissection must be monitored carefully for any sign of aortic enlargement; a yearly MRI or CT evaluation for the remainder of the patient's life is recommended.

CHAPTER 20 - Arterial Disease

Kenneth Ouriel
Richard M. Green

The years following World War II have seen a logarithmic increase in the number of patients seeking treatment for diseases of the peripheral arteries. Today, approximately 1 million arterial reconstructions are performed in the United States annually. As the geriatric population grows at a disproportionate rate compared to the general population, the incidence of peripheral vascular disease will increase accordingly.

Of necessity, the evolution of vascular surgery awaited the development of arteriography, anesthesia, anticoagulation, blood transfusion, and synthetic graft materials. Nevertheless, Hallowell of England reported the first successful arterial operation in 1759 when he performed a lateral arterial repair of a traumatic wound. Eck is credited with the first formal blood vessel anastomosis when he sutured the portal vein to the inferior vena cava of a dog in 1877. Murphy performed the first end-to-end arterial anastomosis in a human being two decades later when he successfully rejoined the femoral artery by invagination of the proximal into the distal end after the excision of an arteriovenous fistula of the thigh. Alexis Carrel and Charles Guthrie made remarkable achievements as a result of collaborative efforts beginning in 1904. They pioneered the use of Dorfler's technique of through-and-through sutures of all layers of the vascular wall, and in 1912 Carrel received the Nobel Prize in physiology and medicine for his work on blood transfusion, vascular suture technique, and organ transplantation in experimental animals.

Rapid advances in vascular surgery began after World War II, beginning with the treatment of arterial lesions with endarterectomy by dos Santos in 1947 and with bypass using autogenous vein by Kunlin in 1951. Dubost first replaced an abdominal aortic aneurysm with an aortic homograft in 1951, and Voorhees and Blakemore used a graft made of synthetic fabric the following year. The successful treatment of carotid disease was first reported by Eastcott, Pickering, and Rob in 1954, when a symptomatic carotid bifurcation was resected and reanastomosed; 2 years later Cooley and his colleagues published a report of carotid endarterectomy for stenotic disease.

PATHOLOGY AND PATHOPHYSIOLOGY

Atherogenesis

Vascular injury and thrombus formation are the major events in the formation and progression of the atherosclerotic lesion. The most widely held view on the genesis of atherosclerosis, the "response-to-injury" hypothesis, was advanced by Ross in 1986. Three categories of vascular injury of increasing severity have been proposed (Table 20-1). In type I injury there is a functional alteration of the endothelial cell without morphologic changes. It has been hypothesized that the injury can occur from flow disturbances in certain parts of the arterial tree. Lipids accumulate in macrophages, and the lipid-laden "foam cells" may represent the earliest sign of atherosclerosis. Type II injuries begin with the release of toxic products from the macrophages. The subsequent adhesion of platelets at sites of injury and the release of a variety of growth factors results in the migration and proliferation of primitive smooth muscle cells and the development of the "fibrointimal" lesion. By the third decade of life some of these lesions become soft plaques with a cap of smooth muscle cells and collagen surrounding the lipid material. Type III injuries are characterized by fissures and disruption of the plaque with penetration into the media, exposed fibrillar collagen, increased platelet adherence and activation, thrombus formation, and extensive proliferation of smooth muscle cells. This mural thrombus deposited at the site of plaque disruption is important in the progression of the atherosclerotic plaque.

Platelets

Experimental injury models have characterized the time course of the platelet response. Phase I occurs with the deposition of thrombus composed of platelets and fibrin, beginning immediately after injury and completed within 24 h. Smooth muscle cells in the media begin to proliferate within 24 h. Phase II begins 4 days after injury and continues through day 14 and is characterized by migration of the smooth muscle cells into the intima. Phase III lasts from day 14 to 3 months and is marked by the process of intimal thickening and the accumulation of an extracellular matrix. Pigs lacking von Willebrand factor, a protein important in platelet adherence to injured vessel wall, do not develop spontaneous atherosclerosis. Furthermore, rabbits rendered thrombocytopenic do not develop the same degree of intimal thickening when subjected to balloon catheter injury as animals with normal platelet counts. These observations attest to the importance of the platelet in atherogenesis.

Macrophages

Macrophages are involved in the earliest stages of atherogenesis. These multipurpose cells facilitate the transport and oxidation of cholesterol, secrete a mitogenic growth factor that stimulates the proliferation of smooth muscle cells, and generate toxic products that produce endothelial damage. Most important, macrophages release proteases that digest extracellular matrix, which may be responsible for the plaque disruption that leads to thrombosis.

Plaque Disruption

The intact endothelium is nonreactive to platelets. Recent pathologic data in patients who died of cardiac events suggest that the occluded coronary artery resulted from recurrent episodes of plaque disruption that were serially covered with layered thrombus of varying ages in a repetitive process. The progression of a stenosis from a mild degree of diameter reduction to total occlusion can occur quite rapidly, resulting in distal ischemia in the form of a stroke, myocardial infarction, or lower-extremity gangrene. It has been found, at operation or in postmortem examination, that many of these patients have small to moderately sized lipid-laden plaques with disruption and that the severe stenosis or occlusion was the result mainly of superimposed thrombus. Angiographic studies in patients with acute myocardial infarction who have received thrombolytic therapy have shown that a considerable proportion of these patients have less than a 70 percent stenosis. The soft, lipid-rich plaque of mild to moderate severity is more prone to disruption than the fibrotic, calcified plaque because of its high fat content. Once a thrombus forms over an area of vascular injury, further clot deposition occurs. The luminal thrombus is thrombogenic itself, encouraging continued deposition. The process encroaches on the vessel lumen, resulting in a further increase in the degree of stenosis and an increase in the shear rate. This augmented shear rate stimulates further platelet activation and deposition, and the cycle repeats itself until occlusion occurs.

Tobacco Effect

Cigarette smoking has a well-documented effect on atherogenesis. The Framingham study documented an incidence of peripheral vascular disease in smokers of 0.65 percent, compared to 0.22 percent for nonsmokers. Other studies have shown that the risk for developing intermittent claudication was fifteen times higher in smokers and seven times higher in female smokers than in nonsmokers. The incidences of abdominal aortic aneurysms, amputations, stroke, and myocardial infarctions are all significantly higher in smokers.

The mechanisms by which cigarette smoking exerts its effect on atherogenesis are complex. Nicotine and carbon monoxide appear to be the most harmful constituents. In addition to the systemic effects of increased heart rate, increased blood pressure, and reduced myocardial oxygen delivery, these compounds exert adverse effects on vascular endothelium. Carbon monoxide causes increased permeability of the vessel wall to lipids. This is important because nicotine produces increased levels of circulating free fatty acids, which increase intracellular lipid deposition. Nicotine infused experimentally causes a significant increase in circulating carcasses of endothelial cells. This finding has been reproduced in human beings after smoking only two cigarettes. Nicotine also decreases cell synthesis of *prostacyclin* (*PGI₂*), the most potent inhibitor of platelet aggregation, and promotes the production of thromboxane A₂, which promotes platelet aggregation. Other deleterious effects of smoking include increased blood viscosity and fibrinogen and low-density lipoprotein (LDL) levels and decreased high-density lipoprotein (HDL) levels.

Cessation of smoking reduces the incidence of amputation and increases longevity in patients with peripheral vascular disease, improves walking distances in patients with claudication, and reduces the risk of stroke and myocardial infarction in the general population. The tobacco industry has responded to these data with the so-called low-yield cigarette. Filtered cigarettes reduce exposure to tar and are associated with a lower cancer mortality than unfiltered cigarettes. However, filtered cigarettes are not associated with any reduction in cardiovascular mortality rates. Therefore, the most important prophylactic advice that physicians can give patients is to refrain from smoking.

Prevention

Since lipid-rich plaques and subsequent thrombosis play a major role in atherogenesis, strategies for prevention have focused on the manipulation of lipid metabolism and platelet function.

Lipid Reduction

Evidence of regression of human atherosclerotic lesions is difficult to obtain because of the lack of reliable methods to serially quantitate the extent of the process. Angiographic studies of patients with coronary and femoral artery plaques suggest that some regression does occur with the use of lipid-lowering drugs. These studies have shown a small increase in residual lumen size and suggest that the regression is limited to the soft, lipid-rich plaque rather than the extensive, calcified fibrotic plaque. Thus, clinical usefulness appears to be confined to early, asymptomatic lesions without significant stenosis or occlusion. The National Cholesterol Education Program has proposed that persons without vascular disease maintain an LDL cholesterol level of 130 mg/dL or less. A patient with a level higher than 160 mg/dL should be treated with cholesterol-lowering drugs if diet and exercise do not reduce the levels to acceptable ranges.

Antiplatelet Therapy

The interaction between platelets and the vessel wall is dependent on the balance between thromboxane A₂ and *PGI₂*. Endothelial cells produce *PGI₂*, which is responsible for some of the thromboresistant properties of vascular endothelium. In addition, *PGI₂* enhances the activity of cholesterol ester hydrolase, suggesting a positive feedback between the *PGI₂* system and lipid accumulation in the vessel wall. *PGI₂* generation from atherosclerotic arterial tissue has been shown to be significantly lower than from normal arterial tissue. Platelets in patients with arterial thrombosis produce more thromboxane A₂ than normal.

Aspirin inhibits platelet activation induced by the release of thromboxane A₂ and is the most commonly used antiplatelet drug. Aspirin binds irreversibly to the active site of cyclooxygenase, inhibiting the conversion of arachidonic acid to thromboxane A₂ in the platelet and to *PGI₂* in the endothelium. Aspirin has theoretical limits as an antiplatelet agent since platelet aggregation is a complex mechanism that can also be initiated by adenosine diphosphate (ADP) and thrombin in the absence of thromboxane A₂. A single dose of aspirin leads to a platelet defect that lasts 7 days. The effect on the endothelium lasts for a shorter period, presumably because the endothelium can synthesize new enzyme, whereas the platelet cannot. Studies on human vascular fragments have revealed that aspirin doses of 40 mg/day inhibit both vascular wall *PGI₂* and thromboxane A₂ formation, with a greater effect on the latter. Fewer data are available on the efficacy of other antiplatelet agents that work via selective thromboxane A₂ inhibition, phosphodiesterase inhibition (dipyridamole and iloprost), thrombin inhibition (heparin, hirudin, and hirudin analogues), platelet membrane receptor inhibitors (ticlopidine 7E3), or angiotensin-converting enzyme (ACE) inhibitors (cilazapril).

Large clinical trials have evaluated the role of antiplatelet drugs in the prophylaxis of myocardial infarction and stroke. Overall, regardless of indication, antiplatelet therapy was most effective in the first year of treatment, there was a smaller but still significant benefit in year two, and there was no benefit in year three and beyond. A cumulative risk reduction of 25 percent was independent of disease categories, age, sex, blood pressure, and type of antiplatelet therapy. A separate analysis of the stroke cohort showed that antiplatelet therapy in high-risk patients resulted in a reduction of occlusive stroke occurrence, a small increase in the number of hemorrhagic strokes, and a substantial and significant net

reduction in total stroke occurrence. The effect of antiplatelet therapy on stroke in low-risk patients, i.e., as primary prevention, was unclear. In a cardiac cohort, antiplatelet therapy was shown to reduce the incidence of nonfatal myocardial infarction by 33 percent. Unlike in the stroke group, the cardiac effect was seen in both primary and secondary prevention.

Thrombogenesis

Thrombogenesis may be conceptualized as the interaction of three pathways: coagulation, platelet deposition, and thrombolysis. Coagulation pathways involve the clotting proteins in the plasma, terminating in the cleavage of fibrinogen and the deposition of fibrin matrix. Platelet pathways involve activating substances in the plasma and, as such, are intimately linked to the coagulation pathway. The end result of these interactions is the activation, attachment, and aggregation of platelets at the site of altered endothelial integrity. Thrombolytic pathways involve the cleavage of fibrin by plasmin to maintain luminal patency and tissue perfusion in the event of vessel thrombosis.

Coagulation

The coagulation pathways involve a cascade mechanism, with activation of clotting proteins through two pathways: the intrinsic pathway and the extrinsic pathway. Many of the clotting proteins have been assigned a Roman numeral by the International Committee on Nomenclature of Blood Clotting Factors.

There are two laboratory tests that are widely used to assess the adequacy of anticoagulation. The activated partial thromboplastin time (aPTT) reflects the potential activity of the intrinsic coagulation pathway, and the prothrombin time (PT) provides an index of the extrinsic system. The vitamin K–dependent factors II, VII, IX, and X are synthesized in the liver by gamma carboxylation–dependent mechanisms. Warfarin compounds inhibit the production of the vitamin K–dependent factors. The therapeutic control of warfarin anticoagulation is best monitored with the PT. Heparin achieves anticoagulation through its actions on antithrombin III, a potent inhibitor of factor X and other components, and therapeutic control is generally monitored with the aPTT.

The intrinsic coagulation pathway is initiated with the activation of Hageman factor (factor XII) by a variety of substances, including collagen, trypsin, and endotoxin. Activated factor XII in turn catalyzes the conversion of factor XI to its activated form, and the cascade continues in this fashion through factors IX and X. Activated factor X accelerates the conversion of prothrombin to thrombin, and thrombin cleaves fibrinopeptide A from fibrinogen to form fibrin monomer. Thrombin also activates factor XIII to cross-link the soluble fibrin monomers to form stabilized, insoluble fibrin clot.

The extrinsic pathway is initiated with the release of thromboplastin (tissue factor) from injured endothelial cells, catalyzing the activation of factor X. The coagulation cascade then proceeds through the common pathway to terminate in the formation of insoluble fibrin polymer.

There are several other factors that are important in coagulation mechanisms. Proteins C and S are vitamin K–dependent factors that inactivate factors V and VIII and thus function as natural anticoagulants. Calcium (factor IV) is instrumental in the activation of almost all the coagulation reactions, which explains the anticoagulant mechanism of calcium chelators such as ethylenediaminetetraacetic acid (EDTA) and citrate-phosphate-dextrose compounds. High-molecular-weight kininogen functions with prekallikrein to orient factors XII and XI on negatively charged surfaces to potentiate their activation.

Platelet Deposition

Platelets are membrane-bound cytoplasmic remnants of bone marrow megakaryocytes. Platelet function is essential in the sealing of vascular defects through the formation of a platelet plug. The intact endothelium normally conceals the adhesive glycoproteins (von Willebrand factor, fibronectin, and collagen) from the blood elements, thereby limiting platelet adhesion to sites of vessel injury. Endothelial damage results in platelet adhesion on the vessel wall, as von Willebrand factor binds to exposed subendothelial collagen and platelet membrane glycoproteins Ib and IIb/IIIa to form a bridge between collagen and the platelet.

Platelet activation follows adhesion, mediated by such agents as ADP, thromboxane A₂, collagen, epinephrine, and thrombin. Platelet arachidonic acid is released from membrane phospholipid and is metabolized by cyclooxygenase to prostaglandins G₂ and H₂, a process that is blocked by aspirin. These prostaglandin intermediaries are subsequently converted to the potent platelet-aggregating agent thromboxane A₂. Thromboxane A₂ produces platelet activation by interacting with a receptor located on the surface of platelets; thus it must exit from the platelet to bind to the same or a neighboring platelet in order to be effective.

Activated platelets undergo a process known as the release reaction, with migration of platelet granules to the cell membrane and release of their contents. The alpha granule contains fibrinogen, platelet factor 4, platelet- derived growth factor, von Willebrand factor, and fibronectin. The secretion of these agents from the platelet amplifies the process of activation, resulting in stimulation of neighboring platelets and initiation of platelet aggregation. It is important to note that the arachidonic acid pathway is not absolutely required for platelet activation. Although aspirin-treated platelets cannot generate thromboxane A₂, two agonists, thrombin and collagen, can cause the release of the contents of platelet storage granules even when the arachidonic acid pathway is blocked.

Platelet aggregation occurs through platelet-platelet cohesive attachment, principally by means of a mechanism involving fibrinogen and platelet glycoprotein IIb/IIIa. Glycoprotein IIb/IIIa is the platelet receptor most densely distributed on the cell membrane, with up to 50,000 molecules present on a stimulated platelet. Glycoprotein IIb/IIIa is unique in its ability to bind multiple ligands, including von Willebrand factor and fibrinogen, because of its binding site for the tripeptide arginine-glycine-aspartic acid (RGD, using the single-letter peptide nomenclature), a sequence that is present in all ligands that bind to the receptor. Through its RDG site, fibrinogen binds to the glycoprotein IIb/IIIa receptors of two platelets and forms a bridge between the two platelets, initiating the process of platelet- to-platelet attachment and the formation of a platelet plug.

Thrombolysis

Thrombolysis of formed clot involves the actions of plasmin, a proteolytic enzyme generated by the activation of plasminogen. Activators of plasminogen are present in the endothelium and the plasma (tissue plasminogen activator [t-PA]) and can be prepared from bacterial sources (streptokinase) or renal parenchymal cell culture techniques (urokinase). Factor XIIa and prekallikrein also activate plasminogen. Inhibition of plasmin occurs principally through the actions of a₂-antiplasmin. The binding of free plasma plasmin to antiplasmin is critical to the physiologic control of thrombolysis to prevent a systemic fibrinolytic state.

Plasmin lyses both fibrinogen and fibrin to produce proteolytic fragments X, Y, and A through E. Laboratory confirmation of thrombolysis is accomplished by measuring the level of generic fibrin degradation products or of *D dimer*, a unique fragment formed by the covalent binding of two fragment D moieties.

Pathophysiology of Arterial Obstruction

Peripheral arterial blood flow follows the physical principles of fluid dynamics as described in Bernoulli's principle, which characterizes the energy changes of liquids flowing in pipes, and Poiseuille's law, which describes the effects of viscosity on blood flow. A full explanation of these laws and the impact of the variables in the circulation is beyond the scope of this text. There are, however, a number of concepts that are necessary for understanding the basic pathophysiology of arterial occlusive disease.

Critical Arterial Stenosis

A critical stenosis may be defined as that degree of narrowing sufficient to produce a pressure drop. Pressure gradients occur as a result of energy losses and do not become evident until the cross-sectional area of a vessel is reduced by more than 75 percent. In practice, the precise measurement of an area reduction is difficult to obtain because most plaques are irregular. If the lesion is concentric, however, a 75 percent reduction in area corresponds to a 50 percent reduction in diameter. Energy losses also depend on the magnitude of blood flow across the stenosis, and blood flow is determined by the blood pressure and the resistance of the runoff bed. Thus in the coronary and carotid systems, where peripheral resistances are low, a critical stenosis may be reached with less luminal narrowing than in higher-resistance circuits such as the lower-extremity vessels. This phenomenon also explains how an iliac artery lesion that looks insignificant on arteriography can severely restrict a patient's activities when the resistance in the runoff bed is reduced during exercise.

The length of a stenosis is far less important than its diameter. Length figures in Poiseuille's equation in the first power, whereas radius is elevated to the fourth power. Doubling the length of a stenosis doubles the energy loss, but halving the radius increases the losses by a factor of sixteen. A considerable energy loss also occurs at the entrance and at the exit of a stenosis, where the losses are related to the fourth power of the diameter ratio of the normal to the stenotic segment. Thus separate stenoses of equal diameter are more significant than a single stenosis of the same diameter whose length equals the sum of the lengths of the two independent lesions.

Collateral Circulation

Flow reduction to the runoff bed distal to a stenosis depends on the collateral network, a group of preexisting pathways that enlarge as a stenosis develops in the main arterial supply. Collateral pathways may provide flow distal to an occlusion sufficient to preserve viability. Perfusion through collateral channels is never as efficient as through a patent artery, however, because the resistance of the collateral network always exceeds that of the major artery. Although arterial flow may be normal at rest, exercise will almost always bring out abnormalities in arterial flow.

Autoregulation

The blood vessels in skeletal muscles are innervated by vasoconstrictor and vasodilator nerve fibers, but these actions are superseded by locally produced metabolites. The term *autoregulation* refers to the ability of vascular beds to provide a constant blood flow regardless of perfusion pressures. This adaptability is the result of a myogenic response of the vessel wall to the local chemical environment. The mechanism fails and flow is not maintained when perfusion pressures fall below 20 to 30 mmHg for skeletal muscle and 50 to 60 mmHg for the brain.

Effect of Exercise

Resting blood flow is decreased in patients with ischemic rest pain but is normal in patients with intermittent claudication because of collateral circulation and autoregulation. With exercise, however, the intramuscular arterioles dilate, resistance falls, flow increases, and a pressure gradient develops across the arterial stenoses and collateral channels. A previously palpable pedal pulse may be lost as the distal perfusion pressure falls. Blood flow is insufficient to meet the local demands of the tissues. Metabolites accumulate, producing the pain characteristic of intermittent claudication.

DIAGNOSIS OF OCCLUSIVE ARTERIAL DISEASE

Clinical Manifestations

Atherosclerotic peripheral arterial disease is a generalized process. The patient who presents with symptoms of peripheral vascular disease is likely to have some degree of coronary artery disease as well. More than 50 percent of the mortality following arterial reconstruction of any type is attributable to cardiac events. Hertzner and colleagues found, in

coronary arteriograms they performed on 1000 consecutive patients undergoing elective vascular procedures, that over 90 percent of the patients had evidence of coronary artery disease. Triple-vessel disease was identified in 30 percent of these patients.

Despite the high prevalence of coronary disease in patients with peripheral vascular disease, routine coronary arteriography has not been found to be an efficient method of screening. The risk of perioperative cardiac morbidity can, however, be predicted with the Goldman cardiac risk index and other indices that stratify patients into risk groups on the basis of such parameters as age, type and setting of operation, general medical condition, cardiac history, and findings on electrocardiogram (ECG). The sensitivity of the Goldman index is not as high as originally suggested, and many patients at high risk for perioperative morbidity will escape detection. Recommendations for preoperative cardiac evaluation are discussed in the section on aneurysms but apply to all types of elective arterial reconstruction.

Acute Arterial Occlusion

Patients with acute arterial occlusion often seek treatment promptly because of the catastrophic nature of their symptoms. It is essential that the treating physician respond rapidly, because the process may quickly become irreversible. There is no fixed time after acute occlusion that ischemia is irreversible and reperfusion no longer indicated. The time interval depends on the preocclusive state, i.e., the status of the collateral circulation. Examination of the extremity is therefore the single most important determinant of urgency.

The P's of Acute Ischemia

The cardinal features of acute arterial ischemia each begin with the letter *p*. They are: pulselessness, pallor, poikilothermia (the tendency to drift toward ambient temperature), pain, paresthesia, and paralysis.

Once the diagnosis of acute arterial ischemia is made, the site of occlusion is localized by the absence of pulses on physical examination; for example, the presence of a palpable femoral groin pulse in the absence of a palpable popliteal pulse localizes the site of obstruction to the superficial femoral artery. Distal pulses are not palpable in patients with acute ischemia of an extremity, and they may or may not be detectable with Doppler ultrasonography. The presence of Doppler signals alone has little bearing on the presence or absence of ischemia. The degree of collateral circulation around the occlusion determines whether an audible signal is present and the urgency of revascularization. An objective determination of the adequacy of circulation can be made only by measuring the Doppler segmental pressures. An embolic occlusion in a previously normal extremity will be poorly collateralized, whereas a thrombotic occlusion of a stenotic vessel is usually well collateralized. Pallor is associated with decreased skin perfusion and often is accompanied by poikilothermia.

Pain is present in the vast majority of patients with acute ischemia. It is not a reliable criterion in an extremity without sensation, in a patient on mechanical ventilation, or in an unconscious patient. In these patients the other signs of acute ischemia must be relied upon.

The peripheral nerves are the most exquisitely sensitive tissues of the extremity. Therefore, the most important signs for evaluating the degree of ischemia are the neurologic signs, namely, paresthesia and paralysis. An extremity that is paralyzed from ischemia will certainly develop gangrene if left untreated. The earliest neurologic findings in the acutely ischemic lower extremity are in the distribution of the peroneal nerve and consist of hypesthesia in the first metatarsal space, inability to dorsiflex the great toe, and eventually a foot drop. Immediate revascularization is indicated when any of these neurologic signs is present.

Chronic Arterial Ischemia

Chronic arterial ischemia is almost always caused by atherosclerotic occlusive disease and is associated with tissue perfusion that is inadequate to meet the metabolic demands of the end organ. In some patients this occurs only when the demands are increased, such as during exercise, and produces the symptom of intermittent claudication, the most common complaint of patients with chronic arterial ischemia. Pain is experienced during exercise in the region of large muscle groups distal to an arterial occlusion or stenosis and gradually disappears as the activity ceases. Walking tolerance is diminished as the degree of arterial insufficiency increases. The symptom of intermittent claudication alone does not indicate that the extremity is immediately threatened. It does indicate, however, that the patient has a 10-year cardiovascular mortality rate up to fifteen times higher than those without peripheral arterial occlusive disease. This observation mandates careful assessment and treatment of underlying cardiovascular disease, including risk factor modification.

When metabolic needs cannot be met at rest, a state of critical ischemia is said to exist, and revascularization is indicated to avoid tissue loss. Symptoms may take the form of ischemic rest pain, nonhealing ulcerations, or frank gangrene. Ischemic rest pain is a constant burning type of pain that typically involves the distal foot, occurs when the foot is elevated, and is relieved when the foot is dependent. Rest pain can be distinguished from other types of severe foot pain because patients with other causes such as diabetic neuropathy do not have the same positional dependency.

Physical Examination

The diagnosis, site of occlusion, and extent of disease can almost always be determined by physical examination of the patient. A complete vascular examination involves inspection, auscultation, and palpation. The skin is inspected for color changes and integrity, the status of the nails, and the presence or absence of hair. The stethoscope is used over the neck, abdomen, and groin and the blood pressure is taken in both arms. Pulses are palpated in the upper extremity (brachial, radial, and ulnar) and the lower extremity (femoral, popliteal, posterior tibial, and dorsalis pedis). The abdomen is palpated for the presence of aortic enlargement. The legs are elevated and the color of the feet is noted. Normally perfused extremities do not blanch, whereas those with significant ischemia will blanch with elevation above the level of the heart. The legs are then lowered, and the time it takes for capillary filling to occur is noted. Finally, the legs are placed in a dependent position. Severely ischemic feet exhibit a cherry-red discoloration known as dependent rubor.

Diagnostic Vascular Testing

Noninvasive vascular diagnosis has emerged as an important tool for screening, preoperative assessment, and postoperative follow-up of patients with peripheral vascular disease. Improvements in instrumentation and techniques have resulted in the development of accurate methods of defining the anatomic and physiologic significance of lesions of the peripheral vascular system with little discomfort to the patient.

The Doppler ultrasonic flow detector is the most frequently used instrument in vascular diagnosis. It detects the frequency shift of ultrasound reflected off moving particles in the blood. The signal is processed in a variety of ways, ranging from an audible sound to a complex color-flow map. The combination of real-time B-mode scanning and Doppler spectral analysis, referred to as Duplex scanning, is the most accurate noninvasive method of detecting and following vascular lesions. In addition to providing an image of vascular lesions, it also permits an estimation of blood flow. The major disadvantages of Duplex scanning are the high cost of the equipment and the need for operator skill.

Plethysmography was once the mainstay of noninvasive diagnosis, but it has been replaced by the direct imaging modalities. Plethysmography detects changes in volume associated with cardiac contractions. Inferences concerning the vascular status are made from the character of the pulse wave. This modality is most often used for measuring segmental limb blood pressures and ophthalmic artery pressures.

Individual Testing Modalities

Doppler Segmental Blood Pressure Determination

In normal extremities the systolic blood pressure is slightly higher in the ankle than in the arm. This pressure differential is best expressed as a ratio, known as the ankle/brachial index (ABI). In normal volunteers the ABI averages 1.1; a value below 0.97 indicates some degree of arterial compromise. Patients with claudication usually have an ABI of 0.5 to 0.7. Patients with critical ischemia have an ABI of less than 0.5 and an absolute ankle pressure of less than 50 mmHg. When the ABI is reduced, segmental pressure measurements are performed by placing blood pressure cuffs on the high thigh, low thigh, midcalf, and ankle to identify the site of the lesion producing the pressure gradient. Patients with diabetes or end-stage renal disease may have vessels that are not compressible, rendering the test uninterpretable. In this situation, plethysmography is more accurate than pressure measurements. Additional information can be obtained by having the patient exercise, which exacerbates a pressure gradient in patients with vascular lesions but has minimal effects in those without.

Duplex Scanning

Duplex testing simultaneously evaluates the velocity of blood flow and displays this information in one of two ways. In the first, older method, the B-mode anatomic image is displayed on a screen and pulsed Doppler measurements are made as the operator positions a cursor at desired points within the vessel. The velocity of blood flow is interrogated within a small sample volume and expressed along an x-axis representing time. In the second, newer method, the machine continuously displays the velocity of particles in real time, expressed on the B-mode anatomic image in color, with slow or negative flow represented on one end of the color spectrum (e.g., blue) and rapid flow on the other (e.g., red). This technique is called a "color-flow" scan. The ease and accuracy of Duplex scanning has allowed the performance of carotid endarterectomy without preoperative arteriography in many institutions.

Arteriography

Significant advances in contrast media, catheter systems, and imaging techniques provide the essential information about arterial anatomy that makes definitive therapy possible. Today's ionic contrast agents use iodine attached to water-soluble carrier molecules. Many of their adverse side effects are related to a high concentration of sodium or meglumine. Contrast agents are excreted in the kidney, and patients with underlying renal dysfunction, particularly those with diabetes, are at higher risk for complications. Caution must be exercised when the serum creatinine concentration is greater than 2.0 mg/dL, and all patients must be well-hydrated before the study. The dye load is generally kept below 200 mL; normal individuals can tolerate volumes exceeding three times this amount. Neurotoxicity with seizures, cortical blindness, or frank stroke can develop, particularly with the concentrated (>60 percent weight/volume) sodium-containing agents. The newer agents have osmolalities of 600 to 900 mOsm, compared to 2000 mOsm in the conventional agents. The low-osmolality agents have clear advantages but cost considerably more than the conventional agents.

Idiosyncratic contrast reactions, with asthma, laryngeal edema or spasm, and cardiovascular collapse occur infrequently. These reactions are independent of dose. Although there is no reliable sensitivity test for these reactions, it is known that alcoholics, those allergic to iodine, and those with prior serious reactions are more likely to be affected. The absence of a reaction does not ensure that no reaction will occur with reexposure. Similarly, one reaction does not imply that subsequent exposure will result in another reaction. Since these reactions appear to be immune system-related, prophylactic steroids and antihistamines are administered to high-risk patients. Low-osmolality agents should be used in any patient who is at high risk for a contrast reaction.

Complications

The common femoral artery is the preferred site of arterial access. The brachial route can be safely employed in most individuals, but patients with small arteries (e.g., women) or calcific upper-extremity vessels (e.g., diabetics) have a higher rate of complications, such as localized hematoma formation and nerve palsy as well as arterial thrombosis. The percutaneous technique described by Seldinger is used by most angiographers. A guide wire is advanced under fluoroscopic guidance to the appropriate site, and a catheter is advanced over the wire. Iatrogenic damage from arterial catheterization may present as hemorrhage, dissection, thrombosis, embolus, false aneurysm, or arteriovenous fistula (Fig.

20-1). The reported incidence of these injuries varies from 1 to 2 percent for diagnostic procedures but is much higher when endovascular therapeutic modalities such as balloon angioplasty are performed.

Prompt diagnosis and intervention are necessary for successful treatment of these complications, which are increasing in incidence as the larger- catheter systems are used for endovascular manipulations. The critical risk factors are the size of the catheter and sheath, the site and method of puncture, and the duration of the procedure. Large, stiff catheter systems, axillary and brachial artery punctures, sheaths left in place for protracted periods, and use of anticoagulants or fibrinolytic agents are all associated with a higher incidence of complications. False aneurysms are more common in obese patients, in whom it is difficult to hold effective pressure over the cannulation site. Punctures of the profunda femoris and superficial femoral arteries are more frequently associated with false aneurysms. The thromboembolic complications require immediate operative intervention. Arteriovenous fistulae also require operative repair but are not as urgent. Femoral false aneurysms may be given a trial of compression with the Duplex probe, applying increasing pressure until flow is obliterated. If the patient is not on anticoagulation therapy, the aneurysm will frequently thrombose after 20 to 40 min of occlusion. Otherwise, operative repair is necessary.

Interpretation

The interpretation of arteriograms is a skill that must be gradually acquired. The older “cut films” clearly displayed bony landmarks; the newer digital subtraction images are more difficult for the novice to decipher. Since atherosclerotic plaques typically form at bifurcations, multiple views are necessary to view these bifurcations in profile. This is particularly important in viewing the bifurcations of the common carotid, femoral, and iliac arteries. Simultaneous biplane arteriography minimizes the chances of missing a significant lesion because of vessel overlap, but is not always available or possible. Several injections may be necessary while filming in different obliquities to open up bifurcations. Occasionally vessels do not fill and are considered occluded because the volume of contrast is inadequate or the exposure is too early after injection. If occlusion is diagnosed, contrast must opacify either the distal portion or a branch of the occluded vessel. This may require delayed filming. Digital recording techniques have improved visualization of distal vessels and reduced interpretive errors due to nonvisualization.

Other Procedures

Spiral Computed Tomography

Spiral computed tomography (CT) is a noninvasive modality that provides computer-reformatted images of a contrast-enhanced arterial lumen. The patient is advanced through a rotating gantry as contrast is administered intravenously. Rapid imaging produces a CT image similar to that obtained from conventional arteriography. Three-dimensional reconstructions of the data using shaded-surface or color display permit images that may be rotated and viewed from a variety of angles. Spiral CT has been most useful in the imaging of aortic aneurysms and plays a pivotal role as a preoperative tool in endovascular aortic reconstruction. Newer software provides reasonably good images of the carotid bifurcation and other vascular structures.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) has been used as a less invasive, contrast-free alternative to conventional angiography and offers the added advantage of improved visualization of patent distal vessels when flow is minimal. The usual contraindications to magnetic resonance imaging exist, including the presence of metallic objects, such as intracranial vascular clips, electronic devices such as pacemakers, and claustrophobia. In addition, MRA requires immobilization for a relatively long period, especially when many vascular segments are interrogated. The cost of the test is considerable, and the most technologically advanced hardware is required to produce acceptable images. MRA has been successfully employed for the carotid bifurcation, the abdominal aorta, and the distal lower-extremity vasculature. Although Duplex ultrasonography still provides sufficient information at a considerable savings, MRA will have an increasing role in the planning of abdominal and lower-extremity arterial reconstructive procedures. MRA provides adequate visualization of venous structures inaccessible to ultrasound and is an excellent choice in the delineation of intracavitary venous disease, such as vena caval, renal, and mesenteric thrombosis.

ANEURYSMS

Classification

An aneurysm is an irreversible dilatation of an artery to at least one and one-half times its normal diameter. The dangers of these pulsatile masses whose “bright red blood ... spurted forth with much violence” have been known since the writings of Galen. Aneurysms may involve all layers of the arterial wall (true aneurysm) or only a portion of the vessel wall or surrounding tissue (false aneurysm). Aneurysms can be classified as nonspecific, traumatic, dissecting, mycotic, anastomotic, childhood, and those associated with pregnancy. Whatever the cause, once an aneurysm is formed it tends to enlarge and may ultimately produce serious and even lethal consequences.

Rupture occurs when the tangential stress at any point exceeds the tensile strength of the wall. Arterial wall strength is dependent on collagen, whose tensile strength is ordinarily far in excess of the wall tension. The collagen content of aneurysmal vessels is less than in atherosclerotic and normal vessels, however, placing a greater load on each fiber. The Laplace's law, which relates the tensile stress to wall pressure and radius, traditionally has been used to explain why large aneurysms rupture. The stress on the arterial wall is best expressed as pressure times radius divided by wall thickness, a modification of Laplace's law that is applicable only to thin- walled structures, in which the difference between inside and outside radius is negligible.

Degenerative Aneurysms

The most common type of aneurysm has been called atherosclerotic, but since the role of atherosclerosis in aneurysmal disease is unclear, the term “degenerative” is more appropriate. This view is supported by histologic evidence that demonstrates degeneration of the arterial wall. The intima usually is absent and replaced with compacted fibrin in multiple layers; the media has fragmented and reduced numbers of elastic lamellae; and, most important, there is focal loss of elastic tissue. Normal aortic tissue contains 12 percent elastin whereas aneurysmal aortic tissue has only 1 percent elastin. Biochemical data suggest that aneurysm pathogenesis may be related to a systemic connective tissue disorder. An imbalance between the two enzymes important in the metabolism of elastin, elastase (degradation) and a α_1 -antitrypsin (synthesis), has been identified in patients with aneurysms as compared to occlusive disease. This imbalance becomes even more pronounced in multiple aneurysms and ruptured aneurysms.

Traumatic Aneurysms

Many early descriptions of aneurysms dealt with traumatic or false aneurysms. Most traumatic aneurysms today are due to arterial catheterization or penetrating injuries. These lesions are characterized by a focal defect in the arterial wall, with the hemorrhage controlled by the surrounding tissues. With time, a fibrous capsule forms around the hematoma, but a definite risk of rupture is present because the surrounding tissues do not withstand arterial pressures and cannot contain the hemorrhage indefinitely.

Poststenotic Aneurysms

True aneurysms (involving all three layers of the normal arterial wall) can occur from the hemodynamic perturbations associated with an arterial stenosis. Aneurysms due to poststenotic dilatation are most often seen in thoracic outlet syndrome distal to a cervical rib, distal to coarctation of the aorta, and distal to aortic or pulmonary valvular stenoses (Fig. 20-2). These aneurysms do not have any preexisting defect but become dilated, possibly as a result of the increased lateral wall pressure suggested by Bernoulli's theorem. Once dilated, these arteries progressively enlarge according to Laplace's law.

Dissecting Aneurysms

The primary pathologic process in a dissecting aneurysm is a longitudinal splitting of the layers of the arterial wall. Whether the process begins with hemorrhage within the medial arterial layer or with a tear in the intima is unclear. The end result is a proximal intimal defect that allows blood to flow into a false channel that “dissects” between the intima and the inner two- thirds of the media. A site of reentry can occur distally, allowing blood to flow through the false channel. External rupture of the outer wall may occur, with exsanguinating hemorrhage. Hypertension is found in 75 percent of patients. Other, less common causes include Marfan's syndrome, Ehlers-Danlos syndrome, cystic medial necrosis, blunt trauma, and cannulation during cardiopulmonary bypass.

Mycotic Aneurysms

Mycotic aneurysms—i.e., aneurysms that are infected—can occur anywhere in the body as a consequence of either a blood-borne infection (intravascular) or an infection introduced from outside (extravascular). Blood-borne mycotic aneurysms can be further divided into preexisting aneurysms that become secondarily infected and mycotic aneurysms secondary to microbial arteritis. The classic type of this latter entity is the syphilitic aneurysm now rarely seen in the Western world, but formerly the cause of over 50 percent of all aneurysms. The only other bacteria with an affinity for arterial walls are *Salmonella* and *Staphylococcus*, which are now the most common organisms cultured from mycotic aneurysms. Infection of a preexisting aneurysm is unusual even though aortic aneurysms often grow bacteria from cultured intravascular thrombi.

The most common type of extravascular infected aneurysm follows a penetrating injury that contaminates the arterial puncture site and infects the resultant hematoma. Common in the era of bloodletting, the incidence of these aneurysms is increasing in intravenous drug users. Another form of extravascular infected aneurysm is the infected anastomotic aneurysm. Contamination can occur at the time of operation, from erosion of the graft material into the gastrointestinal tract, or from a contiguous hematoma secondarily infected from systemic sepsis.

Mycotic aneurysms should be suspected in patients with sepsis and with inflammatory changes around a pulsatile mass. Intravenous antibiotics are begun on the basis of results of blood cultures and clinical history. Since rupture carries a high morbidity and mortality, emergent operation is indicated after the necessary preparations.

Principles of Operation

The first operative decision in mycotic aneurysm is whether revascularization is necessary to prevent tissue loss. If so, a planned two- stage procedure is recommended. The initial stage creates an extraanatomic bypass in a remote operative field through uninfected tissues using autogenous tissue if possible. The second stage consists of resection of the infected arterial segment, debridement of surrounding tissues, and irrigation and drainage with a closed perfusion system of 0.1% povidone-iodine solution. If the clinical situation precludes a first-stage remote bypass or the need for revascularization is not certain, the infected aneurysm is approached directly. The same principles of wide excision, debridement, and irrigation are used. If revascularization is necessary, it is done through uninfected tissues immediately after the wounds are closed and all gowns, gloves, drapes, and instruments have been changed. Antibiotics are continued for many months, usually through a long-term indwelling intravenous-access catheter. Patients with *Salmonella* infections are placed on lifelong treatment.

Anastomotic Aneurysms

Since primary healing of a prosthetic anastomosis never occurs, anastomotic integrity depends solely on the strength of the suture line. Anastomotic aneurysms are the result of a separation between a graft and the host artery, forming a sac that becomes encapsulated with fibrous tissue. These false aneurysms contain no elements of the arterial wall. Most anastomotic aneurysms involve the common femoral artery after aortofemoral bypass.

Etiology

Any suture material that is degradable or easily broken can produce an anastomotic aneurysm. Silk has been abandoned as a vascular suture material because of its high incidence of late fatigue and subsequent anastomotic breakdown. Polypropylene and braided polyester are the most commonly used suture materials in vascular reconstructions and have not been associated with this complication.

In some instances the sutures may remain intact but an anastomotic false aneurysm occurs as they pull through the arterial wall. This may occur when placement of the sutures fails to incorporate sufficient amounts of arterial tissue, when there is excessive tension on the anastomosis from a graft that has been cut too short, and when there is degeneration of the artery. Infection of the graft and neighboring arterial wall is associated with anastomotic breakdown, especially when the organism is gram-negative. An artery that has undergone endarterectomy does not have the same tensile strength as the original artery, and care must be taken to place sutures such that they encompass enough tissue to prevent disruption.

Biologic grafts treated with formaldehyde or glutaraldehyde to prevent rejection are subject to aneurysmal degeneration. Some of the original prosthetic materials, such as Vinyon-N, nylon, and Orlon quickly lost tensile strength and were abandoned. Polyester has withstood the test of time and is the preferred material. Autogenous grafts may develop aneurysmal dilatation. Saphenous vein grafts have a 4 percent incidence of aneurysm formation when used in the extremities but a higher incidence when used in the aortorenal position, especially in children. For this reason, autogenous artery (usually hypogastric) is the conduit of choice for pediatric aortorenal bypass procedures.

Diagnosis

Patients with anastomotic false aneurysms usually present with a painless pulsatile groin mass. Rupture into surrounding tissues is unusual except when the aortic anastomosis is involved (10 percent). Duplex ultrasonography confirms the diagnosis in the case of peripheral false aneurysm, but computed tomography is the test of choice for an abdominal process. Arteriography is necessary to delineate the outflow and assist in the planning of a remedial operation. Anastomotic false aneurysms require repair because they may thrombose, embolize, or rupture.

Treatment

In the case of involvement of the femoral anastomosis, the graft often has retracted into the retroperitoneum. An interposition graft between the old graft limb and the femoral artery is required, and control of the graft limb should be obtained proximal to the inguinal ligament.

False aneurysms involving the proximal anastomosis of an aortic graft occur less frequently than false aneurysms at the distal anastomosis. Rupture into the peritoneal cavity or the duodenum may occur, and so repair is indicated. At operation, proximal aortic control is best obtained at the supraceliac level, approached through the lesser omentum after division of the crural fibers of the diaphragm (Fig. 20-3). In the absence of infection, the anastomosis is disconnected, the aorta debrided, and an end-to-end anastomosis is created just below the renal arteries with a new interposition graft. A flap of greater omentum is used to cover the new anastomoses.

When the aortic graft is infected, the graft should be removed and an extraanatomic bypass performed, routing the new graft through uninfected tissue planes. The procedure is performed in two stages. In stage one, bilateral axillobifemoral grafts are placed, with each distal anastomosis sewn at an uninfected site (distal superficial femoral or profunda femoris arteries). The aortofemoral graft limbs are then disconnected, the femoral defects are closed, and the ligated graft limbs are tucked beneath the inguinal ligament. In stage two, performed several days later, supraceliac aortic control is obtained and the proximal anastomosis is disconnected, removing the graft and oversewing the aortic stump. Aortic stump blowout, the major cause of postoperative mortality, occurs in a significant percentage of patients.

Aneurysms of Childhood

Aneurysms are rare in children. They are most often attributed to an underlying inherited disorder of connective tissue metabolism but can be acquired as a result of trauma or arteritis.

Infection

Infectious aneurysms are the most common pediatric aneurysms and usually involve the aorta. Bacterial endocarditis is the most common source of infection, and *Staphylococcus* and *Streptococcus* are the usual offending organisms. The aneurysms often develop in the aorta distal to a coarctation. Other predisposing conditions are umbilical artery catheters and bicuspid aortic valves. Prompt resection and reconstruction is indicated because of the high incidence of rupture.

Giant Cell Arteritis

This also affects the aorta and progresses to rupture and death. It is characterized pathologically by immune complex deposition in the vessel wall with complement fixation and neutrophil activation. This produces endothelial injury and transmural arterial ischemia from occlusion of the vasa vasorum. Degeneration and weakening of the vessel wall occur, with aneurysm formation and rupture.

Autoimmune Connective Tissue Disease

Children with these aneurysms exhibit the clinical features of an autoimmune process such as polyarteritis nodosa. These aneurysms are less than 3 mm in size and involve the arteries of the kidney, liver, and spleen. Rupture causes symptoms specific to the organ involved but may present as shock from intraperitoneal bleeding and the clinical scenario known as “abdominal apoplexy.” Ligation of the involved artery is indicated, with or without reconstruction.

Kawasaki Disease

Kawasaki disease or syndrome is also known as the mucocutaneous lymph node syndrome. The aneurysms occur in the axillary, brachial, iliac, and femoral segments. Coronary artery aneurysms occur in 20 to 30 percent of patients and are the most serious manifestation of this disease because of the risk of rupture and sudden death from pericardial tamponade.

Aneurysms Associated with Pregnancy

When aneurysms present during pregnancy, they often do so with rupture and shock, with a mortality rate of 65 percent. Splenic artery aneurysms are the most common, followed by aneurysms of the renal and iliac arteries. Pregnancy is also associated with aneurysmal dilatation in the aorta, presumably due to weakening of the arterial wall from the hemodynamic stresses of pregnancy and delivery. Matrix and elastic tissue abnormalities in the arterial wall have been described during pregnancy, making the vessel susceptible to rupture.

Abdominal Aortic and Iliac Artery Aneurysms

The infrarenal aorta is the most common site for the development of the nonspecific abdominal aortic aneurysm (AAA), the most common type of aneurysm presenting for treatment. Aortic aneurysms are typically fusiform in shape and usually arise below the origins of the renal arteries, extending a variable distance to and beyond the aortic bifurcation (Fig. 20-4). These aneurysms are found in 2 percent of the elderly population, and their incidence is increasing. Males predominate, with a ratio of 9:1. There is a definite familial tendency for the development of aneurysms. The tendency is sex-linked and autosomally inherited. The presence of a AAA in a female is almost always associated with aneurysms in family members. The estimated relative risk for first-degree relatives of affected individuals is 11.6 times greater than non-first degree relatives of similar age and sex. Screening with ultrasonography is indicated for relatives of patients with this lesion. Familial aneurysms tend to occur in individuals at a younger age and affect women more than does the noninherited variety.

Early attempts at repair consisted of wrapping the aneurysm with skin grafts or cellophane, injecting sclerosing agents around the aneurysm, intraluminal wiring, and endoaneurysmorrhaphy, a technique introduced by Matas at the turn of the century. The first successful resection was performed in 1951 by Dubost, who restored aortic continuity with a homograft. The modern “intrascaccular” (nonresective) method of repair was introduced by Creech and DeBakey in 1966. Current indications for operation include prevention of rupture, atheroembolization, associated occlusive disease, or pressure or erosion into contiguous structures.

Risk of Rupture

The decision to recommend resection must balance the immediate risk of operation against the risk of rupture, which is directly related to the size of the aneurysm. The natural history of the large aneurysm (> 6 cm) was defined by Estes over 30 years ago, and it is generally agreed that these aneurysms should be operated on unless severe comorbid conditions pose unacceptable operative risks or severely limit the patient's life expectancy. The classic study by Szilagyi and coworkers in 1966 clearly demonstrated that the repair of aneurysms larger than 6 cm in diameter prolonged patient survival. Although operations on smaller aneurysms did not prolong survival, in that report the operative mortality was 14 percent, therefore biasing the conclusions toward no operation. Application of current operative mortality rates (2 to 5 percent) would favor resection of even small aneurysms under the proper conditions. Crawford has reported a decline in mortality rates from 19.2 to 1.9 percent over a 25-year period despite a significant increase in operations on high-risk patients.

Less information is available about the natural history of small aneurysms (<6 cm), but it is clear that small aneurysms can rupture. Aneurysms grow an average of 0.4 cm/year, but growth occurs at an uneven rate. In the series by Szilagyi and coworkers, 19.5 percent of aneurysms smaller than 6 cm ruptured, and these data have been corroborated in more recent series showing a 20 percent risk for rupture in this group over a 5-year period. In a large autopsy study, Darling found a 25 percent rupture rate of aneurysms between 4 and 7 cm and a 9.5 percent rupture rate for aneurysms smaller than 4 cm.

Artery diameter is not a sufficiently accurate predictor of rupture to be used as the sole indication for operation. Cronenwett and coworkers analyzed 30 potential risk factors for a correlation with rupture and found that only diastolic hypertension, initial aneurysm size, and chronic obstructive pulmonary disease were important. The risk of rupture was only 2 percent when the diastolic pressure was less than 75 mmHg, the initial size was less than 3 cm, and there was no reduction in pulmonary function. By contrast, the risk of rupture was 100 percent when the diastolic blood pressure was higher than 105 mmHg, the initial size was greater than 5 cm, and the forced expiratory volume in 1 second (FEV₁) was less than 50 percent of the predicted value. Studies have tried to correlate the size of the aorta relative to the size of the patient and the risk for rupture. Ouriel and associates used computed tomography to measure the transverse diameter of the L3 vertebral body and calculated a ratio of aortic to vertebra size. Although aneurysms were observed to rupture with diameters as small as 3.5 cm, not one aneurysm ruptured with an aneurysm-to-vertebra ratio of less than 1.0. Surgeons should have an elective mortality rate well below 5 percent to justify operation in patients with small aneurysms.

Diagnostic Evaluation

Most aneurysms (75 percent) are discovered when still asymptomatic, either as a pulsatile mass on physical examination or unexpectedly during the course of an evaluation for an unrelated condition.

Physical Examination

This remains a reliable diagnostic method that is accurate in the vast majority of cases. The infrarenal aorta lies at the level of the umbilicus, so the mass should be felt around the navel. If the lateral borders converge below the costal margins, the aneurysm is probably infrarenal. Thin patients, particularly those with a lordotic spine, have a prominent aorta that can be mistaken for an aneurysm. An aneurysm can be distinguished from a tortuous aorta because the latter lies to the left and is moveable. An aneurysm can be felt to the right of the midline as well as to the left and feels expansile. Size can usually be estimated in a thin patient, and when the diagnosis of aneurysm is made in an obese patient by palpation, the aneurysm usually is larger than 6 cm.

Ultrasonography

The proven accuracy, safety, and low cost of ultrasonography make this the imaging procedure of choice for the diagnosis and follow-up of aneurysms (Fig. 20-5). The variability of the test when performed by the same technician is only 3 mm. Ultrasonography also can be used to evaluate blood flow in the renal and visceral arteries. It may not give sufficient information about the juxtarenal aorta or the iliac arteries and may be technically difficult in obese patients and in those with excessive intestinal gas.

Computed Tomography

This imaging technique provides an accurate characterization of the entire aorta. New software allows the data to be displayed in a three-dimensional image (Fig. 20-6). Its accuracy is not influenced by bowel gas or obesity, and it provides information about the character and thickness of the aortic wall, the level of the renal arteries relative to the proximal cuff, and the iliac arteries (Fig. 20-7). It is particularly helpful in evaluating patients with symptoms. As little as 10 mL of blood can be detected outside the lumen of the aorta. CT scanning is used in the postoperative period for the evaluation of suspected aortic graft complications.

Magnetic Resonance Imaging (MRI)

MRI can provide a much more detailed image than ultrasonography or CT. Three-dimensional presentations, showing the aneurysm's lumen and surface anatomy in four separate views, allow the surgeon to visualize the neck, renal arteries, and relationships to other periaortic structures. Unfortunately, progress in vascular imaging with this modality has been limited by lack of appropriate software support and high cost as well as the limitations of scanning obese patients and those with pacemakers.

Arteriography

Although not accurate in determining the size or the presence of an aneurysm, the information provided by arteriography is helpful in defining associated vascular anatomy, particularly the renal arteries (Fig. 20-8). Many vascular surgeons recommend routine arteriography before aneurysm resection, but the issue of whether the information learned is worth the cost, discomfort, and potential risk to the patient is unresolved. Arteriographic findings caused a modification of the procedure in 13 to 75 percent of patients, usually because of a pathologic condition of the iliac, mesenteric, or renal artery (Fig. 20-9). If arteriography is not used, a selective approach should be taken. Absolute indications for arteriography include: (1) symptoms of mesenteric ischemia, (2) hypertension or renal dysfunction, (3) horseshoe kidney, and (4) claudication or other signs and symptoms of coexistent lower-extremity occlusive disease.

Preoperative Cardiac Screening

Cardiac, pulmonary, hepatic, renal, and hematologic screening is essential in selecting patients for operation, deciding what imaging techniques are indicated, and selecting an appropriate incision. Patients with uncorrected coronary artery disease (CAD) undergoing aneurysm resection have an increased risk of myocardial infarction (5 to 10 percent), ischemia-related pulmonary edema (5 to 10 percent), and cardiac death within 30 days (5 to 10 percent). These risks contrast significantly with the 1 to 3 percent cardiac risk in patients without CAD. Preoperative cardiac revascularization has repeatedly been shown to reduce the operative risk in patients with CAD who undergo AAA repair.

Selecting patients at risk for cardiac events has been a difficult task. The Goldman cardiac risk index misses a large proportion of patients at risk. Exercise-induced ECG ST-segment depression misses a smaller but still significant group. Coronary arteriography is costly and carries some risk, and it is not appropriate as a screening procedure in an asymptomatic patient. Resting echocardiography, while missing a subset of patients with occult coronary disease, identifies most patients with impaired cardiac reserve. Invasive coronary studies are not always necessary to discover these high-risk patients because of recent advances in the areas of dobutamine stress echocardiography and dipyridamole-thallium myocardial scintigraphy. In a dobutamine stress echo, changes in myocardial wall motion are evaluated with increasing doses of dobutamine. The dipyridamole-thallium scan is probably the most widely used preoperative test to gauge myocardial risk. Interpretation of this test is based on selective regional uptake of isotope as a marker of perfusion. Normally perfused myocardium has a homogeneous uptake, old infarcts do not take up isotope even on delayed scans, and ischemic areas of viable myocardium exhibit delayed uptake, referred to as redistribution. Patients with redistribution are at increased risk (15 to 35 percent) for a postoperative cardiac event.

The following approach minimizes perioperative cardiac risk in patients undergoing aneurysm resection. Patients without a cardiac history and with a normal ECG (30 to 40 percent of AAA patients) can proceed to operation without further workup. Patients with clinically evident but stable cardiac disease (50 to 60 percent of AAA patients) should have a dobutamine echocardiogram or a dipyridamole-thallium study performed. An abnormal provocative test mandates coronary revascularization (coronary artery bypass or percutaneous angioplasty) before aneurysm repair when there is three-vessel disease or left main stenosis. For patients with clinically severe cardiac disease, catheterization and coronary revascularization can proceed without initial noninvasive testing. AAA repair can follow percutaneous coronary procedures almost immediately, and coronary artery bypass or valve repair can follow within 4 to 6 weeks. In the rare case of a symptomatic AAA and severe coronary disease, aneurysm resection has been performed concurrently with coronary artery bypass grafting.

Operative Management

Significant advances have been made in the anesthetic and medical management of these patients. Healthier patients can be admitted on the day of surgery, but higher-risk patients are brought into the hospital earlier for volume loading and preoperative cardiac optimization. A bowel preparation may be used. Epidural catheters are used to reduce the amount of anesthetic agent required, to allow for prompt extubation, and to control pain in the postoperative period. Swan-Ganz catheters or intraoperative transesophageal echocardiography are used in patients with a cardiac history. Patients are volume-loaded prior to clamping with crystalloid after vasodilatation with nitroglycerin. Blood is returned to the patient with an autotransfusion system to reduce the need for banked blood. Cefazolin or an antibiotic equivalently effective against *Staphylococcus aureus* is administered immediately before operation and continued until central venous access lines are removed.

Incision

The choice between a midline transperitoneal or a retroperitoneal approach to the infrarenal abdominal aorta is usually a matter of surgeon preference. Each offers advantages, and the preferable approach varies from patient to patient. The transperitoneal approach is obligatory when access to the right renal artery is required, when there is extensive disease of the right iliac system, and when access to abdominal contents is necessary. The retroperitoneal approach has advantages when there are extensive intraperitoneal adhesions, gastrointestinal or urinary tract stomata, severe chronic pulmonary disease, or the need for extensive suprarenal exposure.

Exposure

A thorough abdominal exploration is performed. The extent of the aneurysm and the status of the iliac arteries are determined by palpation, taking care to avoid extensive manipulation. The intestines are packed off to the right, retracted with a mechanical device fixed to the operating table. An incision is made in the retroperitoneum to the left of the base of the duodenum and carried proximally and distally over the right iliac artery (Fig. 20-10). The neck of the aneurysm is exposed below the left renal vein, which can be divided if necessary to the right of the adrenal vein to provide additional proximal exposure. Dissection over the aorta is confined to the anterior surface until the neck is clearly identified. Circumferential aortic control is infrequently necessary and is associated with an increased risk of atheroembolization. Instead, the anterior and lateral aspects of the normal aortic neck are cleared, palpating the bony spine to confirm adequate exposure for the application of an occluding clamp. If iliac artery aneurysms are present, the incision in the retroperitoneum is carried distally on the right, and the external iliac and hypogastric arteries are dissected free. The left iliac bifurcation is controlled after lateral mobilization of the sigmoid colon. The inferior mesenteric artery is examined for pulsation and size and is not ligated at this time.

Graft Insertion

The patient is given intravenous heparin and the activated clotting time is checked. The proximal aorta and iliac arteries are clamped, and the aneurysm is opened longitudinally. Intraluminal debris is evacuated, and bleeding from lumbar vessels is controlled with mattress sutures. If the inferior mesenteric artery is bleeding briskly, it is ligated at this point. The aortic cuff is examined. A well-defined sewing ring is usually present, and the graft can be sutured in place without transecting the aorta (Fig. 20-11), with the posterior wall of the anastomosis sewn from within the aneurysm sac. The distal portion of the aneurysm is inspected, and either a bifurcation or a straight tube prosthesis is selected. Anastomoses are sewn with continuous polypropylene suture. The proximal anastomosis is tested for leaking before distal-end suturing by removing the aortic clamp once and repositioning it on the graft. Any bleeding areas are reinforced with pledgeted sutures after the aorta is reclamped. The graft limbs must be passed under the ureters if the distal anastomoses are done beyond the iliac bifurcations. Just before the distal clamps are released, the iliac artery clamps and the graft clamp are removed to flush out any residual debris and evacuate air. The anesthesiologist is notified that clamp release is imminent, and necessary adjustments in pH are made. The proximal clamp is released slowly, with monitoring of the arterial pressure. Rapid release without adequate fluid and acid-base resuscitation may cause significant hypotension.

Prevention of Colon Ischemia

Visual inspection of the colon is notoriously inaccurate as a predictor of ischemia. If the inferior mesenteric artery is excessively large or the circulation to the sigmoid colon is questionable, Doppler ultrasonography or photoplethysmography can be used to assess flow. If a signal is present on the antimesenteric surface, the colon should be viable and no further action is indicated. Otherwise, measures must be taken to restore colonic blood flow by reimplanting the inferior mesenteric artery into the body of the graft using the Carrel patch technique. A cannula may be inserted into the inferior mesenteric artery orifice and a stump pressure measured. If the pressure is less than 40 mmHg, inferior mesenteric artery reimplantation is advocated. This is an uncommon occurrence, particularly when maintenance of perfusion to one hypogastric artery is possible.

Closure

Protamine sulfate is given to reverse the action of the heparin, and the activated clotting time is rechecked. When hemostasis is satisfactory, the wall of the aneurysm sac is sutured over the prosthetic graft to prevent adherence and subsequent erosion of the intestine into the graft or anastomoses. If this cannot be accomplished, a greater omentum flap can be brought in a retrocolic fashion and sutured to the surrounding tissues to cover the graft. The abdominal wound is then carefully closed, because there is a high incidence of late postoperative incisional hernias.

Endovascular Repair of Aortic Aneurysms

A new approach has been investigated for the repair of aortic aneurysms, using endovascular techniques to place a covered stent within an aneurysm, effectively excluding the aneurysm from the circulation. The components of an endovascular system include the graft itself, the stents that secure the graft to the arterial wall, and the delivery system used to thread the prosthesis to its appropriate anatomic location. Several configurations of endovascular grafts exist for use in the repair of aortic or aortoiliac aneurysms. The graft can

be tubular or bifurcated, but the anatomic configurations of most aneurysms require the use of grafts to the iliac arteries. Even when the aneurysm is limited in extent to the aorta, a bifurcated device usually is necessary because of the absence of a suitable distal cuff for adequate fixation and sealing of a tube graft. The graft material of most endovascular prostheses is polyester, and stents are made of stainless steel or nitinol and may be self-expanding or balloon- expandable. The fixation may be through barbs on the outer aspect of the stent, but some stents rely on friction alone. The delivery systems are cumbersome, but newer devices will be more “user friendly.” At present, the outer diameter of the introducers is from 18 to 24 French, allowing placement through most but not all femoral and iliac arteries with a groin cutdown.

The ultimate goal of all endovascular techniques for aortic aneurysm repair is to prevent the risk of aneurysm rupture through a less invasive procedure than standard open aneurysmectomy. The major problem of endovascular grafting is the leakage of blood into the aneurysm sac at the proximal or distal anastomosis. Immediate thrombosis of graft limbs also has occurred; this risk may be minimized by the placement of continuous stents along each iliac limb.

Controlled clinical studies are now in progress to compare the results of endovascular and open repair of aortic aneurysms. The results of these trials are be expected to allow governmental approval of appropriate devices, minimizing the morbidity and mortality of abdominal aortic aneurysm resection.

Ruptured Aortic Aneurysms

The mortality rate following rupture of an abdominal aortic aneurysm approaches 90 percent. Of patients who reach the hospital alive, the mortality rate averages 50 percent or more, depending on the status of the patient, the type of rupture, the experience of the surgical team, and the delay in controlling hemorrhage. Patients present with a variety of dramatic symptoms, ranging from generalized abdominal pain, severe back or flank pain, and/or circulatory collapse. Diagnosis may be delayed because this condition may mimic a perforated peptic ulcer, renal or biliary colic, or a ruptured intervertebral disc. The rupture may be contained in the retroperitoneal space, flow freely into the peritoneal cavity, or, in rare instances, flow into another anatomic structure such as the vena cava or duodenum.

Emergency Department Management

This is a true emergency, and prompt diagnosis, resuscitation, and control of hemorrhage are critical. Factors associated with an increased mortality are a history of cardiac disease, hypotension upon arrival, renal insufficiency, and inexperience of the surgical team.

The amount of time spent on diagnosis depends on the condition of the patient. When a patient presents in shock with a pulsatile mass and a known history of AAA, no further testing is needed and the patient is taken to the operating room immediately. An obese patient with normal vital signs and severe abdominal, back, or flank pain should undergo an emergency CT scan. If the patient is in shock and the diagnosis is in question, a portable ultrasound examination can be done in the emergency department. Operation should not be delayed in order to resuscitate the patient. Instead, the patient should be brought to the operating room while rapid infusions of fluid are continued and the patient is prepared for exploration.

Operating Room Management

The operating team should be scrubbed and the patient's abdomen prepared before anesthesia is induced. This is a period of significant risk for hypotension because of the vasodilatory effects of the anesthetic agents. If there is free intraperitoneal blood, aortic control is rapidly achieved at the diaphragm using a right-angled retractor to compress the supraceliac aorta against the vertebral column. This maneuver allows the anesthesiologist to resuscitate the patient. The retroperitoneum should not be opened before proximal aortic control has been achieved if the hematoma is contained. The right-angled retractor can be replaced with a well-placed supraceliac aortic clamp, or the retroperitoneal hematoma can be opened while an assistant holds pressure on the supraceliac aorta and the neck of the aneurysm can be carefully clamped below the renal arteries. The aneurysm is opened when iliac control is achieved. We prefer to leave a secure clamp on the supraceliac aorta and suture the proximal anastomosis without a clamp on the infrarenal aorta. This reduces the incidence of left renal vein injury. Heparin is given after the completion of the proximal anastomosis, the iliac arteries are back-bled and reclamped, and the distal end of the graft is sutured to the appropriate outflow vessel (distal aorta, iliac or femoral arteries).

Complications

Renal Failure

Renal failure (rise of >20 percent in blood urea nitrogen and/or creatinine) occurs in roughly 6 percent of elective aneurysm repairs and 75 percent of ruptured AAAs. Acute tubular necrosis can follow prolonged hypotension from excessive intraoperative blood loss or from declamping hypotension. It is probably the most common form of renal failure after resection of a ruptured AAA but is uncommon in elective repairs. Atheroembolization from the juxtarenal segment during aortic clamping is the most common cause of renal failure in elective repairs. This complication can be avoided by proper selection of a proximal clamp site. In cases in which degenerative changes in the cuff are present or the aneurysm is “juxtarenal” the proximal clamp should be placed on the supraceliac aorta to avoid renal damage (Fig. [20-12](#)).

Gastrointestinal Complications

Ischemic colitis involving the sigmoid colon is a dreaded complication of operations on the abdominal aorta with an incidence of 1 to 6 percent. The onset of bloody diarrhea, abdominal distention, leukocytosis, or signs of peritonitis should prompt immediate sigmoidoscopy. In most instances the injury is mucosal and the process is self-limited. When the muscularis is involved, a segmental stricture may occur and at a later date might require resection. In cases of full-thickness involvement, immediate resection of the involved intestine is required, with creation of an end colostomy and mucous fistula, before the prosthetic graft is contaminated.

Spinal Cord Ischemia

Paraplegia after operations on the infrarenal aorta is rare and is usually caused by pelvic devascularization; it is often accompanied by colon ischemia and necrosis of the skin of the buttocks. This is to be differentiated from the paraplegia that follows operations on the lower thoracic aorta after interruption of the greater medullary artery of Adamkiewicz (Fig. [20-13](#)). Although the complication is not entirely preventable, its incidence can be reduced by maneuvers that prevent atheroembolization into the hypogastric arteries and ensure the perfusion of at least one hypogastric artery and therefore of the iliolumbar and lateral sacral arteries. Reimplantation of the inferior mesenteric artery should be considered in patients who have occlusion of both hypogastric arteries.

Iliac Artery Aneurysms

Iliac artery aneurysms are usually dealt with in conjunction with operations for abdominal aneurysms but rarely can occur independently. The common iliac artery is involved in 90 percent of cases, with the remaining 10 percent involving the hypogastric arteries. The external iliac artery is never associated with degenerative aneurysmal disease. Iliac aneurysms are not often identified on physical examination, and imaging techniques are necessary for diagnosis. A hypogastric artery aneurysm may present as a pulsatile mass palpable on rectal examination. Isolated iliac aneurysms do rupture, and resection is indicated when the size exceeds 3 cm in diameter. Follow-up ultrasonography at 6-month intervals is recommended for patients who do not undergo operation.

Isolated unilateral iliac artery aneurysms can be approached through an ipsilateral retroperitoneal flank incision. Common iliac aneurysms are treated with interposition prosthetic grafts. Hypogastric aneurysms usually can be ligated proximally, and the outflow vessels can be controlled from within the sac. Bilateral aneurysms are best treated with concomitant replacement of the infrarenal aorta and insertion of a bifurcation graft (Fig. [20-14](#)).

Visceral Artery Aneurysms Renal Artery Aneurysms

Renal artery aneurysms are uncommon. They may present with rupture or distal embolization but are often identified as asymptomatic rings of calcification on an abdominal plain film. Women are more likely to be affected because of the association with fibromuscular dysplasia. The risk of rupture is greatest during pregnancy and for aneurysms larger than 1.5 cm in patients with hypertension. Direct repair with resection of the aneurysm and interposition bypass grafting is the procedure of choice for the extraparenchymal lesion. Renal salvage is possible in more than 90 percent of patients. Intraparenchymal lesions often require total or partial nephrectomy, especially if rupture has occurred. In some patients, an ex vivo repair can be performed for an intraparenchymal lesion prior to rupture.

Splanchnic Artery Aneurysms

See Chap. [33](#).

Peripheral Aneurysms Popliteal Artery Aneurysms

Popliteal artery aneurysms are the most common peripheral aneurysm (70 percent), but their incidence is low. They are often bilateral (50 to 75 percent); are associated with other aneurysms, particularly in the abdominal aorta (50 percent); and occur predominantly in males between the ages of 50 and 70 years. Retrospective studies have shown that roughly 60 percent of untreated patients develop the complications of thrombosis or distal embolization, and 20 percent require amputation. Some patients who suddenly develop symptoms present with inoperable situations because of occlusion of the distal arterial tree by embolic material. Early series reported excellent limb salvage rates after ligation, which attests to the importance of these embolic events (Fig. [20-15](#)).

Physical examination alone may not distinguish a popliteal artery aneurysm from arterial ectasia or a Baker's cyst. Imaging of the popliteal space with ultrasonography is necessary for diagnosis; arteriography should be performed to define the runoff bed (Fig. [20-16](#)).

Indications for operation are debated, but it is clear that long-term results are better when these aneurysms are treated before the onset of symptoms. Reports showing that aneurysms larger than 2 cm in diameter were more likely to cause complications than smaller ones have prompted many to advocate repair when the aneurysm reaches that critical size. However, the claim has also been made that thrombosis is more common in the smaller aneurysms. It appears that both statements may be valid—i.e., large aneurysms embolize and small aneurysms thrombose. In our view, then, repair is indicated in any patient with a popliteal aneurysm without serious comorbidity. Operative management can be done with excision and interposition bypass grafting through a posterior incision, or ligation and bypass around the popliteal space through medial incisions. Saphenous vein should be used in most instances.

Femoral Artery Aneurysms

Most of these uncommon aneurysms are found on physical examination. Diagnosis can be verified with ultrasonography. Most femoral artery aneurysms are degenerative in nature and associated with aortic dilatation, but mycotic and traumatic aneurysms also can occur. Most patients develop symptoms of an enlarging groin mass, local pain, venous obstruction, distal embolization, or thrombosis. All symptomatic aneurysms and asymptomatic aneurysms larger than 2.5 cm in diameter should be repaired. The operation of choice is resection with prosthetic graft replacement.

ACUTE ARTERIAL OCCLUSION

Acute occlusion of the arterial supply to an extremity often is an emergency. In patients without extensive collateral circulation, or in circumstances in which the occluded artery is the only vessel supplying the end organ, progression to irreversible ischemia may begin 6 h after the event. Prompt diagnosis and treatment in such situations is imperative, both to reestablish flow through the initial site of occlusion and to prevent propagation of the thrombotic process to the distal arterial tree and venous system.

Restoration of perfusion to the threatened limb is the principal objective at the time of initial evaluation. Nevertheless, establishing the nature of the occlusive process is an important secondary goal and should be attempted whenever feasible, since treatment options are affected by the cause. The differential diagnosis of acute arterial occlusion includes embolism, trauma, and thrombosis. Emboli may originate from the heart or from a more proximal artery; in either case there may be no prior or concurrent history of the underlying disorder. Injuries most often associated with arterial occlusion are posterior knee dislocation, long bone fractures, penetrating trauma, and catheter-related iatrogenic trauma. Thrombosis may occur in the presence of an atherosclerotic lesion or, less commonly, in the presence of an aneurysm.

Pathophysiology

Acute arterial occlusion results in anoxic ischemia of the tissues supplied by the involved arterial segment. Gangrene develops in approximately 50 percent of patients with this condition, depending on the site and length of occlusion and the presence of collaterals. The initial clinical features of pain, paresthesia, and paralysis reflect the greater susceptibility of nerves to ischemia in comparison to other structures. Striated muscle is only slightly less susceptible to ischemia, and therefore loss of nervous function heralds impending muscle necrosis. Tissue death typically begins 6 to 8 h after the embolic event, but this interval can vary markedly, depending on the presence of collateral circulation; in some instances tissue death may not occur at all. Thrombus does not propagate beyond branch points when flow through collaterals is sufficiently great, and the clinical findings are less serious. In the presence of stasis, however, thrombosis of the arterial and venous system distal to the initial occlusion does proceed, rendering attempts at operative and pharmacologic therapy futile.

Clinical Manifestations

The most significant features of acute arterial occlusion and the resultant ischemia can be summarized as the six *p*'s: pain, paralysis, paresthesia, pallor, pulselessness, and poikilothermia (Table [20-2](#)). Over 75 percent of patients with acute arterial occlusion experience pain as the presenting symptom. Pain may be absent from the clinical syndrome because of diabetic neuropathy, adequate collateral flow resulting in less severe ischemia, or rapid progression to advanced ischemia, with immediate anesthesia. Paresthesia and paralysis are the most critical features to evaluate in the patient with acute arterial occlusion. When present, these findings indicate anoxia of the sensory and motor nerve endings of the extremity, the structures most susceptible to ischemia. Sensory fibers are slightly more sensitive than motor fibers, hence the clinical observation that paresthesia usually precedes paralysis. Paralysis also may be the result of striated muscle necrosis in more advanced ischemia. The presence of paresthesia and paralysis is an ominous finding, indicating that the limb will almost certainly develop gangrene if the underlying condition is not alleviated within 6 to 8 h, and signals the need for rapid treatment. By contrast, the patient who does not exhibit these findings is at a much reduced risk of developing ischemic necrosis acutely.

Reduction in blood flow to an extremity results in a pale appearance of the limb and is frequently associated with the sixth *p*, poikilothermy, or coolness. Discolored, mottled skin that fails to blanch in response to digital pressure is an indicator of irreversible ischemia and is due to extravasation of blood into the dermis from ruptured capillaries. The level at which temperature and color changes occur can provide information regarding the level of the arterial occlusion; tissue ischemia usually develops one joint level below the segment of occluded artery. For example, an embolus occluding the origin of the superficial femoral artery produces ischemia distal to the knee joint.

The absence of pulses supports the diagnosis of acute arterial occlusion but does not prove it with certainty, since pulses may be absent chronically in the patient with peripheral vascular disease. The examination of the pulses also assists in locating the level of occlusion. In general, the occlusion can be localized to the segment of the arterial tree immediately proximal to the site of pulselessness. For instance, a patient with a palpable or exaggerated femoral pulse and an absent popliteal pulse can be assumed to have an occlusion of the superficial femoral artery.

In addition to the clinical findings, evaluation of the muscle turgor in the affected limb yields important information regarding the severity of ischemia and the degree to which the changes are reversible after reperfusion. The muscles are soft immediately after the onset of ischemia. With time, the muscles develop edema, which is associated with a doughy feeling on physical examination. Necrosis occurs at a more advanced stage, and the muscles feel stiff and hard; when this occurs, the ischemic changes are irreversible, regardless of therapy.

Diagnosis

In some instances the diagnosis of acute arterial occlusion can be made with relative certainty on the basis of the patient's history and physical examination, and no further workup is required before definitive treatment is initiated. An example of this is a patient who presents with the sudden onset of a cold, painful leg and is found to have an absent femoral pulse and atrial fibrillation. Groin exploration and femoral embolectomy without preoperative arteriography may be appropriate in this case. In the majority of patients, however, the presence or the precise location of an acute arterial occlusion may be uncertain, and further evaluation with arteriography is necessary to optimize treatment.

Acute arterial occlusion can be confused with nerve root compression, deep venous thrombosis, phlegmasia cerulea dolens, and infectious processes. Rarely, acute dissection of the thoracic aorta mimics multiple visceral and extremity emboli if these vessels are occluded by the false lumen. Noninvasive studies such as segmental arterial pressures can be helpful in establishing the diagnosis and localizing the site of occlusion. Arteriography is performed when additional information is required, for instance, to determine the appropriate sites of inflow and outflow for a bypass graft. If the ischemia is severe, however, the urgency of revascularization may preclude preoperative arteriography.

Arterial Embolism

Arterial emboli can be divided into two categories: emboli that lodge in large-diameter vessels, such as the common femoral artery, the vast majority of which are of cardiac origin; and atheroemboli to smaller vessels, such as branches of the digital arteries, that invariably originate from a plaque or thrombus in a more proximal vessel.

Cardiac Emboli Etiology

An embolus from the heart may be the first indication of a serious underlying cardiac disorder and may occur in three clinical settings: atrial fibrillation, myocardial infarction, and valvular disease. Appropriate evaluation and treatment of the cardiac disease, when necessary, must be undertaken concurrently with the therapy of the arterial occlusion, and the severity of the underlying cardiac condition must be taken into consideration when deciding on therapy for the arterial occlusion.

Cardiac emboli in the patient with mitral stenosis may result either from valvular vegetations or from mural thrombi that form in a dilated left atrium. Atrial fibrillation, occurring alone or in conjunction with mitral stenosis, predisposes to the formation of mural thrombi, which may then embolize to the peripheral circulation. Similarly, transmural myocardial infarction is associated with the formation of mural thrombus on the subendocardial surface overlying the infarcted ventricle, usually 2 to 3 weeks after the cardiac event. Rare sources of arterial emboli originating in the heart include bacterial endocarditis, atrial myxoma, prosthetic heart valves, and paradoxical embolization originating in the veins and passing through a patent foramen ovale. A diligent search must be made for the embolic source in all patients, including the use of electrocardiography, echocardiography, and Holter monitoring. Despite a thorough evaluation, however, the source cannot be identified in a significant percentage of patients.

Distribution

The two factors that influence the site in the arterial tree in which an embolus will lodge are patterns of blood flow and changes in vessel diameter. Consequently, 70 percent of cardiac emboli lodge in the arteries of the lower extremities, 13 percent in the arteries of the upper extremities, 10 percent in the cerebral circulation, and 5 to 10 percent in the visceral circulation. In addition, emboli generally lodge at arterial branch points, where the vessel diameter is abruptly reduced. Common sites in the lower extremity include the bifurcation of the abdominal aorta, the common iliac artery, the common femoral artery, and the popliteal artery (Fig. [20-17](#)). A corresponding pattern is seen in the arteries of the upper extremity, with involvement of the brachial artery at its bifurcation into the radial and ulnar arteries or, less commonly, at the takeoff of the profunda brachii artery. The ischemic insult is more severe when the bifurcation of a vessel is occluded, because collateral circulation cannot be supplied by a patent branch vessel.

Evaluation

Once the diagnosis of acute arterial occlusion has been established, it is desirable to differentiate between embolism and thrombosis as the underlying cause, since the treatment options may differ accordingly. A patient with embolic occlusion of an otherwise normal vessel (Fig. [20-18](#)) may only require thromboembolectomy under local anesthesia, whereas a patient with thrombosis of an atherosclerotic artery will likely require a bypass graft around the involved segment, under regional or general anesthesia. Clinical findings suggestive of an embolic cause include the presence of cardiac arrhythmia, myocardial ischemia, and valvular disease; the absence of factors predisposing to atherosclerosis; and the absence of prothrombotic hematologic disorders. The presence of normal pulses on the contralateral side is strongly indicative of an embolic source.

Arterial Atheroemboli Etiology

The vast majority of emboli that originate in arteries are fragments of an ulcerated atherosclerotic plaque that become dislodged and travel downstream, lodging in a more distal artery. These fragments may be composed of cholesterol crystals or of fibrin-platelet debris that deposits on the surface of the plaque and is then displaced into the circulation. The artery of origin, usually the aorta, iliac, or femoral vessels, is often some distance from the artery in which the embolus finally lodges, since these fragments are usually tiny and do not become trapped until they reach a small vessel (Fig. [20-19](#)). It is rare for large vessels such as the common femoral or popliteal arteries to become occluded by atheroemboli, except during operative manipulation of a diseased abdominal aorta. Fragments of intraluminal thrombi, such as those that are seen in association with aneurysms, also may dislodge and occlude distal vessels. This is much less common than atheroemboli but is typically seen in association with popliteal aneurysms. In either case, patients may experience repeated embolic episodes that are individually minor; the additive effects, however, may be quite significant.

Clinical Syndromes

The most common example of atheroemboli is the "blue-toe" syndrome. Patients with this syndrome develop severe ischemia of the toes and forefoot in the presence of palpable pulses. The superficial femoral artery, the popliteal artery, and at least one tibial vessel are usually patent in order for emboli to travel to the digital arteries; therefore, patients with blue-toe syndrome generally have palpable pedal pulses. This physical finding enables the clinician to differentiate this disorder from lower-extremity gangrene resulting from large-vessel atherosclerotic disease. Renal failure or mesenteric ischemia may accompany digital gangrene if the thoracic upper abdominal aorta is the source of emboli. If the digits of the upper extremity are involved, the subclavian artery usually is the source, with disease caused by proximal atherosclerosis or more distal poststenotic aneurysm formation secondary to thoracic outlet obstruction.

Evaluation

Atheroemboli should be suspected when the physical examination reveals digital ischemia in a patient with palpable pulses. The location of the embolic source can be estimated on the basis of the sites where the emboli have lodged. The source must be proximal to the site of the embolus; bilateral emboli to the feet indicate a source above the aortic bifurcation, and repeated unilateral emboli suggest a source distal to the bifurcation. A thorough arteriographic evaluation is required to confirm the diagnosis and to identify

precisely the offending lesion in preparation for operative intervention.

Arterial Thrombosis

Etiology

Spontaneous acute arterial thrombosis occurs most commonly in the presence of an underlying stenosis caused by atherosclerotic disease. The thrombotic event may be precipitated by plaque disruption and exposure of the thrombotic core, by hypoperfusion due to inadequate cardiac output, or from a critical reduction in flow across the involved arterial segment. Acute arterial occlusion also may occur because of an aneurysm, commonly popliteal, in which distal embolization of thrombotic material produces occlusion of the outflow tract, ultimately resulting in thrombosis of the aneurysm itself because of inadequate outflow. Hypercoagulable states, such as the antiphospholipid syndrome, resistance to activated protein C, and deficiencies in protein C, protein S, or antithrombin III also may cause acute arterial occlusion. These disorders should be suspected when the patient lacks the usual risk factors for atherosclerosis (Table 20-3). Rarely, acute arterial thrombosis develops as a result of repeated mild trauma, as occurs with a cervical rib compressing the subclavian artery or from occupational trauma such as the operation of a pneumatic tool, the vibrations of which cause injury to the digital arterial wall. Acute arterial thrombosis also may occur after diagnostic and therapeutic intraarterial procedures, such as cardiac catheterization and peripheral vascular arteriography. An intimal flap can be created by the catheter even with the most careful technique, resulting in thrombosis of the vessel.

Clinical Manifestations

The clinical picture of acute arterial thrombosis may range from no symptoms whatsoever to severe, limb-threatening ischemia, depending on whether or not an adequate collateral network is present and the size and location of the involved vessel. A patient with a chronic superficial femoral artery stenosis may progress to complete occlusion of the vessel and remain asymptomatic because blood flow is maintained by means of a well- established collateral network. By contrast, a young patient with a coagulation disorder may develop occlusion of the same vessel and have far more severe symptoms because of the absence of collateral circulation. In addition, occlusion of the superficial femoral artery is less serious than occlusion of the popliteal artery, because the profunda femoris artery can provide blood flow to the extremity when the superficial femoral artery is thrombosed, whereas the popliteal artery is the only major vessel to the foot at the level of the knee.

Diagnosis

The clinical findings in acute arterial thrombosis vary with the severity of ischemia but are essentially the same as those observed with acute arterial embolism and are described by the six *p*'s. In contrast to patients with straightforward peripheral embolism, all patients with suspected acute arterial thrombosis should undergo preoperative arteriography unless the degree of ischemia precludes the delay required for the procedure.

The nature of the acute arterial occlusion should be established as either thrombotic or embolic whenever possible. The distinction is often difficult to make, but certain findings on history, physical examination, and arteriography are helpful. A history of peripheral vascular disease (e.g., claudication) in the involved or contralateral limb suggests a thrombotic cause, as does a personal or family history of popliteal or aortic aneurysm. Similarly, physical findings indicative of arterial insufficiency, such as skin and nail changes or the absence of distal pulses in the uninvolved extremity, suggest thrombosis rather than embolus. Conversely, the absence of evidence of peripheral vascular disease on history or physical examination implies an embolic cause. Occasionally an embolus is visible arteriographically as a rounded structure at the most proximal site of occlusion. Often, however, this is not seen because of retrograde propagation of the thrombus. Differentiation between these two entities is very important; both require treatment, but the treatment may be very different. Patients with embolic disease have normal vessels, and operative or pharmacologic treatment is limited to elimination of the thromboembolus. By contrast, the vast majority of patients with thrombotic disease have underlying atherosclerotic occlusive disease and will require correction of the lesion responsible for the thrombotic event in addition to removal of the thrombus itself.

Operative Therapy

Operative therapy has been the standard of care for acute peripheral arterial occlusion since the 1950s. The introduction and refinement of thrombolytic agents, however, has led to confusion and controversy regarding the indications for use of these two effective therapeutic modalities. In general, thrombolytic therapy with *recombinant tissue plasminogen activator (rt-PA)* or, more frequently, urokinase is reserved for patients in whom the ischemic event is not so severe that reperfusion cannot be delayed for the time required to perform arteriography and effect clot lysis.

Arterial Embolus

Acute arterial embolism is a disorder that virtually always requires therapy. Most patients with emboli to the peripheral circulation have cardiac disease, and embolectomy can usually be performed through a small incision under local anesthesia. Embolectomy should not be avoided on the basis of its risk to the patient, as the development of extremity gangrene and amputation incurs a far greater physiologic and operative stress. Attempts should not be made to restore blood flow to nonviable limbs, as reperfusion may result in the return of toxic substances such as potassium, lactic acid, and myoglobin to the circulation. The risk of death under these circumstances is high, and amputation should be accomplished expeditiously.

The urgency with which blood flow must be restored to the ischemic limb can be estimated on the basis of clinical findings, and when possible, patients should be medically stabilized before even the simplest procedure. Systemic heparinization is accomplished as soon as the diagnosis is established and is continued throughout the operation. The incision is placed over the presumed site of the embolus. A groin incision is used if the thromboembolic process involves the femoral vessels, and a medial incision just below the knee is used for a popliteal embolus. When there is an embolic occlusion of the aortoiliac segment, the thromboembolus is removed through bilateral groin incisions. A transverse arteriotomy is performed after the patient has been heparinized and proximal and distal control of the artery has been obtained. The embolus is extracted through the arteriotomy by passing an embolectomy catheter proximally and distally to remove all propagated thrombus (Fig. 20-20). Additional incisions may be required to remove thrombus from distal vessels. For example, a below- knee incision would be used to expose the popliteal trifurcation in the case of retained anterior tibial thrombus, since this vessel is often difficult to catheterize from the femoral approach because of the acute angle at which it branches from the popliteal artery. A completion arteriogram should be obtained if there is concern about residual thrombus. Intravascular angiography has recently been used to ascertain the effectiveness of thrombectomy. Although usually reserved for trauma, fasciotomies may be performed if compartment swelling is anticipated.

Anticoagulation should be instituted during the early postoperative period. The majority of patients will require long-term oral anticoagulation with warfarin because of cardiac mural thrombi or valvular vegetation. The prognosis for limb salvage is determined by the preoperative condition of the extremity and the success of clot removal. Muscle necrosis and clot propagation are reduced when embolectomy can be accomplished within 6 h of the onset of ischemia. Beyond this interval, the preoperative finding of a soft, pliable calf muscle is predictive of a good outcome. The overall in- hospital mortality in patients with arterial emboli is 25 percent or more, with the majority of deaths occurring as a result of underlying cardiac disease.

Arterial Thrombosis

The operative choices are more complex when acute arterial occlusion develops as a result of thrombosis rather than embolization. Fortunately, time constraints are usually less stringent, as the degree of ischemia is rarely as severe. Operative therapy is generally a combination of the strategies of thrombus removal discussed in the section on arterial emboli and of bypass grafting discussed in the section on chronic arterial occlusion.

Thrombolytic Therapy

The use of thrombolytic agents in the treatment of acute arterial occlusion, introduced by Sherry and associates in the 1950s, has become increasingly popular. Many advances and technical refinements have been made over the years, including the use of catheter-directed administration of thrombolytic agents, coaxial catheter systems, and the use of safer, more effective agents. Thrombolytic agents may be used instead of or in addition to standard operative techniques, depending on the nature of the occlusion. Thrombolytic agents are unlikely to completely supplant operation in the treatment of acute arterial occlusion, since many patients have fixed arterial lesions that must be addressed in order to prevent rethrombosis. In addition, some thromboemboli are not susceptible to thrombolysis. In cases of severe ischemia, the time required to perform a diagnostic arteriogram and achieve pharmacologic clot removal may jeopardize limb salvage.

All thrombolytic agents work by activating the plasmin system, thus effecting lysis of fibrin and dissolution of the clot infrastructure. Streptokinase is a bacteria-derived compound that binds plasminogen, and it is this complex that converts plasminogen to form plasmin. Urokinase is derived from renal parenchymal cells, and *rt-PA* is derived from vascular endothelial cells; both of these agents activate plasminogen directly. Unlike streptokinase and urokinase, rt-PA has a greater affinity for plasminogen at the site of the thrombus than for circulating plasminogen but has not been proved to decrease the incidence of distant bleeding complications associated with local or systemic administration.

Thrombolytic therapy is indicated in any patient with an acute native arterial or graft occlusion and is most effective when administered within 2 weeks of thrombosis. There are a number of important contraindications to the use of lytic therapy, including a history of gastrointestinal or intracerebral lesions, pregnancy, and any contraindication to arteriography. As with catheter thromboembolectomy, blood flow should not be restored to nonviable limbs, since the consequences of reperfusion may be lethal.

The patient is given an antithrombotic agent such as aspirin or heparin once the decision to administer thrombolytic therapy has been made. This decreases thrombus formation around the catheter itself, reducing the incidence of embolization as the catheter is removed. In addition, platelet activation occurs during thrombolytic therapy and may result in the inhibition of clot lysis or early rethrombosis. Heparin or aspirin may prevent these platelet-associated complications.

Thrombolytic therapy is instituted with catheter placement proximal to the level of the occlusion, after which a diagnostic arteriogram is performed. The catheter is then advanced into the clot itself and is used to administer the thrombolytic agent. If the catheter cannot be advanced into the thrombus, attempts at lysis are rarely successful. A high dose of thrombolytic agent is usually administered for the first 4 h (e.g., 4000 IU/min urokinase), followed by a smaller dose (e.g., 2000 IU/min urokinase), which is continued up to 48 h. Arteriograms are repeated at regular intervals to assess the effectiveness of clot lysis. Therapy is discontinued before 48 h if satisfactory clot lysis has been obtained, if a complication occurs, if no significant lysis is achieved, or if the rate of lysis is inadequate for limb salvage. There are several treatment options after the thrombolytic agent is discontinued. No further treatment is needed if complete lysis is achieved and there is no arterial lesion, although most of these patients will require evaluation and treatment of the underlying cause of the occlusion. Patients with appropriate arterial or graft lesions may be treated by percutaneous balloon angioplasty. Other patients will require replacement or revision of a bypass graft to correct the underlying lesion.

Thrombolytic therapy has been postulated to be associated with a number of advantages over operative therapy in the treatment of acute arterial occlusion. In the case of thromboembolic disease involving an otherwise normal artery, for example, in a patient with a cardiac embolus or in a hypercoagulable state, operative intervention may be avoided entirely with successful thrombolysis. Benefit may also be conferred to the patient with an underlying arterial lesion, as the stenosis can be identified arteriographically after clot lysis. As a result, a vein graft may be revised using a patch angioplasty, rather than by replacing it with a new graft, and isolated lesions involving both arteries and grafts can often be treated by percutaneous methods. Finally, thrombolytic agents can lyse thrombi that are inaccessible by operative methods, such as those in the distal tibial vessels, potentially

improving the chances of limb salvage.

The risks and complications associated with the use of thrombolytic agents must be weighed against the potential benefits. Administration of any thrombolytic agent may result in a systemic lytic state, which predisposes patients with occult lesions to hemorrhage. The most common site is the gastrointestinal tract, but intracerebral hemorrhage, occurring in 0.5 to 1.0 percent of patients, is the most devastating. Bleeding may occur at the catheter site in approximately 15 percent of patients receiving thrombolytic agents, usually in the form of a hematoma that develops after catheter removal. Bleeding complications may be more frequent when the fibrinogen falls below 100 mg/dL, but this has not been demonstrated definitively. The treatment of hemorrhagic complications during thrombolytic therapy involves immediate discontinuation of the thrombolytic agents and appropriate medical or surgical management of the bleeding site. In cases of severe bleeding, particularly intracerebral, aminocaproic acid (Amicar) should be administered without delay. Streptokinase, derived from beta- hemolytic streptococcus, is antigenic and is associated with an allergic reaction in patients recently exposed to the bacteria or who have recently received streptokinase. The agent should not be given to these individuals. As clot lysis progresses, fragments from the dissolving clot frequently embolize to distal vessels, such as the tibial and digital arteries. When this occurs, the extremity becomes ischemic again, mimicking reocclusion of the vessel. Distal embolization of thrombus responds to continuation of thrombolytic therapy in almost all cases, preferably with advancement of the catheter into the involved segment.

The results of thrombolytic therapy for acute arterial occlusion have been encouraging, with most series reporting success rates of 60 to 80 percent, as determined by clot lysis and clinical improvement. Several prospective, randomized studies have compared initial thrombolysis with immediate operation for the treatment of peripheral arterial occlusion, including the Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial and the Thrombolysis or Peripheral Arterial Surgery (TOPAS) study. From the conclusions of these and other trials, several pertinent caveats may be drawn. First, the appropriate use of thrombolytic therapy often includes subsequent endovascular or open surgical intervention to correct the lesion responsible for the occlusive event. For instance, successful thrombolysis of a saphenous vein femoropopliteal bypass graft almost always uncovers a vein graft stenosis, which must be repaired to prevent rapid rethrombosis of the conduit. Second, patients with acute occlusion (e.g., less than 14 days) represent better candidates for thrombolysis than patients with chronic occlusion. Third, the results of thrombolysis appear to be better for graft occlusions than for occlusions of native arteries, and successful clot dissolution is almost never possible if the catheter cannot be guided into the substance of the thrombus. The best clinical results are achieved when these factors are considered, weighing the morbidity from bleeding complications and delays in reperfusion against the potential benefit of avoiding a larger, frequently urgent operation to restore adequate arterial perfusion.

CHRONIC ARTERIAL OCCLUSION

Atherosclerosis is the most common cause of occlusive disease of the arteries supplying the extremities. Although peripheral atherosclerosis is a diffuse process affecting the arterial tree, the most severe lesions tend to occur at discrete sites. Symptomatic peripheral arterial lesions are most frequently located in the infrarenal abdominal aorta, the iliac arteries, and the superficial femoral artery at the level of the adductor canal. The presence of arterial stenoses in other locations is usually indicative of coexistent disease processes such as diabetes mellitus (profunda femoris and tibial arteries) or inflammatory arterial processes (axillary arteries).

The incidence of symptomatic peripheral atherosclerotic occlusive disease is lower than that of coronary disease, but individuals with significant coronary disease frequently display manifestations of peripheral arterial disease as well. This finding is not surprising, given the common pathogenesis of the two diseases. Symptomatic peripheral arterial disease occurs predominantly in males over the age of 50 years. Additional risk factors that were documented in the Framingham study include systolic hypertension, cigarette smoking, hyperlipidemia, and diabetes mellitus (Table 20-4). The pathology observed in affected arteries is usually that of advanced atherosclerosis, with large cholesterol- and calcium-containing plaques encroaching on the lumen. As in all forms of symptomatic atherosclerotic occlusive disease, the pathophysiology is that of gradual plaque enlargement, with eventual thrombosis of the residual lumen. Arterial thrombi are initiated by the deposition of platelets on the plaque surface, attachment and aggregation of additional platelets, activation of the coagulation pathways, and deposition of fibrin, terminating in a platelet-fibrin thrombus and occlusion of the vessel. Thrombus formation on the exposed core of an ulcerated plaque can result in acute occlusion of highly stenotic lesions. This luminal thrombus provides the opportunity to recanalize chronic arterial occlusions with fibrinolytic agents, restoring a small channel in an apparently chronically occluded vessel.

Aortoiliac Occlusive Disease

The pathophysiology of the symptoms produced by atherosclerotic occlusive disease of the infrarenal aorta and iliac vessels was first described by Leriche, and the characteristic syndrome of claudication, impotence, and diminished femoral pulses bears his name. Three patterns of aortoiliac disease have been identified (Fig. 20-21). Localized disease confined to the aorta and the common iliac arteries is found in 10 percent of patients (type I). The disease extends into the external iliac arteries in approximately 25 percent of patients (type II). The occlusive process is multisegmental, involving the infrainguinal vessels, in the remaining 65 percent of patients (type III).

Clinical Manifestations

Aortoiliac occlusive disease typically is characterized by intermittent claudication involving the thigh, buttock, and calf, and sexual impotence in males. Symptoms may remain stable for years and may even improve as collateral vessels enlarge with exercise or cessation of smoking. Limb- threatening ischemia is rare with isolated aortoiliac occlusive disease; symptoms are limited to claudication in the absence of concurrent infrainguinal disease. Aortoiliac occlusive disease also may be manifested by atheromatous embolization from ulcerated plaques in the involved arterial segment. The emboli may lodge in the digital arteries of the toes, producing gangrene of one or more digits; as previously mentioned, this phenomenon has been termed the blue-toe syndrome. Microemboli also may travel to dermal vessels, resulting in a blue reticular cutaneous pattern. Biopsy examination of these lesions reveals cholesterol debris within the terminal arterioles.

Impotence represents a symptom complex of diverse causes. Satisfactory male sexual function requires adequate blood flow to the penis via the hypogastric and internal pudendal arteries, an intact pelvic parasympathetic system, and an appropriate hormonal and psychologic milieu. Impotence can be ascribed to a vascular cause in only a small minority of patients.

Diagnosis

An accurate history and physical examination can establish or exclude the diagnosis of aortoiliac occlusive disease with certainty in the vast majority of patients. The classic findings of thigh claudication and decreased groin pulses may be accompanied by lower abdominal and femoral bruits. The diagnosis is occasionally confused with that of lumbosacral nerve root compression caused by disc herniation or spinal stenosis. Patients with these disorders can be distinguished from those with claudication by the fact that their pain is temporally related to changes in position rather than ambulation.

The clinical suspicion of aortoiliac occlusive disease may be difficult to confirm using the noninvasive vascular laboratory. Arterial cuff pressures obtained at the proximal thigh level do not necessarily reflect pressures within the iliac or common femoral systems, since the cuff cannot be positioned high enough to occlude these vessels. A decreased proximal thigh cuff pressure may therefore represent occlusive disease of both the proximal superficial femoral and profunda femoris arteries rather than an inflow lesion of the aortoiliac segment. Common femoral Doppler waveforms have been of some use in the diagnosis of inflow disease. The normal waveform is triphasic, with a negative diastolic component. Loss of the triphasic waveform and the presence of a blunted, biphasic configuration occurs relatively early in aortoiliac occlusion and is evidence of inflow disease (Fig. 20-22). Percutaneous needle cannulation of the common femoral artery is an invasive but extremely precise means of identifying inflow occlusive disease. The presence of a pressure gradient between the brachial and the femoral vessels is indicative of significant aortic or iliac stenotic lesions. When a lesion is suspected but no gradient is present, papaverine administration may be helpful in identifying the stenosis. Papaverine is injected intraarterially at the time of cannulation to dilate the distal vasculature, thus reducing peripheral resistance and increasing blood flow across the aortoiliac segment. If a stenosis is present, this will result in a decreased pressure in the femoral artery. A decrease in the femoral-to-brachial pressure ratio of more than 15 percent after papaverine administration-induced hyperemia implies significant occlusive disease involving the aortoiliac segment. It also has been shown to be predictive of symptomatic relief with aortoiliac reconstruction alone, even in the presence of concurrent, uncorrected infrainguinal disease.

Vasculogenic impotence can be differentiated from impotence caused by other disorders using noninvasive laboratory techniques. The penile systolic pressure is measured using a small pneumatic cuff placed around the shaft of the penis and a photoplethysmographic probe on the glans. The penile/brachial index is defined as the penile systolic pressure divided by the brachial systolic pressure, and is approximately 1.0 in potent men. A penile/brachial index above 0.8 confirms the adequacy of penile arterial inflow and virtually excludes the diagnosis of vasculogenic impotence. The converse is not necessarily true; some men are potent despite indices of less than 0.6.

Preoperative standard or digital arteriography is required in patients undergoing elective operation for aortoiliac occlusive disease. The arterial tree should be visualized from the renal arteries to the feet, and the presence of concurrent disease in the inferior mesenteric, hypogastric, and profunda femoris vessels assessed. A transfemoral approach to arteriography is preferable for reasons of ease and safety, but the absence of palpable femoral pulses on either side may necessitate use of a brachial or translumbar route. Intravenous digital studies have been widely used in patients with aortoiliac occlusive disease and absent femoral pulses, but the resolution of this technique is poor because of factors such as bowel gas motion in the abdomen and sluggish blood flow in the extremities.

Treatment

The primary indications for aortoiliac reconstruction are threatened limb loss with rest pain, ulceration, or gangrene and atheroembolic phenomena such as the blue-toe syndrome. There is some disagreement on the advisability of operation for symptoms of claudication alone. In general, claudication of sufficient severity to restrict livelihood or lifestyle is considered an acceptable indication for aortoiliac reconstruction procedures in medically fit individuals.

Aortoiliac reconstruction can be accomplished by four methods: aortofemoral bypass, aortoiliac endarterectomy, extraanatomic bypass, and balloon catheter dilatation. The durability of aortofemoral bypass and aortoiliac endarterectomy is greater than that of extraanatomic bypass or balloon angioplasty. Extraanatomic procedures, typically in the form of axillofemoral or femorofemoral bypass, are usually reserved for medically unstable patients who are at high risk for perioperative complications with an intraabdominal procedure. Femorofemoral bypass has a higher patency rate than axillofemoral bypass, but it requires one normal iliac artery for inflow, and so it is not suitable for patients with bilateral disease. Femorofemoral bypass avoids any possibility of pelvic autonomic nerve injury and is therefore frequently employed as a primary reconstructive procedure in young male patients in whom maintenance of normal sexual function is an important issue. Balloon angioplasty is the least invasive method of restoring inflow to the lower extremity and has the same success rates as operative bypass in the treatment of isolated common iliac artery lesions.

Operations on the abdominal aorta are associated with a perioperative mortality of 2 to 10 percent, depending on the presence and severity of associated medical conditions. Complications are most often related to concomitant atherosclerosis involving the coronary and cerebral vasculature. The presence of chronic obstructive lung disease is associated with an increased risk of perioperative pulmonary complications, the most serious of which is the need for prolonged ventilatory support. The preoperative testing for aortoiliac procedures may include pulmonary function tests, dipyridamole-thallium myocardial imaging, dobutamine echocardiography, and coronary angiography, and the evaluation frequently uncovers unsuspected cardiac and pulmonary disease.

The perioperative technical complications of aortoiliac reconstruction are hemorrhage, thrombosis of the reconstruction, and distal embolization of atherosclerotic debris from aortic manipulation. Ischemia of the rectosigmoid colon may be a result of interruption of the inferior mesenteric and hypogastric arteries or from atheroembolization to the bowel.

Paraplegia is a rare complication that may be secondary to ligation or embolization of a prominent lumbar vessel providing blood flow to the spinal cord through the greater medullary artery of Adamkiewicz (arteria radicularis magna). Damage is usually limited to the anterior two-thirds of the spinal cord in the distribution of the anterior spinal artery, producing a loss of motor function with preservation of sensation. Sexual dysfunction is common after reconstruction of the abdominal aorta; retrograde ejaculation occurs in over 40 percent of patients, and impotence in 25 percent of patients. The frequency of postoperative sexual dysfunction may be decreased by minimizing periaortic dissection, thus preserving the sympathetic and parasympathetic nerves, and by maintaining blood flow through at least one hypogastric artery.

Aortofemoral Bypass

Aortofemoral bypass is the treatment of choice for symptomatic aortoiliac occlusive disease. A bifurcated prosthetic graft made of polyester or, less commonly, *expanded polytetrafluoroethylene (ePTFE)* is used to bypass the stenotic lesions. Although there are advantages and disadvantages to each of the prosthetic materials, this is of less concern in aortofemoral grafting, since patency is excellent with any conduit. The 5-year and 10- year patency rates of aortoiliac reconstructions are 90 and 75 percent, respectively.

Polyester grafts are constructed in either a knitted or woven configuration. The advantages of the knitted structure are the excellent tissue ingrowth that occurs through the wide interstices of the graft and the technical ease of handling at the time of operation. Prec clotting with the patient's blood is required, however, to avoid massive hemorrhage through the interstices when blood flow through the graft is initially established. Knitted grafts have been associated with degeneration and aneurysmal dilatation over time. With woven polyester grafts, prec clotting is infrequently required and graft dilatation is less common. Polyester grafts have been coated with albumin or collagen, eliminating the need for prec clotting but substantially increasing the cost of the grafts. Using *ePTFE* grafts for aortofemoral bypass also eliminates the need for prec clotting, since these grafts are impermeable to blood and aneurysmal degeneration has not yet been reported. Despite these potential advantages, the use of ePTFE grafts in the aortofemoral position has not gained widespread acceptance. The choice of graft material for aortoiliac reconstruction is determined by surgeon preference, since there is no difference in patency between the fabrics.

Once the graft has been selected and the patient has been systemically heparinized, the proximal anastomosis between the graft and the infrarenal aorta is created using either an end-to-end or a end-to-side technique (Fig. 20-23). The type of anastomosis chosen is determined by the need to maintain antegrade blood flow to the hypogastric vessels. An end-to-side proximal anastomosis is indicated when the external iliac arteries are stenotic or occluded bilaterally, since the arterial flow to the spinal cord and colon in this situation may be dependent on antegrade flow through the distal aorta to the hypogastric and inferior mesenteric arteries. The graft limbs are then delivered to the femoral vessels through tunnels that are created beside the external iliac arteries. The distal anastomoses should be placed at the common femoral level, through bilateral groin incisions. Unlike in patients with aneurysmal aortic disease, bypass to the iliac arteries is unwise in the presence of aortoiliac occlusive disease. Although aortoiliac bypass eliminates the need for groin incisions, the patency rate of this procedure is substantially lower than that of aortofemoral bypass. In addition, bypass to the femoral vessels provides the opportunity to correct proximal profunda femoris artery stenoses by placing the hood of the graft onto the profunda femoris artery beyond the area of narrowing.

Endarterectomy Procedures

Aortoiliac endarterectomy was introduced before the advent of prosthetic graft conduits. The aorta and iliac arteries are exposed and all branch vessels are controlled in preparation for clamping. The patient is heparinized, and occlusive vascular clamps are placed. The atherosclerotic plaque is removed through one or more arteriotomies, and the arteriotomies are subsequently closed, with or without a patch. Endarterectomy does eliminate the use of prosthetic material, but the procedure is not suitable for patients in whom the atherosclerotic process extends to the external iliac artery. Endarterectomy requires localized atherosclerotic disease with an appropriate ending of the plaque on relatively normal vessel. Early failure of the endarterectomized segment can be predicted in the absence of a suitable end point within 1 or 2 cm of the origin of the external iliac artery. Nevertheless, aortoiliac endarterectomy may be the procedure of choice for young patients with a long life expectancy and disease localized to the aorta and common iliac vessels. It achieves excellent patency rates and avoids some of the complications associated with prosthetic graft material.

Extraanatomic Bypass

Extraanatomic revascularization procedures include axillofemoral, femorofemoral, and obturator bypasses (Fig. 20-24). Axillofemoral and femorofemoral procedures are preferred when the patient's medical condition renders the risk of a major intraabdominal operation unacceptable. Other indications include lower-extremity ischemia in the presence of an infected aortic graft, reoperation for aortofemoral graft occlusion, and revascularization in a sexually active male to avoid the possibility of postoperative sexual dysfunction. Prosthetic graft materials are almost always employed. The axillary artery provides inflow for an axillofemoral graft; the graft is tunneled subcutaneously along the lateral trunk to the ipsilateral femoral artery in the case of an axillounifemoral bypass, or to both femoral arteries in an axillobifemoral bypass. The patency of axillounifemoral bypasses is poor, averaging well below 50 percent at 5 years. The flow through axillobifemoral bypass is twice that of the axillounifemoral graft, resulting in a significantly higher 5-year patency rate. Thus, axillobifemoral bypass is often employed for unilateral leg ischemia in order to improve graft longevity.

The best results of extraanatomic bypass procedures are achieved with femorofemoral bypass grafts; the 5-year patency rate of these grafts is between 50 and 75 percent. The procedure involves exposure of both femoral arteries in the groins and subcutaneous placement of a prosthetic conduit in the suprapubic region. A nonstenotic donor iliac vessel is required; the adequacy of this vessel can be evaluated with femoral artery pressure measurements made before and after papaverine injection. Concomitant iliac balloon angioplasty has been successfully employed in the presence of iliac stenotic disease to establish adequate inflow to the donor side. The obturator bypass is a rarely used but extremely effective procedure that is employed primarily to circumvent an infected graft in the groin area. The inflow site is the aorta, the iliac artery, or an aortofemoral graft limb within the abdomen. The graft is tunneled through the obturator foramen and joins the superficial femoral artery distal to the groin, thus completely avoiding the infected area.

Endovascular Procedures

Percutaneous transluminal angioplasty (PTA) was introduced in 1964 by Dotter as a method of reestablishing flow through stenotic vessels. A decade later, Gruntzig further refined the technique of balloon catheter dilatation of arterial stenoses. Today the procedure is initiated by the percutaneous cannulation of an accessible vessel, either the common femoral artery or the brachial artery. After a diagnostic arteriogram has been performed and pressure gradients have been measured, a balloon catheter is advanced across the arterial stenosis. The balloon is inflated to several atmospheres of pressure, and completion arteriograms and pressure measurements are obtained. Initially, the mechanism underlying balloon dilation was believed to be circumferential dilatation of all layers of the arterial wall with compression and remodeling of the plaque. Later studies suggested that this is not the case; rather, the plaque is cracked, forming fissures and false channels. The media is overstretched, causing destruction of its elastic components. The adventitia remains intact unless the artery has been overdilated. Rupture of the wall with hemorrhage or false aneurysm formation occurs if the artery is excessively overdilated, but this complication is rare.

The results of PTA have been satisfactory in relatively short nonoccluding lesions of the aortoiliac segment, with patency rates (60 to 90 percent at 5 years) approaching those of operative correction. However, balloon angioplasty procedures have generally been reserved for patients with less extensive atherosclerosis. Moreover, the long-term results of PTA have been determined with subjective methods rather than with the laboratory methods routinely used in evaluating the results of vascular surgical procedures. These two factors may have resulted in an overestimation of the success of PTA, rendering direct comparisons of patency rates between angioplasty and operative revascularization impossible.

A plethora of new devices designed to relieve arterial stenoses by relatively noninvasive means have been introduced over the past decade. In procedures collectively termed *endovascular interventions*, these devices are placed percutaneously or through femoral artery cutdowns. The devices have included: (1) laser-heated metallic probes designed to remodel plaque as the instrument is advanced through an atherosclerotic lesion; (2) catheters that vaporize atheromata by direct delivery of laser light; (3) "atherectomy" devices that remove plaque with rotational cutting blades; and (4) intraluminal metallic stents designed to maintain the artery in an expanded state and thus decrease the frequency of postprocedural restenosis.

Vascular endoscopes are frequently used to evaluate the results of these interventions, and these instruments have been helpful also in the assessment of operative procedures such as balloon catheter thrombectomy and valve disruption in in situ saphenous vein bypass. Intravascular ultrasound devices have been introduced to provide high- resolution images of atherosclerotic vessels both before and after endovascular manipulation. Unfortunately, the introduction phase of each new device has been associated with unwarranted optimism, prompting premature promotion of the device before long-term safety and efficacy have been demonstrated. To date, none of new devices has matched the results of standard operative revascularization procedures. It is hoped that the continued development, refinement, and objective long-term evaluation of newer endovascular techniques may someday provide less invasive means of restoring arterial flow to the compromised extremity.

Infrainguinal Occlusive Disease

The infrainguinal vessels are defined as those vessels distal to the inguinal ligament, including the common femoral, superficial and deep femoral, popliteal, and infrapopliteal arteries. The superficial femoral artery is the most common site of atherosclerotic obstruction in the lower extremity. The process usually is first evident at the level of the adductor canal, but recent studies suggest that this is not because the atherosclerotic process begins here. Rather, as Zarins and associates have shown, the deposition of atherosclerotic plaque occurs at an equal rate throughout the superficial femoral segment. The normal response to plaque deposition is dilatation of the vessel such that the lumen diameter is maintained. Zarins and associates have suggested that the most severe obliterative process occurs at the level of the adductor canal because this area of the vessel is least likely to display compensatory dilatation in response to plaque deposition.

The risk factors for infrainguinal atherosclerotic arterial disease are the same as those of atherosclerotic disease in general, namely, advanced age, systolic hypertension, cigarette smoking, hyperlipidemia, and diabetes mellitus.

Clinical Manifestations

Stenosis or occlusion limited to only one segment of the arterial tree seldom results in a threatened limb. The most frequent clinical scenario is that of solitary superficial femoral artery occlusion at the level of the adductor canal, producing calf claudication after the patient has walked several blocks. Critical ischemia manifested by rest pain, ulceration, or gangrene is seen only with the development of multisegmental disease involving the aortoiliac, deep femoral, or tibial vessels in addition to the superficial femoral artery. Rest pain is characteristically located in the forefoot or the medial arch and is most severe when the foot is elevated in bed at night. Nighttime calf pain usually is the result of benign conditions such as nocturnal cramping and should not be confused with pain from arterial ischemia.

The natural history of infrainguinal arterial occlusive disease depends on the severity of the patient's symptoms. Boyd prospectively followed more than 1400 patients with intermittent claudication and found that only 7 percent required amputation at 5-year follow-up. The results of the Framingham study were even more optimistic, with less than 2 percent of patients with claudication losing a limb over a 10-year interval. It must be kept in mind, however, that many of the patients in these studies eventually required arterial reconstructive procedures. Nevertheless, it is clear that symptoms of intermittent claudication alone are not a harbinger of limb loss, and operative procedures designed to relieve claudication must weigh this relatively small risk against the somewhat higher risks of perioperative morbidity and mortality. In contrast to intermittent claudication, symptoms of severe ischemia with pain at rest, ischemic ulceration, and gangrene are associated with a high risk of limb loss unless successful revascularization can be achieved. Over 50 percent of untreated patients with limb-threatening symptoms will require amputation within several months of presentation, and this risk increases as the severity of the ischemic process evolves from rest pain to tissue loss.

The life expectancy of patients with lower-extremity occlusive disease must be taken into account when considering options of operative revascularization. Given the systemic nature of the atherosclerotic process, it is not surprising that the survival of patients with lower-extremity occlusive disease is significantly decreased as a result of coexistent coronary disease, cerebrovascular disease, and an increased risk of lung cancer. Recent studies reliably suggest a 70 percent 5-year and a 50 percent 10-year survival rate in patients with chronic lower-extremity arterial disease; these rates on average are 20 to 30 percent below those of age-matched controls.

Diagnosis

The diagnosis of infrainguinal arterial occlusive disease is based on the characteristic clinical findings of intermittent calf claudication, rest pain in the foot, or tissue loss in the form of ischemic ulceration or gangrene. Claudication can be differentiated from other causes of leg pain on the basis of its reproducible relationship to ambulation. Patients with claudication develop pain after walking a distance that is constant for any given patient, and exhibit regression of the pain on cessation of activity, even if the standing position is maintained. By contrast, patients with leg pain secondary to disorders such as nerve root compression exhibit pain that is related to position rather than ambulation.

The physical examination is the most important tool in the diagnosis and localization of lower-extremity occlusive disease. Whereas the patient with aortoiliac occlusive disease manifests absent femoral pulses in the groin, patients with infrainguinal disease have normal femoral pulses and absent popliteal pulses (superficial femoral artery occlusion) or absent pedal pulses (tibial artery occlusive disease). The differential diagnosis of lower-extremity ulcerations can frequently be made on the basis of location and appearance. Ulcerations secondary to inadequate arterial blood flow are characteristically found on the lateral aspect of the ankle or on the foot and are pale and devoid of granulation tissue. Ulcerations resulting from venous stasis are located above the medial malleolus, are pink with abundant granulation tissue, and are accompanied by other stigmata of venous disease such as brown discoloration of the pretibial skin.

The noninvasive laboratory examination of the patient with infrainguinal occlusive disease parallels the physical findings. The common femoral Doppler waveforms have the normal triphasic configuration. Proximal-thigh Doppler segmental pressures may be normal if the superficial or profunda femoris artery is free of disease, but will be decreased if the proximal portions of both vessels are affected. The distal superficial femoral artery is the most frequent site for occlusive disease. The most common Doppler segmental findings, therefore, consist of a proximal-thigh cuff pressure equal to or greater than the brachial pressure and a gradient of at least 30 mmHg between the proximal and distal thigh pressures.

Vessel wall calcification, a change characteristically seen in diabetic patients, renders the arterial wall incompressible. Doppler cuff pressures are unobtainable in this case, since flow through the calcific, rigid vessels cannot be obliterated, even with cuff pressures exceeding 300 mmHg. Pulse volume recordings (PVRs) play an important role in the evaluation of the diabetic with incompressible vessels. The PVR does not require compression of the vessels; rather, it relies on volume changes in the leg between systole and diastole. The presence of blunted PVR tracings between two levels in the extremity is indicative of an interval stenosis. Despite the common misperception that diabetic arterial disease is an entity involving the small arteries and arterioles, the larger vessels are actually the most common location of arterial lesions even in diabetics, while the smaller, digital arteries are frequently spared. This feature of diabetic arterial disease makes it possible to use toe pressures to detect arterial insufficiency when the large vessels are incompressible. Toe pressures are obtained by placing a small pneumatic cuff around the base of the digit and a photoplethysmographic sensor distal to the cuff. The systolic pressure at the toe level is normally somewhat less than the brachial pressure, with normal toe indices (toe pressure divided by brachial pressure) averaging 0.70 or more. Patients with claudication usually have toe indices in the range of 0.40, and patients with rest pain, ulceration, or gangrene have toe indices of 0.10 to 0.20.

Arteriography is the most precise method of documenting the location and severity of infrainguinal arterial occlusive disease. Transfemoral standard or intraarterial digital studies offer the highest-quality images. The small caliber and slow flow characteristic of diseased lower-extremity vessels diminishes the resolution of intravenous digital studies and renders this form of arteriography inappropriate in most patients with infrainguinal occlusive disease. Duplex ultrasonography has been used as a less invasive alternative to contrast arteriography in patients with lower-extremity occlusive disease, but its lack of precision makes it a less adequate method of preoperative evaluation.

Treatment

The indications for infrainguinal arterial reconstruction, similar to those for aortoiliac reconstruction, include severe claudication and limb-threatening ischemia manifested by rest pain, ulceration, or gangrene. Nonoperative management is indicated in patients with mild claudication, and treatment regimens include cessation of tobacco use and institution of a daily program of regular exercise. Vasodilators, including calcium channel blockers, have been used with limited success.

Pentoxifylline is an oral agent that reduces blood viscosity, theoretically increasing blood flow through stenotic arteries and small collateral vessels. In a randomized, double-blind, multicenter trial, pentoxifylline was found to reduce symptoms of claudication in 45 percent of patients, as compared to 23 percent with placebo. The therapeutic benefit from pentoxifylline has been unpredictable in actual clinical usage, with many patients having little or no relief of claudication. The documented improvement in microcirculatory flow, however, has led to interest in using pentoxifylline to improve tissue perfusion in patients with limb-threatening ischemia. Encouraging results have been reported in patients with arterial ulcerations, although randomized, blind studies have yet to be completed.

Three factors are required for successful infrainguinal revascularization: adequate inflow, adequate outflow, and a suitable conduit. As in the case of aortoiliac disease, endarterectomy and bypass grafting both may be used in the management of arterial insufficiency. For patients requiring infrainguinal reconstruction, however, the concerns of inadequate inflow, inadequate outflow, and type of conduit assume much greater importance. These three issues are rarely of concern in aortoiliac revascularization but are fundamental in more distal reconstructions.

Endarterectomy

Infrainguinal endarterectomy was introduced more than four decades ago, before the development of adequate bypass conduit materials. The segment of artery containing the atherosclerotic lesion is exposed, the artery is opened, and the atheroma is removed using a spatula or mechanical stripper. The arteriotomy or arteriotomies are then closed primarily or with a venous or prosthetic patch. The long-term success of the procedure appears to depend on the size of the artery and the length of the lesion. As with any endarterectomy procedure, the atherosclerotic lesion must terminate distally in an area of normal arterial wall. If care is not taken to ensure that this is the case, dissection of blood beneath the shelf of the atheroma may result in the creation of a flap and acute postoperative thrombosis of the reconstruction. Endarterectomy is generally limited to the treatment of short lesions of the superficial femoral artery at the adductor canal and localized stenoses at the origin of the deep femoral artery. Popliteal and tibial artery endarterectomy procedures are rarely successful, because the atherosclerotic disease usually is diffuse in these vessels.

Bypass Procedures

Bypass procedures are described in terms of the inflow and outflow sites. Thus in a *femoropopliteal bypass* the site of inflow is the femoral artery and the site of outflow is the popliteal artery. The two most commonly performed infrainguinal reconstructions are the femoropopliteal and femorotibial bypasses (Fig. [20-25](#)). Popliteal-to-tibial and popliteal-to-pedal bypasses are important but are performed less commonly, as are more distal reconstructions to the arteries of the foot.

The common femoral artery is the standard site of inflow for infrainguinal bypass procedures. The superficial femoral or popliteal arteries also may be used for inflow in the absence of significant proximal stenoses, and these alternative sources of inflow become particularly important when the length of vein available for the bypass is limited. The choice of inflow and outflow sites is relatively straightforward when a single segment of the arterial tree is involved with an occlusive lesion. For example, a femoropopliteal bypass is appropriate when the occlusive process is limited to the superficial femoral artery between its origin and the knee joint. The presence of multisegmental arterial occlusion, however, requires that a decision be made regarding which levels of occlusion should be bypassed. In general this decision is based on the magnitude of the ischemic process. The presence of extensive tissue loss in the foot mandates bypassing all levels of occlusion. For example, a patient with a superficial femoral artery occlusion, an open popliteal artery, and short proximal occlusions of all three tibial arteries will be well served by a femoropopliteal bypass to the "isolated" popliteal segment if the symptoms are of claudication or even rest pain. By contrast, a patient with the same arteriographic configuration but with a large necrotic ulceration over the dorsum of the foot will require bypass to an open distal tibial artery.

The selection of conduit material is of paramount importance in infrainguinal arterial reconstruction, as the long-term patency rate is highly dependent on two primary factors: the site of outflow and the type of bypass material. The graft choices are autogenous vein and prosthetic graft materials (Table [20-5](#)). Among the prosthetic materials, *ePTFE* is the most commonly used, and polyester is infrequently employed. Bovine heterografts have been abandoned because of the propensity for late aneurysm formation, and human umbilical vein biografts have decreased in popularity because they are cumbersome to sew and also are associated with late aneurysm formation. Saphenous vein is the best infrainguinal bypass conduit material. The long-term patency rate of saphenous vein grafts is better than that of prosthetic grafts, and there are fewer postoperative infections than with prosthetic material. The difference in patency is of sufficient magnitude that vein should be used for all infrainguinal bypasses, even if this requires use of the lesser saphenous or cephalic veins. Possible exceptions to this rule may occur when the bypass graft does not cross the knee joint, as in a femoral-to-supragenicular popliteal artery bypass. In this instance, the patency rates of venous and prosthetic bypass grafts do not differ substantially, and use of a prosthetic graft preserves the vein for use in the event of graft failure or for use in a subsequent coronary artery bypass.

There are two general techniques used in autogenous vein bypass procedures, differentiated by the orientation of the vein in relation to the direction of blood flow and the alignment of the venous valves. Advantages and disadvantages have been demonstrated with each method, but most studies have failed to document significant differences in long-term patency rates when precise operative technique has been employed. The *reversed* bypass technique, the first method of infrainguinal vein bypass employed, excises the vein in its entirety and reverses it such that the caudal end is anastomosed proximally and the cranial end distally. The reversed orientation allows blood flow to proceed in the natural direction allowed by the valves, but the small end of the vein is anastomosed to the larger (inflow) artery, and the large end of the vein is anastomosed to the smaller (outflow) artery (Fig. [20-26](#)).

In situ vein bypasses are a second technique, first performed in the 1960s. The vein is left in its usual orientation, disrupting the venous valves to allow blood to flow from the cranial end of the vein to the caudal end. The large and small ends of the in situ venous conduit are connected to the arterial vessels of corresponding size, and venous vasa vasorum are preserved if the vein is left in its natural bed. A variety of instruments have been devised to assist in the disruption of the valves; some are passed through side branches of the vein and others through the caudal cut end of the conduit. An alternative technique, representing a modification of the in situ method, involves excising the vein, disrupting the valves, and connecting the conduit in an "excised, nonreversed" fashion. This technique interrupts the potentially advantageous venous vasa vasorum but decreases the risk of vein injury during the valve-cutting process, since the vein may be straightened and shortened in an "accordion" fashion onto a semirigid valve-cutting instrument.

Endovascular Procedures

Infrainguinal endovascular procedures include percutaneous transluminal balloon angioplasty, laser angioplasty, and catheter atherectomy. None of the devices has matched the success of endovascular procedures in the aortoiliac segment. Balloon angioplasty with or without the use of a stent may have a role in selected patients with superficial femoral disease, but the current results only justify the routine use of this technique for iliac lesions. Laser angioplasty and catheter atherectomy must be considered experimental techniques, and assessment of their safety and efficacy awaits the results of randomized, controlled trials that adhere to uniform reporting standards.

The Diabetic Foot

Diabetes mellitus is the risk factor associated with the highest rate of limb- threatening ischemia of the lower extremity; the incidence of gangrene in diabetics is more than fifty times greater than in nondiabetics. The anatomic distribution of arterial lesions in diabetics differs from that of the nondiabetic population, but the underlying histopathology is similar. Diabetic arterial disease is more common in the distal profunda femoris artery, the distal popliteal and tibial arteries, and the digital arteries of the foot. The aortoiliac segment is usually spared. The widespread belief that diabetic arterial disease is primarily localized to the small vessels is erroneous. Although diabetics do develop a microangiopathy characterized by thickening of the intima and basement membrane, the primary pathologic process is that of typical large-vessel atherosclerosis. The media of muscular arteries is often heavily calcified in diabetics, rendering the vessels incompressible and difficult to occlude with standard vascular clamps.

Diabetics are predisposed to ulceration and gangrene of the foot with relatively rapid progression to limb loss. A variety of complex and interrelated factors are responsible for this. Diabetic neuropathy produces motor and sensory deficits in the foot. The loss of efferent motor fibers results in atrophy of the intrinsic muscles, a characteristic high-arched deformity of the foot, and markedly increased pressure on the metatarsal heads. Sensory loss compounds the problem, because the patient is unaware of pressure-induced skin necrosis and minor injuries. Arterial disease accelerates the process, and the presence of apparently minimal external pressure may lead to the development of extensive tissue damage.

The impression that infection is more common in diabetic patients has never been proved, but when infections do occur, they are often very aggressive and are associated with a high incidence of gangrene and limb loss. Infection may develop from seemingly trivial skin defects and can quickly spread along musculofascial planes to involve the tendon sheaths and muscles of the foot and leg. The bacteriology of foot sepsis in the diabetic patient is multimicrobial, with gram-negative, gram-positive, and anaerobic organisms acting in synergy. The bacteria most commonly cultured in diabetic foot ulceration are *Peptococcus* (80 percent), *Proteus* (55 percent), and *Bacteroides* (45 percent), with an average of five or more species per specimen. The organism populations cultured from superficial sites usually differ from those deep within the wound. The inaccuracy of bacterial identification obtained from superficial wound cultures emphasizes the importance of broad-spectrum antibiotic therapy in the treatment of diabetic foot infections. The time-honored approach is to begin treatment with an aminoglycoside, clindamycin, and ampicillin, and instituting a more specific therapy when results are obtained from deep- wound cultures taken at the time of operation. Newer cephalosporins and penicillin derivatives have been used successfully and are particularly useful for patients with renal insufficiency.

The classic diabetic foot ulcer, the “mal perforant” plantar ulcer, is located over the metatarsal heads on the plantar aspect of the foot. This is a *neurotrophic ulceration*, as it results from the sensory neuropathy of the diabetic. The ulcer begins to form beneath a callous and may eventually erode into the bone, producing a secondary osteomyelitis.

Treatment

The treatment of diabetic foot ulcers differs from the treatment of ulcers in nondiabetic patients in a number of ways. The exclusion of significant underlying arterial disease is of primary importance. The presence of calcific, incompressible vessels may falsely elevate Doppler pressure measurements, and a normal ankle/brachial index does not eliminate the possibility of arterial disease in the diabetic patient. Toe pressure determination is an accurate means of evaluating arterial insufficiency in the diabetic, since digital artery medial calcinosis is rare. Arterial disease is unlikely when the toe/brachial pressure ratio exceeds 0.70. Arteriography is frequently required to exclude the possibility of reconstructible arterial disease of the infrapopliteal, tibial, and pedal vessels. Revascularization procedures are indicated whenever ulceration occurs in the presence of significant arterial disease. In the absence of arterial disease, local wound care, avoidance of repetitive trauma, and the use of specially fitted shoes are appropriate. Amputation may be necessary when the disease is limited to the most distal vessels or when gangrenous changes have progressed despite apparently adequate arterial supply. Minor resections, including digital amputations, transmetatarsal amputations, or other, case-specific resections involving variable portions of the foot, may be appropriate in the diabetic. The presence of a palpable dorsalis pedis or posterior tibial pulse is an excellent predictor of healing, and debridement and amputation should be conservative under these circumstances. Myocutaneous free flaps have been of value in covering seemingly insurmountable exposure of subcutaneous tissue and bone. Latissimus dorsi or rectus abdominis muscle has been utilized, basing the inflow on a patent tibial artery or vein bypass graft.

Sepsis resulting from diabetic foot infection demands urgent treatment. Control of hyperglycemia, drainage of purulent collections, debridement, and rapid institution of broad-spectrum antibiotic therapy are the important initial interventions. Arterial reconstructive procedures are performed after the septic process has been controlled, minimizing the risk of graft infection by avoidance of prosthetic conduits.

Upper-Extremity Occlusive Disease

The causes of chronic upper-extremity ischemia are multiple, and although atherosclerosis is the usual cause, nonatherosclerotic causes are also common. Vasospastic and inflammatory arteritides affect the upper extremity more often than the lower extremity, whereas the reverse is true of atherosclerotic disease. The characteristic symptom of chronic upper- extremity ischemia is arm claudication. Rest pain and tissue loss are unusual because of the extensive collateral network about the shoulder and elbow. When digital gangrene does occur, it is usually a result of microemboli originating from atherosclerotic lesions of the subclavian artery.

Diagnosis

The diagnosis of upper-extremity arterial occlusive disease begins with palpation of the axillary, radial, ulnar, and brachial pulses. The most common site of atherosclerotic disease of the upper extremity is the origin of the subclavian arteries proximal to the vertebral artery, a lesion that may produce a supraclavicular bruit. More distal lesions generally are not atherosclerotic in origin, and disorders such as giant cell arteritis and thoracic outlet syndrome should be considered. Proximal subclavian lesions may produce the arteriographic finding of flow reversal in the vertebral artery, since this vessel may serve as a major source of collateral blood flow to the arm. Serial images performed after injection of contrast material into the contralateral nonstenotic subclavian artery will reveal normal antegrade flow in the uninvolved vertebral artery, with retrograde flow in the vertebral artery on the side of the subclavian stenosis. This arteriographic finding is associated with the clinical picture known as the *subclavian steal syndrome* and is characterized by nonhemispheric cerebrovascular symptoms in association with mild arm claudication. This symptom complex develops as a result of a reduction in posterior cerebral arterial flow secondary to the “steal” of blood as it flows in a retrograde direction through the vertebral artery into the subclavian artery. The isolated arteriographic finding of retrograde vertebral artery flow is rarely associated with cerebral symptoms, since the collateral circulation through the circle of Willis usually is sufficient to compensate for the amount of blood diverted to the arm. The presence of neurologic symptoms in the subclavian steal syndrome should suggest the presence of a coexistent carotid stenosis, limiting the compensatory capacity of the cerebral circulation.

Treatment

The indications for operation in upper-extremity arterial occlusive disease include incapacitating arm claudication, emboli to the hand or posterior cerebral circulation, and symptomatic subclavian steal syndrome in the absence of a coexistent carotid lesion. Significant carotid lesions should be corrected first in the subclavian steal syndrome, reserving direct subclavian reconstruction for patients without carotid lesions or in whom carotid endarterectomy fails to alleviate cerebral symptoms.

Endarterectomy of the subclavian artery has decreased in popularity because of the fragility of the subclavian artery and the intrathoracic nature of the procedure. Extrathoracic approaches to the subclavian artery are more commonly used, employing a transverse supraclavicular incision to expose the common carotid artery for inflow and the distal subclavian artery for outflow. A carotid–subclavian artery bypass is generally performed with a polyester or *ePTFE* conduit; this is one of the few situations in which prosthetic material may have a better patency than vein (Fig. 20-27). Operative alternatives include transposition of the end of the subclavian artery onto the side of the common carotid artery (Fig. 20-28), and axillary–to–axillary artery bypass. Treatment of multiple aortic arch vessel involvement requires a median sternotomy and placement of bypass grafts from the ascending aorta to one or more vessels in the neck. Embolic disease is treated by exclusion of the involved segment of artery from the circulation, usually with a standard carotid–subclavian artery bypass, and ligation of the subclavian artery proximal to the origin of the vertebral artery. Lesions of the axillary and brachial arteries are treated with saphenous vein bypass grafts around the occluding lesion; the patency of these grafts is excellent. Cervical sympathectomy has been used in the treatment of nonreconstructible disease such as digital artery occlusion, but the results have been discouraging.

MESENTERIC AND RENAL ARTERY OCCLUSIVE DISEASE

Occlusive disease involving the arteries to the viscera is associated with the life-threatening complications of intestinal infarction and renal insufficiency. The process may develop suddenly, as in the case of embolization to the vessels, or the process may evolve insidiously, as in the case of progressive encroachment on the arterial lumen by an atherosclerotic plaque. The relative rarity of these disorders, along with the inaccessibility of the organs to physical examination, renders the diagnosis elusive.

Acute Mesenteric Ischemia

Acute mesenteric ischemia is associated with astonishingly high mortality rates, around 75 percent in most series, despite advances over the past few decades in operative technique and perioperative management. There are two basic explanations for these dismal results. First, the rarity of the disease renders prompt diagnosis difficult, and an improved outcome can be achieved only with rapid identification of the problem and restoration of blood flow before the onset of irreversible intestinal gangrene. Second, acute mesenteric ischemia usually develops in elderly, medically compromised patients who do not tolerate the physiologic insult well.

There are four basic causes of acute mesenteric ischemia; superior mesenteric artery embolization, superior mesenteric artery thrombosis, nonocclusive mesenteric ischemia, and acute mesenteric venous thrombosis. Emboli generally originate from the heart and occur in patients with atrial fibrillation or after myocardial infarction. Thrombosis occurs in the presence of underlying mesenteric atherosclerotic disease, as a critical stenosis progresses to occlusion. Nonocclusive mesenteric ischemia develops in patients with low-cardiac-output states, especially in the presence of digoxin or vasopressors. The pathophysiology of nonocclusive ischemia is that of mesenteric artery vasoconstriction, which is frequently manifested as segmental spasm of the secondary and tertiary branches of the superior mesenteric artery. The precise mechanisms causing nonocclusive ischemia are unclear, but the process probably involves a vicious circle in which vasoconstriction is induced in the mesenteric artery bed by a remote stimulus such as cardiogenic shock; local hypoxia follows, and the resultant bowel ischemia leads to bacterial transudation, worsening shock, and sympathetic stimulation, and perpetuation of the mesenteric vasoconstriction. Venous thrombosis may be secondary to infection or dehydration.

Changes discernible in electron microscopy occur in the intestinal mucosa after only 10 min of ischemia, and in light microscopy after 1 h. Hemorrhagic necrosis develops later, with sloughing of the mucosa, edema of the bowel wall, and hemorrhage into the lumen. The bowel wall becomes permeable to the luminal bacteria once the mucosa is shed. Peritonitis ensues from transudation of microflora across the intestinal wall, and septicemia and bacteremia develop as the organisms enter the portal circulation and overload the filtering capacities of the liver. Massive fluid shifts into the bowel wall and peritoneum follow, resulting in hemoconcentration, oliguria, and hypotension. Serum levels of lactate dehydrogenase (LDH), serum glutamic oxaloacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), and creatine phosphokinase (CPK) become markedly elevated with the death of intestinal cells.

Diagnosis

The classic presentation of acute mesenteric ischemia is the sudden onset of abdominal pain out of proportion to the physical findings. The patients complain of periumbilical pain as a result of the small-intestinal ischemia and spasm. The spasm results in gastrointestinal emptying, with emesis and bloody diarrhea. Laboratory changes occur later, with leukocytosis, elevation of the hematocrit, lactate, LDH, SGOT, SGPT, and CPK levels, acidosis, and hyperkalemia.

Arteriography has played a crucial role in the early diagnosis of acute intestinal ischemia. Differentiation of the three forms of mesenteric artery occlusion can be made with lateral views on a transfemoral aortic injection. Mesenteric emboli generally lodge at the orifice of the middle colic artery, generating the characteristic arteriographic picture of a normal-appearing proximal superior mesenteric artery terminating in a “meniscus sign” several centimeters from its origin on the aorta. By contrast, mesenteric thromboses occur at the level of the most proximal superior mesenteric artery, before the middle colic takeoff. A tapering termination of the superior mesenteric artery is seen within 1 or 2 cm of its origin, and the development of collateral circulation may be evidence of a long-standing stenotic lesion. Nonocclusive mesenteric ischemia produces the characteristic arteriographic finding of segmental mesenteric vasospasm with a relatively normal-appearing main superior mesenteric artery trunk.

The differentiation of superior mesenteric embolus, thrombosis, and nonocclusive ischemia often can be made at the time of laparotomy on the basis of the distribution of the ischemic process. Emboli lodge at the origin of the middle colic artery, distal to the first few jejunal branches of the superior mesenteric artery. Continued perfusion of these jejunal branches spares the proximal jejunum from the gangrenous process. By contrast, thrombotic occlusion occurs at the origin of the superior mesenteric artery, proximal to all the jejunal branches. The gangrenous process runs from the ligament of Treitz to the mid–transverse colon, without sparing of the proximal jejunum. Finally, nonocclusive mesenteric ischemia involves the branches of the superior mesenteric vessel in a segmental fashion and is associated with a patchy appearance of alternating pink and dusky bowel.

Treatment

The treatment of acute mesenteric artery occlusion varies with the cause of the process. It is useful to obtain a preoperative arteriogram so that appropriate management can be planned accordingly. This is not always possible, since the diagnosis of mesenteric ischemia may not have been made before laparotomy; also, some patients present in a moribund state, and the delay required for arteriography may be ill-advised.

Mesenteric Embolus

The basic goal of operation in superior mesenteric artery embolus is the rapid restoration of arterial perfusion with removal of the embolus from the vessel. Usually a long midline abdominal incision is used. The transverse colon is lifted superiorly, and the small bowel is reflected toward the right upper quadrant. The superior mesenteric artery is approached at the root of the small-bowel mesentery, usually as it emerges from beneath the pancreas to cross over the junction of the third and fourth portions of the duodenum. A transverse arteriotomy is made in the vessel, and a balloon catheter is inserted proximally and distally to remove the embolus and propagated thrombus. An assessment of intestinal viability must be made after perfusion has been restored, and segments that are obviously nonviable must be resected. Numerous technical aids have been employed to predict viable from nonviable bowel, including intraoperative intravenous fluorescein injection and inspection with a Wood's lamp and Doppler assessment of antimesenteric intestinal arterial pulsations. A second-look procedure is necessary in many patients and is usually scheduled 24 to 48 h after embolectomy. The rationale for second-look procedures is that the precise extent of intestinal viability may not be evident immediately after reperfusion, and additional resection of ischemic bowel may be necessary. An important tenet of second-look laparotomy is that the decision to proceed with the additional operation must be made at the time of the initial laparotomy. Subsequent analysis of the patient's postoperative course should not alter the decision, since the early postoperative status of these patients bears no correlation with the presence or absence of residual nonviable bowel.

Mesenteric Thrombosis

The therapy of mesenteric thrombosis differs from that of embolization because of the nature of the superior mesenteric artery. The vessel itself is normal in embolic disease, and simple removal of the thromboembolus is all that is necessary. By contrast, the thrombotic process occurs in a severely atherosclerotic proximal superior mesenteric artery. Therefore, patients with thrombotic disease require placement of a bypass graft to the superior mesenteric artery distal to the occlusive process to restore adequate mesenteric flow. The aorta or the iliac artery may be used as the origin of the bypass graft. There are two advantages to using the supraceliac, infradiaphragmatic aorta rather than the infrarenal aorta as the origin for the graft. First, this segment usually is soft and does not present the problems associated with clamping of the frequently calcific infrarenal aorta. Second, the use of the more proximal aorta allows placement of an antegrade graft, which is less prone to kinking when the small bowel is returned to its normal location after construction of the anastomoses. Saphenous vein is usually the graft material of choice in patients with acute mesenteric ischemia; prosthetic materials should be avoided because of the risk of bacterial seeding from transudation or during intestinal resection.

The principles behind the resection of nonviable bowel are the same for patients with thrombotic and embolic mesenteric ischemia. Doppler and fluorescein techniques can be worthwhile, and a second-look procedure may be advisable. Not infrequently, the length of viable intestine is so short as to be unable to sustain life. The treatment of these patients must be individualized on the basis of an understanding of the patient's wishes with respect to permanent intravenous hyperalimentation. Closure of the abdomen without revascularization or resection of bowel may be the most appropriate management for many of these patients.

Thrombolytic therapy is a potential consideration in patients with acute mesenteric ischemia, with intraarterial delivery of the agent into the thrombus at the time of arteriography. Successful lysis of the central core of acute thrombus will return the mesenteric circulation to its chronic, stable state, and subsequent operative revascularization or even balloon angioplasty of the stenotic superior mesenteric artery can be electively undertaken. Percutaneous intraarterial thrombolysis, however, does not provide the opportunity to inspect the bowel for viability after reperfusion. In addition, many hours may be lost during the time required for clot lysis, and attempts at operative revascularization will be significantly delayed if thrombolysis is unsuccessful. Thrombolytic interventions in acute mesenteric ischemia must therefore be considered investigational at present and should be reserved for selected patients.

Nonocclusive Mesenteric Ischemia

The therapy of nonocclusive mesenteric ischemia is primarily nonoperative. A metabolic cause of the problem should be sought and corrected whenever possible. Intraarterial vasodilating agents such as tolazoline or papaverine can be administered directly into the superior mesenteric artery at the time of arteriography, and the effects of the agents can be objectively documented with serial arteriograms. Resection of nonviable bowel may be required when the patient's condition permits.

Chronic Mesenteric Ischemia

Chronic mesenteric ischemia occurs as the result of atherosclerotic occlusive disease of the superior mesenteric and celiac vessels. Less frequent causes include fibromuscular dysplasia, radiation arteritis, autoimmune arteritides, and a secondary mesenteric arteritis after aortic coarctation repair. A disorder known as the “celiac band syndrome” has been described in which the celiac axis is compressed by the median arcuate ligament. The significance of this finding as a cause of abdominal symptoms is doubtful, because a large percentage of normal individuals manifest a moderate celiac stenosis on lateral aortography.

The mesenteric atherosclerotic process usually begins with stenotic plaque formation at the origins of the visceral arteries as they exit the aorta. In contrast to acute mesenteric occlusion, which produces intestinal infarction with superior mesenteric artery occlusion alone, the chronic form of the disease is not associated with symptoms until both the celiac axis and the superior mesenteric arteries are significantly stenosed. The classic symptom complex of postprandial abdominal pain and weight loss is almost uniformly present and is in keeping with the alternate name of “intestinal angina” used to describe the disorder.

The anatomy of the collateral arterial circulation is an important feature in chronic mesenteric ischemia (Fig. 20-29). The celiac and superior mesenteric artery circulations communicate through the gastroduodenal artery and pancreatic branches, respectively. Significant stenotic disease of one system results in dilatation of the gastroduodenal artery to accommodate the increased collateral flow. The inferior mesenteric artery communicates with the superior mesenteric system through two routes. First, a clinically insignificant pathway exists through the left colic artery, the marginal artery of Drummond, and the middle colic artery. Second, a hemodynamically important pathway may evolve through a “meandering mesenteric artery.” This artery is not present in the absence of mesenteric occlusive disease; it develops as a tortuous vessel running through the medial aspect of the left mesocolon to provide anastomotic collateral flow between the proximal inferior mesenteric artery and the superior mesenteric artery. A meandering mesenteric artery can be distinguished arteriographically from a normal marginal artery of Drummond by its more medial location, tortuosity, and shorter route between the inferior and superior mesenteric vessels.

Diagnosis

The most common presentation in patients with chronic mesenteric ischemia is postprandial abdominal pain and weight loss. The pain occurs 20 min to 1 h after a meal, and its intensity is correlated with the amount of food ingested. The relationship between food and pain is so striking that patients decrease the size and frequency of meals, giving rise to the term “food fear.” This conscious restriction of food intake is the cause of the patients' weight loss, rather than a malabsorption syndrome secondary to ischemic bowel injury.

Physical examination in chronic mesenteric ischemia is remarkable only for the obvious cachectic appearance of the patient and the frequent finding of a midabdominal bruit. Occult blood in the stool is unusual and implies a different diagnosis or a more acute ischemic process. Remote stigmata of diffuse atherosclerotic disease are usually present, including carotid and femoral bruits and the absence of palpable lower-extremity pulses. Laboratory tests generally are not helpful. Absorption studies such as fecal fat analysis and urinary excretion of orally administered d-xylose are of limited value. Upper and lower gastrointestinal barium contrast studies usually are normal in patients with chronic mesenteric ischemia, although some patients manifest decreased motility and mucosal edema. Duplex scanning of the celiac and superior mesenteric origins has been reported to be a useful screening method in patients with suspected mesenteric ischemia, but arteriography is necessary to confirm the diagnosis. Lateral aortography reveals stenosis or occlusion of both the celiac axis and the superior mesenteric artery, frequently in association with a large meandering mesenteric vessel on the anteroposterior views. Mesenteric ischemia so rarely occurs in the presence of a solitary visceral arterial occlusion that the accuracy of the diagnosis is called into question when only one visceral vessel is involved.

Treatment

Revascularization is indicated in all patients with symptomatic mesenteric ischemia in order to prevent the development of catastrophic bowel infarction. Nevertheless, rather impressive visceral artery disease may appear arteriographically in the absence of symptoms. The coexistence of abdominal pain and arteriographic findings does not necessarily imply a causative relationship, and other diagnoses such as occult malignancy or inflammatory bowel disease should be excluded in all patients, irrespective of the arteriographic findings.

A transperitoneal approach to operative revascularization provides the opportunity to thoroughly explore the abdomen to exclude nonvascular causes for the patient's symptoms. Historically, endarterectomy was the first method used in visceral arterial revascularization. Endarterectomy is most easily accomplished through a lateral or posterior aortotomy, removing a plug of atheroma from the celiac trunk and the superior mesenteric artery through a “transaortic” exposure. The danger in this technique lies in the inability to adequately visualize the termination of the endarterectomy on the visceral vessel, risking the inadvertent creation of an intimal flap and early thrombosis of the reconstruction.

Bypass procedures have gained widespread acceptance in visceral arterial reconstruction. As in any arterial reconstructive procedure, the surgeon has three decisions to make: the

inflow site, the outflow site, and the type of bypass graft material. The infrarenal aorta, the supraceliac aorta, and the iliac artery are all satisfactory choices as the site of inflow. The supraceliac aorta has the advantage of a much lower incidence of atherosclerotic change than the more distal sites, thereby decreasing the danger of iatrogenic embolization secondary to the clamping of a diseased vessel. Supraceliac inflow also allows the bypass graft to be placed in an antegrade fashion, avoiding the kinking tendency associated with retrograde grafts from an infrarenal location. Both the celiac and superior mesenteric systems should be revascularized if possible, to provide a margin of safety if one reconstruction fails. Anastomosis of one end of the graft to the side of the common hepatic artery will revascularize the celiac system and a similar anastomosis to the superior mesenteric artery will revascularize that arterial bed. Satisfactory results have been achieved with both saphenous vein and prosthetic conduits. The use of a bifurcated polyester graft from the supraceliac aorta is a commonly performed operation for mesenteric ischemia. This procedure is an antegrade reconstruction that preserves the saphenous vein and reduces the number of vascular anastomoses needed to be performed.

Endovascular treatment of mesenteric artery stenoses, using percutaneous balloon angioplasty with or without placement of a stent, is gaining acceptance as a viable treatment option. The procedure must still be considered experimental, pending the availability of long-term clinical follow- up data.

Renovascular Disease

The proximal renal arteries are a common location for the development of atherosclerotic lesions. Two important disorders occur as a result of significant renal artery disease: renovascular hypertension and renal insufficiency. Renovascular hypertension has emerged as the leading cause of surgically correctable hypertension, stimulated by the work of Goldblatt in 1934. In the years that followed, the recognition that renal function improved after renal artery reconstruction fostered interest in the salvage of functioning renal parenchyma, irrespective of the presence or absence of hypertension.

Renovascular Hypertension

Hypertension secondary to renal artery disease is thought to affect 5 to 10 percent of the hypertensive population. Renovascular disease tends to produce a marked elevation in the systolic and diastolic pressures, causing the prevalence of a renovascular etiology to be negligible in the subpopulation of patients with mild to moderate hypertension. Age is also an important correlate of renovascular causes of hypertension. Severe hypertension in young children and elderly adults has the highest probability of a renovascular cause, while hypertension in young and middle-aged adults is usually essential hypertension.

Etiology

There are two basic causes of renovascular hypertension: atherosclerosis and fibromuscular dysplasia. The ratio of atherosclerotic to fibromuscular cases is roughly 21. Atherosclerosis typically occurs at the renal artery ostia, more commonly on the left than on the right. Severe atherosclerosis of the abdominal aorta frequently coexists with renal artery disease.

Fibromuscular dysplasia of the renal artery is an idiopathic disorder encompassing a variety of histopathologic subgroups, all producing stenotic lesions of the intima, media, or adventitia. The most common variety consists of medial fibroplasia with alternating stenoses and small aneurysms, producing the characteristic string-of-beads appearance on arteriography (Fig. 20-30). Fibromuscular dysplasia most commonly occurs in young, multiparous women. In contrast to atherosclerotic disease, the right renal artery is involved more frequently than the left and the lesions frequently occur at the midportion of the renal arteries rather than proximally.

Pathophysiology

Richard Bright was the first to call attention to the relationship between hypertension and renal disease when he observed an association between “hardness of the pulse” and scarred, shrunken kidneys in 1836. Goldblatt defined the cause of the process in his classic canine experiments reported in 1934. Unilateral renal artery constriction produced ipsilateral renal atrophy and systemic hypertension.

The renin-angiotensin-aldosterone system has since been defined as the critical hormonal pathway responsible for the maintenance of the normotensive state. Systemic hypertension may develop as a result of overfilling of the arterial system, arteriolar vasoconstriction, or a combination of the two. Renal artery stenosis produces a low renal perfusion pressure, a compensatory increase in unilateral renin secretion, increased angiotensin-II formation, and elevated blood pressure secondary to vasoconstriction and hyperaldosteronemia-induced volume overload. A normal contralateral kidney can partially compensate for the hyper-renin state by increasing natriuresis. This compensatory response does not occur in the presence of a diseased or absent contralateral kidney or in the presence of contralateral renal artery stenosis.

Two forms of Goldblatt hypertension provide experimental corollaries to renovascular hypertensives with unilateral versus bilateral renal disease. In the “two kidney, one clip” Goldblatt model a single renal artery is clamped and the opposite kidney is left undisturbed. In the “one kidney, one clip” model one renal artery is clamped and the contralateral kidney is removed. Renin levels are elevated indefinitely in the two-kidney model, and the administration of angiotensin-II inhibitors results in decreases in blood pressure both initially and in the established phase. By contrast, renin levels are only transiently elevated in the one-kidney model. Elevated renin secretion is soon suppressed by volume expansion from sodium and water retention, and the established phase of hypertension is maintained by volume expansion and not by renin-mediated vasoconstriction. Predictably, angiotensin-II blockade is ineffective in ameliorating the hypertensive state in the established phase of the one-kidney model.

Diagnosis

Although renovascular hypertension is more common when the hypertension is severe, is of recent onset, is associated with an abdominal bruit, and occurs very early or very late in life, none of these characteristics is sufficiently predictive to substantiate or exclude the diagnosis. It is important to rule out such diagnoses as pheochromocytoma or other adrenal tumors with urinary 17-hydroxy ketosteroid and catecholamine levels.

A widely used but highly inaccurate screening test for renovascular hypertension is the intravenous pyelogram. Findings consistent with renovascular causes include a delay in the appearance of contrast on one side, a difference of 1.5 cm or more in the length of the two kidneys, defects in the renal parenchymal outline consistent with segmental infarction, and ureteral notching from compression secondary to dilated collateral vessels. As many as 30 percent of patients with renovascular hypertension will demonstrate no abnormal findings on pyelography, with a significantly higher false-negative rate in pediatric patients and in patients with bilateral disease.

Radioisotopic renal nuclear scans have been employed in the assessment of renovascular artery disease using iodine-131 hippurate as an indirect measure of renal plasma flow and technetium-99 chelated diethylenetriamine pentaacetic acid (DTPA) as an index of glomerular filtration rate. The diagnosis of renal artery disease is suggested by an asymmetry between appearance and excretion of radiopharmaceutical by the two kidneys. Unfortunately, the nuclear medical techniques are associated with a high incidence of false-negative and false-positive results.

Hypersecretion of renin from a kidney supplied by a stenotic renal artery is the hallmark of surgically curable hypertension. Theoretically, peripheral renin levels should correlate well with renin hypersecretion, since the clearance of renin from the blood remains a constant proportion of the arterial renin concentration. In practice, many patients with curable hypertension exhibit normal peripheral renin determinations. Angiotensin-II blockade provides a means of increasing the sensitivity of peripheral renin determination. The administration of the oral angiotensin-converting enzyme captopril results in an increase in plasma renin activity to a markedly greater extent in patients with renovascular hypertension than in patients with essential hypertension. The single-dose captopril test accurately discriminates between renovascular and essential hypertension, although the test does not establish which kidney is responsible for the problem.

Split renal function tests were among the first diagnostic tools used to predict whether patients would benefit from renovascular reconstructive procedures. These evaluations specifically identify which kidney is responsible in the majority of instances. The ureters are individually catheterized and urine is collected. Split function tests are considered suggestive of a renovascular cause for hypertension when one kidney demonstrates a 40 percent reduction in urine volume, a 50 percent increase in creatinine concentration, or a 100 percent increase in para- aminohippuric acid concentration.

Selective renal vein sampling has proved to be a valuable method of determining the presence of a renovascular cause for hypertension. Renal vein renin ratios greater than 11.5 between the two kidneys are correlated with a renovascular cause for hypertension and predict a satisfactory response from renovascular reconstruction. Recent appreciation that the kidneys do not remove renin from the arterial blood has fostered the use of subtraction methods for improving the accuracy of renal vein renin testing. Contralateral suppression of renin secretion results in negligible differences between renal arterial and venous renin concentrations on the uninvolved side, and the renin concentration in the inferior vena cava has been shown to approximate the renal arterial renin concentration. In practice, renovascular hypertension should be suspected when the difference between caval and renal vein renin levels is near zero on the uninvolved side and when the renal vein renin increment is 50 percent higher than the caval level on the involved side.

Intravenous digital subtraction angiography, a minimally invasive procedure that may be performed on an outpatient basis, has been used as a screening test for the identification of renal artery stenoses. In this procedure dye is injected through an antecubital or femoral vein into the central venous circulation. A computer-subtracted image is obtained as the dye enters the abdominal aorta and the renal arteries, and the test is frequently combined with selective renal vein renin sampling. The disadvantages of intravenous digital angiography include its poor resolution, its dependence on adequate cardiac output, and the large amount of dye necessary to obtain adequate images. Intraarterial contrast studies are the most reliable method of delineating renal artery lesions. Conventional or intraarterial digital techniques provide satisfactory images, and oblique views may be useful to more clearly define proximal stenoses. Intraarterial arteriography is a prerequisite for operative correction of renal artery disease, and many centers perform this procedure regardless of the results of prior screening tests.

Diagnostic Tests Predictive of Outcome

Renal artery disease may produce significant deterioration in renal excretory function in addition to hypertension. The development of an elevated serum creatinine level implies significant bilateral renal disease. Renal artery reconstruction can be expected to result in retrieval of function in the azotemic or nonazotemic patient, with objective improvements in glomerular filtration rate and increases in the size of the kidneys after the procedure. A successful surgical outcome is correlated with a preoperative glomerular filtration rate of less than 20 mL/min. Interestingly, the greatest increase in renal size after revascularization occurs with small kidneys.

Treatment

The indications for reconstructive procedures in patients with renovascular disease include documented renovascular hypertension and chronic renal insufficiency secondary to renal artery lesions. Operative therapy has been shown to be safer than long-term medical management of renovascular hypertension, with significantly greater relief of hypertension and survival rates, whether the cause is fibrodysplastic or atherosclerotic. Moreover, long-term therapy with angiotensin-converting enzyme inhibition may be associated with substantial decreases in renal excretory function. Therefore, pharmacologic management of renovascular hypertension is contraindicated in all but the most medically compromised patients. Thrombolytic therapy has been employed in acute renal artery occlusion, such as occurs with emboli to the kidneys. The thrombolytic agent is infused into the renal artery thromboembolus at the time of arteriography. The results of thrombolytic therapy in acute renal ischemia remain anecdotal, and therapy must be individualized.

There are four choices in the treatment of chronic symptomatic renal artery disease: unilateral nephrectomy, percutaneous transluminal angioplasty, renal artery bypass, and renal endarterectomy. Nephrectomy is indicated in patients with significant renovascular hypertension when the involved kidney is the source of renin production but is so severely damaged from chronic ischemia that the prospects for retrieval of renal function are remote. Renal size and the presence of viable glomeruli on biopsy examination have been used to predict the likelihood of improving renal function with revascularization, with nephrectomy reserved for unilateral renal artery disease in a small kidney with minimal residual excretory function. Balloon angioplasty has been used successfully in renovascular hypertension, but the best results are achieved with lesions distal to the renal artery ostia. Relative contraindications to balloon angioplasty include lesions involving renal artery bifurcations and bilateral renal artery stenoses. The most favorable results with balloon dilation occur in patients with fibromuscular dysplasia; for this patient group the procedure is the initial intervention of choice, although its long-term benefits remain undefined. Placement of an intraluminal stent has been helpful in the treatment of ostial lesions and in other renal lesions refractory to simple balloon angioplasty. Data on the long-term results of renal stenting are unavailable.

Renal artery bypass and endarterectomy are the two main operative procedures performed to correct renal artery stenoses and occlusions. Exposure of the renal arteries is most easily accomplished by reflecting the left colon medially in the case of left renal artery reconstructions and by reflecting the right colon and duodenum medially in the case of right renal reconstructions. Both renal arteries may be exposed with mobilization of the right colon and ileum and reflection of these structures cranially. The choice of the type of renal reconstruction depends on the status of the abdominal aorta. An aortorenal bypass using autogenous saphenous vein is the procedure of choice when the aorta is relatively spared from atherosclerotic change and clamping will not produce injury or distal embolization. Prosthetic grafts with *ePTFE* or polyester are acceptable alternatives to saphenous vein. Saphenous vein should be avoided in children, because it is prone to the development of aneurysmal change. Hypogastric artery is the best choice for aortorenal grafting in the pediatric patient. In the presence of aortic atherosclerotic disease, saphenous vein bypass from the hepatic artery to the right renal artery or splenic artery bypass to the left renal artery the most appropriate alternative. Both procedures avoid the embolic and hemodynamic consequences of aortic clamping. Splenorenal grafts are performed by transecting the splenic artery and constructing an anastomosis of one end of the splenic artery to one end or the side of the left renal artery; collateral flow from the short gastric vessels obviates the need for splenectomy. Distal renal artery lesions may be difficult to expose and revascularize with the kidney in situ; in such cases removal of the kidney, ex vivo bench reconstruction, and autotransplantation has provided an excellent alternative.

Renal endarterectomy is appropriate for atherosclerotic lesions but is not applicable in fibrodysplastic disease. The procedure may be accomplished through a transaortic exposure, endarterectomizing the renal orifices through an aortic incision. This procedure is useful in bilateral renal artery lesions, and a transverse aortotomy across the aorta into both renal arteries avoids the problems associated with a blind ending of the distal extent of the endarterectomy.

EXTRACRANIAL CEREBROVASCULAR DISEASE

The term “carotid” originates from the Greek *karotides*, which in turn is from *karoun*, to stupefy. The term was first used by Galen, who found that compression of these vessels produced a soporific state. Thomas Willis, a seventeenth-century English physician, clearly defined the carotid and vertebral artery supply to the brain in his work *Cebri Anatome*. Despite extensive study of the anatomy of the cerebral vasculature, the relationship between carotid artery disease and ischemic stroke was not appreciated until the early twentieth century. In 1913 Ramsay Hunt described the relationship between cerebral softening and occlusive lesions involving the main arteries to the brain. He urged that evaluation of the carotid arteries in the neck become a routine part of the physical examination. These early observations were followed by advances in cerebral angiography by Moniz in the 1920s, the elucidation of the pathophysiology of transient neurologic deficits by C. Miller Fisher in 1950, and the first operative carotid artery reconstruction by Eastcott, Pickering, and Rob in 1953. The first major series describing carotid artery reconstructions was reported by Lyons and Galbraith in 1957, and carotid endarterectomy soon became established as a safe procedure, although its role in improving the natural history of ischemic stroke continues to elicit much controversy.

Nomenclature

Focal cerebral ischemic disease, or stroke, results from insufficient blood flow to the affected portion of the brain. Stroke may be classified in a number of ways, including the anatomic location of the ischemic cerebral insult, the location of the causative arterial lesion, the pathogenesis, and the time sequence. It is helpful to categorize stroke with regard to two of these parameters in particular: location of the cerebral defect, and time course of the event (Table [20-6](#)).

Location

Neurologic deficits may be divided into those that are focal and those that are diffuse. Focal deficits are those that may be specifically localized to a discrete area of the brain. It is useful to classify these deficits into anterior or *hemispheric* symptoms and posterior or *vertebrobasilar* symptoms, since hemispheric symptoms are frequently caused by emboli from the carotid circulation and vertebrobasilar symptoms originate from either flow-limiting or embolic lesions of the aortic arch vessels, the vertebral arteries, or the basilar artery. Symptoms not referable to the carotid territory are often referred to as *nonhemispheric* symptoms; these include true vertebrobasilar symptoms as well as the more poorly defined global symptoms of dizziness and syncope. The confluence of both vertebral arteries to form the basilar artery provides a margin of safety with respect to hindbrain ischemia. Disease in one vertebral artery does not produce cerebral hypoperfusion unless the contralateral vertebral artery is also diseased or atrophic. Unilateral vertebral artery lesions can, however, be associated with nonhemispheric symptoms as a result of embolization to the ipsilateral or the contralateral hindbrain.

The *subclavian steal syndrome* is a variant of nonhemispheric ischemia in which a subclavian artery stenosis proximal to the origin of the vertebral artery results in retrograde vertebral artery perfusion as a source of collateral blood flow to the arm (see earlier section, [Upper-Extremity Occlusive Disease](#)). The arteriographic finding of retrograde vertebral artery flow is common in the presence of a subclavian lesion, but cerebral symptoms are rare unless concomitant carotid artery disease exists. A small proportion of cerebral infarctions occur as a result of cardiac emboli, which may travel to the anterior or the posterior cerebrum. *Amaurosis fugax* is defined as transient monocular blindness; persistence of the deficit indicates that the ischemic process has progressed to infarction, and the patient has suffered a *retinal stroke*. The cause of monocular visual symptoms usually is an embolus arising from an atherosclerotic plaque at the carotid bifurcation and traveling through the ophthalmic artery to the terminal arterioles of the retina. The embolus is visible on funduscopic examination in about 10 percent of patients with amaurosis fugax, appearing as bright intraarteriolar bodies. Although C. Miller Fisher was the first to report this finding in patients with amaurosis fugax, the clinical sign has been given the eponym *Hollenhorst plaque*, after Hollenhorst's report of 27 patients with this finding.

Time Course

Neurologic deficits can be grouped into three categories on the basis of the duration of the signs and symptoms. An incident of transient symptoms resolving completely within 24 h is termed a *transient ischemic attack (TIA)*, although most TIAs actually resolve within minutes rather than hours. When the frequency of TIAs is greater than two or three per day, the term *crescendo TIAs* is applied. When symptoms last longer than 24 h but resolve within 3 weeks, the condition is known as *reversible ischemic neurologic deficits* (RINDs). When a deficit lasts longer than 3 weeks, it is considered a *completed stroke*. These definitions are based only on clinical findings. Imaging techniques such as CT and MRI have documented cerebral infarction in a significant proportion of patients with transient symptoms, blurring the distinction between TIA and stroke.

There are two types of stroke that represent an unstable clinical situation; the *stroke-in-evolution* and the *waxing-and-waning neurologic deficit*. In patients with stroke-in-evolution the neurologic deficit worsens through a series of discrete exacerbations. Waxing-and-waning deficits fluctuate between mild and severe neurologic compromise, usually over a period of several hours. Stroke-in-evolution and waxing-and-waning deficits occur in the presence of critical carotid stenoses, usually in excess of 90 percent diameter reduction. The pathophysiology may be repeated episodes of embolization or recurrent, borderline cerebral ischemia from low arterial blood flow. In either case, urgent carotid endarterectomy is indicated before irreversible cerebral infarction develops.

Pathophysiology

Carotid and subclavian artery atherosclerotic lesions usually occur in predictable, focal sites. Atherosclerotic disease involving the carotid artery is almost always limited to the carotid bifurcation and ends several centimeters distal to the origin of the internal carotid artery. This makes it possible to perform endarterectomy procedures rather than bypasses for carotid bifurcation disease, removing all the atherosclerotic plaque and ending the endarterectomy distally on an uninvolved segment of the internal carotid artery. Subclavian atherosclerosis tends to occur at the origin of these vessels, with left-sided stenoses prevailing by a ratio of 41.

The particular susceptibility of the carotid bifurcation to atherosclerotic change is most likely due to hemodynamic conditions at this location. Initially it was assumed that the atherosclerotic propensity of the carotid bifurcation was a result of local turbulence and elevated blood flow rate. Investigators speculated that high wall shear stresses produced endothelial damage, predisposing to atherosclerotic degeneration. Zarins and associates refuted this theory and offered convincing evidence that plaque formation is accelerated within areas of low flow velocity and inhibited in areas with high flow velocity and elevated shear stress. They evaluated transverse light microscopic sections of postmortem human carotid bifurcation specimens. Atherosclerotic plaque was most prominent along the outer, posterior aspect of the proximal internal carotid artery. This finding was correlated with hemodynamic observations in transparent models of human carotid bifurcations. The areas of cadaver artery most susceptible to plaque formation corresponded to regions of low velocity and wall shear stress in the models, while the zones that were relatively free of plaque formation corresponded to regions of high flow and high shear stress.

Mechanism of TIAs

There are two possible mechanisms for the development of TIAs: emboli to the intracranial arteries, and temporary cerebral hypoperfusion. The older literature commonly attributed TIAs to transient decreases in systemic factors such as blood pressure and cardiac output. This theory predicts that TIAs would occur only in patients with hemodynamically significant stenoses. Recent studies, however, have failed to demonstrate a good correlation between the severity of carotid stenosis and prognosis or clinical manifestations of hemispheric, carotid-territory TIAs. Further, cardiac disease was less common in patients with carotid TIAs than in the nonhemispheric TIA group. These observations support the concept of an embolic cause for carotid-territory TIAs. Nonhemispheric TIAs are likely to be embolic when the symptoms are focal, but global symptoms are more likely to be caused by transient hemodynamic compromise in the presence of posterior circulation disease.

Pathologic specimens of carotid artery lesions from symptomatic patients frequently contain irregular luminal surfaces with exposed subintimal structures. Areas of the vessel lacking the normal intimal layer are termed *ulcers*. Aggregates of platelets and fibrin as well as cholesterol crystals are commonly observed in carotid artery ulcers (Fig. [20-31](#)).

There are at least three possible causes of embolization from a carotid bifurcation plaque. First, fragments of the cholesterol-calcium plaque may break off and be discharged into the lumen. Second, roughened, thrombogenic subintimal structures may be exposed to the flowing blood, and platelet thrombi may be formed that are easily detached. A third mechanism involves intramural carotid artery hemorrhage. The pathophysiologic mechanisms underlying this process are incompletely understood, but the presence of acute or recent intramural hemorrhage has been reported in over 90 percent of symptomatic patients, compared with less than 30 percent of asymptomatic patients. It is possible that intramural hemorrhage results in rapid, unpredictable progression of a moderate asymptomatic carotid artery lesion to a high-grade symptomatic stenosis, with eventual rupture of the intramural process and discharge of the plaque contents into the arterial lumen.

There are several unusual causes of carotid artery pathologic conditions that may be associated with cerebrovascular symptoms. The artery may be elongated, tortuous, or kinked;

these anatomic abnormalities are rarely associated with symptoms. Radiation therapy may induce a symptomatic carotid artery injury similar in appearance to an atherosclerotic lesion. The internal carotid artery may undergo spontaneous dissection, resulting in neurologic symptoms and thrombosis of the vessel. Treatment of carotid artery dissection is nonoperative, with anticoagulation therapy and control of hypertension.

Fibromuscular dysplasia is the most common nonatherosclerotic lesion of the carotid artery. The cause of the process is unknown, but it tends to involve long arteries with few branches. The vast majority of affected individuals are females, and the disease is usually bilateral. Four histologic types have been described: intimal fibroplasia, medial hyperplasia, medial fibroplasia, and perimedial dysplasia. Medial hyperplasia is the most frequently encountered variety. Operative intervention is indicated in symptomatic patients, usually in the form of intraluminal dilatation of the involved segment, with an open or a percutaneous approach. Prophylactic operation in the asymptomatic patient is not recommended, since no objective data exist on the natural history of the process.

Patients with repeated *TIA*s often experience symptoms in exactly the same anatomic region of the brain with each episode. For example, a patient with crescendo *TIA*s involving right arm monoplegia will frequently exhibit repeated identical episodes without other deficits such as aphasia or left-sided amaurosis fugax. It is reasonable to wonder why the pattern of neurologic dysfunction is frequently reproduced identically, since one would expect carotid embolization to occur in a random fashion throughout the distribution supplied by that carotid vessel. This apparent paradox is answered by the fluid dynamics associated with laminar flow. Embolic material originating from a point source in the arterial system tends to travel to the same terminal arterial branch, as illustrated by Millikan. He serially injected small metal pellets through a needle placed in the internal carotid artery of monkeys. Subsequent examination of the animals' brains revealed that the pellets stacked up one on the other within the same cortical branch (Fig. [20-32](#)).

Diagnosis

The most valuable tool in the diagnosis of carotid artery disease is a careful history and physical examination. A thorough neurologic evaluation is of great importance. The diagnosis of carotid bifurcation disease is facilitated by the relatively superficial location of the vessel, rendering it accessible to study. The cervical carotid pulse is usually normal in patients with carotid bifurcation disease, since the common carotid artery is the only palpable vessel in the neck and is rarely diseased. The superficial temporal artery pulse provides some indication of the status of the external carotid artery, but the internal carotid artery pulsation is inaccessible to digital palpation. Auscultation has been the most widely employed method of assessing the carotid bifurcation. Carotid bifurcation bruits may be heard just anterior to the sternocleidomastoid muscle, near the angle of the mandible. Auscultation in the supraclavicular fossa may reveal bruits originating from stenotic lesions of the subclavian artery. Carotid and subclavian artery bruits must be differentiated from one another as well as from murmurs due to cardiac lesions such as aortic stenosis, which may be transmitted along the great vessels into the neck. Bruits do not develop until the stenosis is large enough to reduce the diameter by approximately 50 percent. Bruits may be absent in extremely severe lesions because of the extreme reduction of flow across the stenosis.

Oculoplethysmography

The development of noninvasive carotid artery testing modalities has provided more precise information regarding the nature and severity of the lesion. Oculoplethysmography (OPG) is a test designed to measure ophthalmic artery pressure indirectly through the use of plastic suction cups applied to the sclera. The ophthalmic artery pressure is a good indicator of internal carotid artery pressure, and abnormalities in this measurement can identify hemodynamically significant carotid artery stenoses. Stenoses of the common carotid artery and the ophthalmic artery must be excluded, as these lesions will produce an abnormal OPG in the absence of significant carotid bifurcation disease.

Duplex Ultrasonography

The most useful noninvasive test is the Duplex ultrasound carotid artery examination. This test combines pulsed-Doppler measurements with a B- mode ultrasound image to provide data on the velocity of blood flow and the anatomic profile of the carotid bifurcation, respectively. The Duplex scan is an extraordinarily accurate noninvasive means of identifying carotid artery stenoses. The subclavian and vertebral arteries also may be evaluated, but the accuracy in identifying disease is much lower in these vessels. The technical difficulty of the test has been largely overcome with the introduction of the color-flow Doppler. This instrument is a modified Duplex scanner that provides a color image in which the velocity and direction of blood flow are keyed to the color of the image at all points within the vessel so that arterial flow can be seen as red and venous as blue. Standard Duplex scans cannot assess the cerebral arterial circulation beyond the first few centimeters of the internal carotid artery. A transcranial Doppler has been developed to evaluate the middle cerebral artery and other intracranial vessels, using a low-frequency Doppler signal to penetrate the thin bone of the temporal and occipital regions. The test is most easily performed when coupled with an ultrasound image (transcranial Duplex), allowing the technologist to visualize the intracranial vessels on the color- flow ultrasound image, measuring blood velocities by placing the pulsed- Doppler within the exact anatomic area of interrogation.

Magnetic Resonance Imaging

Magnetic resonance imaging has been used as a noninvasive means of imaging the carotid arteries, displaying the image as a two-dimensional scan of the carotid system analogous to conventional arteriography. The procedure is called magnetic resonance angiography (MRA). The resolution of early MRA was insufficient to accurately define the location and extent of carotid artery disease, but technical improvements in software and hardware have markedly improved the image quality of the scans.

Arteriography

Arteriography remains the gold standard for the diagnosis of extracranial arterial disease. Intraarterial standard and digital-subtraction arteriograms provide the best images and usually are performed via the transfemoral approach, with views obtained in the anteroposterior and lateral planes (Fig. [20-33](#)). Most images are of sufficient quality to allow precise determination of the severity of the carotid artery lesion, expressed as the percent diameter reduction in comparison to the normal artery distal to the stenotic process (Fig. [20-34](#)). Intravenous digital images have been disappointing, with images less precise than those obtained with Duplex ultrasonography.

The major problem with contrast arteriography of the carotid system has been a significant incidence of stroke associated with the procedure. Some studies have documented a rate of cerebral infarction of 1 percent. Because of this, along with the increasing accuracy of Duplex ultrasonography, many surgeons have forgone preoperative contrast arteriography in the majority of patients undergoing carotid endarterectomy.

Treatment

The therapy of cerebrovascular occlusive disease is best considered by dividing patients into two subgroups: those with posterior circulation lesions involving the subclavian or vertebral arteries, and those with anterior circulation lesions involving the carotid arteries.

The indications for operation are relatively straightforward and noncontroversial in patients with subclavian and vertebral artery disease; operative correction is recommended for symptomatic lesions that are surgically accessible. Proximal subclavian artery lesions are best treated with a carotid-to-subclavian artery bypass, using end-of-graft to side-of-artery anastomoses at each end. Alternatively, a subclavian-to-carotid artery transposition may be performed, with division of the subclavian artery proximal to the origin of the vertebral artery and construction of an end-of-subclavian to side-of-carotid artery anastomosis. Embolic symptoms caused by lesions of the subclavian artery require exclusion of the embolic source from the arterial stream. Ligation of the subclavian artery proximal to the vertebral artery origin is performed in the case of a carotid-to-subclavian artery bypass. Disease involving the vertebral arteries may also be responsible for posterior cerebral symptoms. Vertebral artery lesions usually occur at the origin of the vessel and end within the first centimeter of its course. The stenotic lesion may be endarterectomized and the arteriotomy closed with a patch graft. More commonly, the vertebral artery is transected beyond the stenosis, the stump is ligated, and the distal end is anastomosed to the side of the common carotid artery.

The medical management of symptomatic carotid artery disease includes reduction of risk factors such as smoking and hypercholesterolemia, and the use of antiplatelet agents. Current recommendations include a regimen of one to four 325-mg aspirin tablets daily, although recent studies have suggested that doses as low as 30 mg/day produce similar antiplatelet effects. Ticlopidine and other antiplatelet agents also have been used with success. Dipyridamole was once widely employed, both alone and in combination with aspirin, but the drug has not been shown to be more effective than aspirin alone. Oral anticoagulation therapy with warfarin has been recommended for patients who continue to experience symptoms while they are taking antiplatelet agents.

A number of well-designed, randomized trials of antiplatelet therapy for symptomatic carotid artery disease have been undertaken. Although all the studies revealed a trend toward reduction of the risk of subsequent stroke, none documented a statistically significant benefit of aspirin compared with placebo. It was only when the end points of mortality, myocardial infarction, *TIA*, and stroke were combined that a significant advantage was achieved with antiplatelet therapy. The effects of aspirin on the incidence of myocardial infarction and on mortality were the most important benefits; the effects on cerebrovascular disease were less striking. A metaanalysis of these results suggested a 15 percent reduction in stroke risk with aspirin and a 40 percent reduction in myocardial infarction and deaths.

The benefit of carotid endarterectomy for patients with symptomatic cerebrovascular disease has recently been established (Table [20-7](#)). The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST) have documented a significant reduction in cerebrovascular events following the procedure compared with patients managed medically. The NASCET study randomized patients with symptomatic carotid artery disease to either carotid endarterectomy or optimal medical care including antiplatelet therapy (generally 1300 mg aspirin daily). In the subset of over 600 patients with stenoses that reduced artery diameter by 70 to 99 percent, a 26 percent incidence of ipsilateral stroke was observed in the medically managed group at 2-year follow-up, compared with a 9 percent incidence in the surgical group, a difference that was statistically significant and prompted early termination of the study. On the basis of these results, patients with symptomatic high-grade carotid artery stenoses should undergo carotid endarterectomy by a surgeon with the low rate of perioperative morbidity that has characterized the centers in the NASCET trial. Patients with minimal stenoses (less than 30 percent diameter reduction) are best managed medically, reserving operative considerations for recurrent symptoms on antiplatelet therapy or for disease progression. The management of the group of patients with moderate stenoses (30 to 69 percent) has not been settled and awaits the results of ongoing randomized trials.

The appropriate treatment of asymptomatic carotid artery stenosis has become less controversial with the availability of data from the Asymptomatic Carotid Artery Study (ACAS). This trial documented an improvement in clinical results when patients with carotid artery lesions with reductions of 60 percent or more in vessel diameter underwent surgical repair. Carotid endarterectomy appeared to halve the risk of cerebral events at 5-year follow-up, although the overall rate of stroke was relatively low. Moreover, the differences were most prominent in men. Despite these limitations, the ACAS data would appear to suggest that surgical candidates with severe carotid artery lesions should undergo repair whether or not they have symptoms.

Patients with nonhemispheric cerebral symptoms appear to benefit from correction of carotid artery lesions, if the symptoms are classic and the stenosis is significant (greater than 60 percent diameter reduction). Patients with nonclassic symptoms such as dizziness or syncope are rarely improved by carotid artery reconstruction. These patients should be managed as though the lesions were asymptomatic, reserving operation for the healthy patient with a relatively long life expectancy and a high- grade carotid artery lesion.

The timing of operation is a critical consideration in the treatment of carotid artery disease. Patients with unstable neurologic symptoms such as crescendo *TIA*s or a waxing-and-waning deficit invariably have severe disease and should undergo urgent arteriography and operation. Because of the high risk of cerebral infarction from recurrent embolization or carotid artery thrombosis, patients with these symptoms should be started on anticoagulation therapy at the time of presentation. Patients with a completed stroke

should undergo carotid endarterectomy a minimum of 4 weeks after the event, as the risk of perioperative intracerebral bleeding is high immediately after a stroke. Emergency carotid endarterectomy is indicated for an acute carotid artery thrombosis if the procedure can be performed within a few hours after the event. It is unusual to have the opportunity to restore carotid artery perfusion so expeditiously; the possibility arises in early postoperative carotid artery occlusion or when occlusion occurs during cerebral arteriography. Operation is contraindicated for an occlusion that is several hours old, since the danger of intracerebral edema and hemorrhage from reperfusion outweighs the potential benefits of revascularization.

Carotid endarterectomy can be performed under local or general anesthesia. The advantage of local anesthesia is that the surgical team can be aware of the patient's mental status at all times, most importantly when the carotid artery is clamped. Changes in level of consciousness or motor deficits at the time of interruption of blood flow signal the need for placement of an intraoperative shunt. General anesthesia confers the advantages of ventilatory support and increased cerebral blood flow with the use of halogenated agents, but alternative methods of assessing the adequacy of cerebral perfusion must be implemented.

The exposure of the carotid bifurcation is accomplished with a vertical incision made along the anterior border of the sternocleidomastoid muscle (Fig. 20-35). The dissection is carried down through the platysma muscle, and the internal jugular vein is mobilized laterally after ligation and division of the facial vein. The carotid bifurcation is exposed along with an adequate length of the common and internal carotid arteries to allow clamping of these structures above and below the plaque. The hypoglossal nerve can be mobilized and reflected cranial for additional exposure. Exposure of the distal internal carotid artery can be achieved by dividing the posterior belly of the digastric muscle when needed; further proximal exposure can be accomplished by dividing the omohyoid muscle. The patient is systemically heparinized, the carotid vessels are clamped, and a longitudinal arteriotomy is started on the common carotid artery and carried onto the internal carotid artery, with the distal termination on normal vessel. The plaque is removed using an endarterectomy spatula, and every attempt is made to achieve a smooth, tapering distal end point. The termination of the endarterectomy should have a normal adherent intima and media to ensure that the resumption of forward blood flow will not create an occlusive flap. The arteriotomy may be closed primarily with nonabsorbable suture. Alternatively, a vein or prosthetic patch may be employed if the vessel is small.

In a small proportion of patients the collateral cerebral circulation is inadequate to compensate during the period of carotid artery cross-clamping. The use of an indwelling shunt intraoperatively reduces the incidence of intraoperative cerebral infarction in these patients. Some have advocated the routine use of a shunt because it is difficult to predict which patients will not tolerate the period of relative cerebral ischemia. There are disadvantages to the use of a shunt; the shunt can injure the intima at the time of placement, and it impedes visualization of the end point of the endarterectomy. For these reasons, intraoperative electroencephalographic (EEG) monitoring and internal carotid artery stump pressure determination have been employed in an effort to identify patients at greatest risk of stroke with temporary carotid interruption. EEG leads are placed on the patient's scalp preoperatively; any slowing of the EEG waveform is indicative of cerebral ischemia and necessitates the insertion of a shunt. Carotid artery stump pressures below 25 mmHg after clamping also are predictive of an increased risk of cerebral infarction during clamping and mandate the placement of a shunt. Use of either EEG or stump pressure determination allows the surgeon to limit the use of indwelling shunts to less than one in five patients undergoing carotid procedures.

The complications of carotid endarterectomy include cranial nerve damage resulting from nerve division, excessive traction, or perineural dissection. The most frequently injured nerves are the vagus, the hypoglossal, the glossopharyngeal, and the marginal mandibular branch of the facial nerve. Revascularization of a severely stenotic carotid artery may result in the "hyperperfusion syndrome," characterized by headache, seizures, and, occasionally, intracranial bleeding. This phenomenon is believed to result from reperfusion of a chronically ischemic tissue bed in which the arterioles are maximally dilated. With the sudden restoration of blood flow, the area becomes markedly edematous and the clinical picture described above develops. Beta blockers may reduce the severity of symptoms and should be instituted in high-risk patients with the first signs of the syndrome, usually a headache.

The most dreaded complication of carotid endarterectomy is perioperative stroke. Perioperative strokes can occur as a result of inadequate cerebral perfusion during the clamp period, embolization of debris from the plaque at the time of operation, or early postoperative thrombosis. Refinements in operative technique have reduced the perioperative stroke rate to less than 5 percent in most institutions and to less than 2 percent in centers with the greatest experience.

The incidence of perioperative myocardial events is distressingly high; they are at least as common as perioperative neurologic events in patients undergoing carotid endarterectomy. Preoperative cardiac screening procedures include myocardial imaging using thallium or echocardiography, often supplemented with exercise, dipyridamole, or dobutamine. In a study performed at the Cleveland Clinic, routine coronary arteriography was used as a screening test in a series of 1000 patients in whom elective vascular procedures were planned; 295 of these patients presented because of pathologic cerebrovascular conditions. Significant coronary lesions were detected in 33 percent of patients with symptoms of cardiac disease and in 17 percent of patients without clinical manifestations of cardiac disease. The 75 percent 5-year survival rate observed in patients who underwent staged cardiac and carotid artery revascularization procedures was surpassed only by that of the group of patients with normal or minimally diseased coronary arteries (91 percent). Given these results, it seems reasonable to use one of the minimally invasive screening tests, such as dipyridamole-thallium studies, before carotid endarterectomy. Coronary arteriography is reserved for patients with overt cardiac symptoms or a positive screening test, and coronary artery bypass is used for patients with severe arteriographic coronary artery disease.

NONATHEROSCLEROTIC DISORDERS

Thoracic Outlet Syndrome

The thoracic outlet is the space through which the subclavian artery and vein and the brachial plexus pass from the neck into the upper extremity. Its anatomic boundaries are the chest wall, the scalene muscles, the clavicle, and, potentially, a variety of anomalous, sometimes compressive structures such as fibrous bands or cervical ribs (Fig. 20-36). Proper treatment of *thoracic outlet syndrome (TOS)* requires a detailed history and physical examination, appropriate diagnostic tests, and understanding of the intricate anatomic relationships in this area.

Arterial Component

The arterial complications of *TOS* are caused by a bony cervical rib or an anomaly of the first rib. Patients may present with an asymptomatic pulsatile cervical mass, or, more often, with upper-extremity ischemia ranging from unilateral Raynaud's phenomenon to acute ischemia with absent pulses. Symptoms are caused by atheroemboli from a poststenotic dilatation or true aneurysm (rarely thrombosis) of the subclavian artery (Fig. 20-37). The evaluation should include cervical x-rays, noninvasive vascular testing, and arteriography when appropriate.

Treatment requires removal of the embolic source, resection of the bony anomaly, and reperfusion, if possible, of the ischemic extremity. The subclavian artery aneurysm is best approached through a supraclavicular incision with or without removal of the medial half of the clavicle. The aneurysm is resected and replaced with an interposition saphenous vein graft. The cervical and first ribs can be excised through this approach, or the patient can be repositioned and the operation completed through the axilla. If the artery is dilated but not aneurysmal, resection is not indicated, because bony decompression is sufficient to prevent further atheroemboli in most instances. In this situation the transaxillary approach is preferred, because it simplifies removal of the first rib. Any distal embolic material that must be removed should be approached through separate arteriotomies in the arm. Sympathectomy can be a useful adjunct when distal emboli are irretrievable.

Venous Component

Venous obstruction of the upper extremity is caused by a narrowing of the costoclavicular space between the medial aspect of the first rib and the clavicle. This is the site where the axillary vein passes over the rib and under the clavicle to join the internal jugular vein. Both hyperabduction of the arm and hyperextension of the shoulders can narrow this space, causing venous obstruction. Venous obstruction takes one of three forms: intermittent obstruction, acute thrombosis, and postthrombotic intermittent obstruction.

Intermittent Obstruction

These patients present with arm swelling, cyanosis, and pain when the arm is abducted or the shoulders hyperextended. The diagnosis can be made by phlebograms with the arm in both the relaxed and symptomatic positions. A positive examination shows a beaklike appearance in the vein proximal to the first rib when the arm is stressed and a normal venous anatomy with the arm in a neutral position. Venous pressure measurements also can be made in the same arm positions. Treatment consists of transaxillary first rib resection or medial subtotal claviclectomy.

Acute Thrombosis

Patients usually are young and healthy and present with the sudden onset of arm pain, swelling, and cyanosis. The problem often follows some repetitive activity, such as throwing a ball, house painting, paper hanging, swimming, or rowing a boat, and has been called the Paget-Schroetter syndrome or "effort thrombosis." Phlebograms show a complete obstruction of the subclavian vein, often with thrombus distally in the axillary vein.

Treatment options include elevation and heparinization, venous thrombectomy, and local thrombolysis; the latter has gained much support in recent years. Once the diagnosis is confirmed, a coaxial catheter is inserted into the basilic vein and placed directly into the thrombus. Thrombolytic infusion is begun and its progress monitored with serial venography. If successful thrombolysis uncovers an underlying stenotic lesion, decompression of the thoracic outlet should be undertaken (usually clavicular resection), with simultaneous surgical repair of the venous lesion (patch angioplasty or venous bypass). The results of percutaneous balloon dilation of these lesions have been unsatisfactory. Stents should almost never be used in this group of patients, because they may be compressed between the first rib and clavicle. The patient is discharged on warfarin, which is continued for 3 months.

Postthrombotic Intermittent Obstruction

Patients with acute obstruction and unsuccessful clot removal, whether chemical or mechanical, have a 50 percent chance of developing residual symptoms of venous obstruction. Venograms usually demonstrate an occluded vein with large collateral vessels around the first rib (Fig. 20-38). Hyperabduction of the arm results in compression of these collateral veins. Either first rib resection or a medial claviclectomy will relieve these symptoms in some patients. Direct repair of the chronically occluded subclavian vein may be preferable and can be achieved by mobilizing the internal jugular vein and turning it down for anastomosis into the divided patent axillary vein.

Neurologic Component

The subjective nature of the symptoms and the lack of objective diagnostic criteria make the management of the neurologic component of *TOS* potentially very difficult. Some would restrict this diagnosis to only those patients with symptoms and signs limited to the T1 nerve root (ulnar nerve), while others would broaden it to include any neurologic symptoms of the neck, upper back, and upper extremity. These symptoms are exacerbated by elevation and abduction of the arm. Trauma may precipitate the symptoms in a susceptible individual.

An accurate and complete history is important, because the diagnosis is often one of exclusion. Most elements of the differential diagnosis have reliable diagnostic tests. All these

patients should have cervical spine films to identify any bony anomalies and to rule out cervical disc protrusion or spondylitis. Nerve conduction studies are indicated to rule out carpal tunnel syndrome and ulnar nerve compression at the elbow. Orthopaedic and neurologic consultations may be necessary to rule out specific pathologic conditions of the shoulder, multiple sclerosis, and spinal cord tumors. Physical examination includes blood pressure measurements in both arms. The hands are examined for signs of atrophy of the ulnar nerve–innervated interosseus muscles and the median nerve–innervated thenar muscles (Fig. 20-39). Percussion over the median nerve (Tinel's test) and rapid wrist flexion (Phalen's test) are performed to further evaluate the median nerve. A complete neurologic examination of the neck and upper extremity is performed, including the application of pressure in the supraclavicular space over the brachial plexus. The traditional Adson's test is totally unreliable in detecting brachial plexus compression and is of no use in making the diagnosis of neurologic TOS. The elevated arm stress test (EAST) described by Roos has the patient raise the arm to 90 degrees and open and close the hands for 3 min. This may reproduce the patient's symptoms but is unfortunately also positive in 90 percent of patients with carpal tunnel syndrome.

When neurologic TOS is the considered diagnosis and treatment is indicated, a conservative approach should always be followed. Patients with severe pain and cervical muscle spasm are initially treated with physical therapy directed at relieving the muscle spasm. Peets' shoulder strengthening exercises are started as the pain subsides. Methods of opening the costoclavicular space by hunching the shoulders upward and forward are used when the patient first feels symptoms recurring. Indications for operation include failed physical therapy, intractable pain, and/or progressive neurologic dysfunction.

Technique of First Rib Resection

Clagett suggested in 1962 that the first rib was the “common denominator” in the various compression syndromes of the thoracic outlet and recommended its resection in appropriate cases. In 1966 Roos described the technique of transaxillary first rib resection, which, because of its cosmetic appeal, simplicity, and safety has become the most frequently performed operation for neurologic TOS.

With the patient in the lateral decubitus position with the arm elevated, a skin incision is made in the axillary hair line between the pectoralis major and latissimus dorsi muscles. The first rib is reached by blunt dissection in the axillary tunnel, taking care to avoid the intercostobrachial nerve. The subclavian artery and vein are identified and the subclavius muscle tendon divided. The anterior scalene muscle can now be identified and divided at the point where it inserts on the first rib anterior to the artery. At this time a digital search for anomalous bands is performed. These may originate from the C7 transverse process, from an incomplete cervical rib, from attachment to two places on the first rib, or from the middle scalene muscle. After any bands have been divided, the middle scalene muscle and the intercostal muscle attachments are pushed off the first rib. When all muscle fibers are cleared and the T1 nerve root is visualized and protected, the rib is divided and removed. The wound is irrigated with saline to detect any pneumothorax, which, if present can be treated by inserting a small chest tube into the pleural space. The tube can be removed in the recovery room if the lung is fully expanded and there is no air leak.

A number of brachial plexus injuries have been reported with this approach, and there are proponents of a supraclavicular approach that avoids any traction on the brachial plexus.

Popliteal Artery Disease

There are two causes of nonatherosclerotic popliteal artery disease that characteristically produce symptoms of calf claudication in young males: popliteal entrapment syndrome and adventitial cystic disease of the popliteal artery.

Popliteal Entrapment Syndrome

Calf claudication in a young male should suggest the diagnosis of popliteal entrapment syndrome. The popliteal artery normally traverses the popliteal fossa between the two heads of the gastrocnemius muscle, but the artery courses medial to the medial head of the gastrocnemius or popliteus muscle in patients with the disorder (Fig. 20-40). The popliteal vein accompanies the artery and is entrapped in just over 10 percent of the cases. Popliteal entrapment is infrequently encountered in women, with a male-to-female ratio of 151. Bilateral involvement has been observed in one-quarter of the cases.

The findings on physical examination are dependent on whether the popliteal artery is occluded at the time of presentation. The majority of patients present with thrombosis of the vessel and absent pedal pulses. The pedal pulses are present in only one-third of the patients with compressed but nonoccluded vessels. Passive dorsiflexion and active plantar flexion of the foot tense the gastrocnemius muscle, which compresses the artery, obliterating the pedal pulses. Femoral arteriography with and without plantar flexion of the foot may be instrumental in confirming the diagnosis. Three arteriographic abnormalities of the popliteal artery have been described: medial deviation, occlusion, and poststenotic dilatation. A CT scan of the popliteal fossa can be indispensable if the popliteal artery is occluded, defining an abnormal position of the artery with respect to its surrounding muscles.

Operative intervention is indicated in both symptomatic and asymptomatic patients. A posterior approach to the artery is preferred if the artery is patent and extensive proximal and distal exposure is not necessary. Lysis of the constricting head of the gastrocnemius muscle is all that is required in these instances. Complete resection of the medial head of the gastrocnemius muscle is well tolerated, with minimal alteration of function.

Intraarterial thrombolytic agents or balloon catheter thrombectomy is used in the recently occluded popliteal artery, followed by lysis of the compressing band if the artery appears otherwise normal. Chronic occlusions necessitate a bypass of the involved segment, with exposure of the proximal popliteal or superficial femoral artery and the distal popliteal or tibial artery. A medial approach offers advantages in this subgroup, as it facilitates exposure of the inflow and outflow vessels and provides access to the greater saphenous vein.

Adventitial Cystic Disease of the Popliteal Artery

Adventitial cystic disease of the popliteal artery is a rare disorder characterized by cystic degeneration of the adventitia of the artery, producing extrinsic compression of the lumen at the level of the knee joint. The cause of the process is unclear, but the two most widely accepted theories invoke a pathogenesis similar to simple ganglia of the wrist, with formation of the cystic cavities as a result of developmental rests of mucin- secreting cells within the adventitia, or abnormal connections between the synovial space of the knee and the wall of the popliteal artery. The cyst contents consist of a viscous material high in hyaluronic acid, similar to the fluid found in ganglia. The fluid is colorless in most instances but may take on the appearance of currant jelly if hemorrhage into the cyst has occurred. The cyst may be unilocular or septate.

Popliteal adventitial cystic disease generally produces symptoms of calf claudication in middle-aged men. Arteriography reveals curvilinear stenotic lesions in two-thirds of the patients; popliteal artery occlusions are observed in the remaining one-third of the cases. Ultrasonography and CT are useful in delineating the cyst and its relationship to the arterial lumen.

Although percutaneous cyst aspiration under ultrasound or CT guidance has been used in the treatment of this disorder, the long-term results have been discouraging, with rapid reaccumulation of the cyst fluid. Operative exploration, incision into the cyst, and evacuation of the contents is the most appropriate treatment if the stenotic process has not progressed to occlusion. Autogenous vein bypass is necessary in the presence of popliteal artery occlusion, with the level of the proximal and distal anastomoses determined by the extent of propagated clot.

Vasospastic Disorders

Arterial vasospasm in the extremities occurs in a variety of clinical situations, including immunologic disorders such as scleroderma and systemic lupus erythematosus, the thoracic outlet syndrome, mechanical (vibratory) or cold-induced small-vessel injury, and the use of drugs such as ergotamine and oral contraceptives.

Raynaud's Syndrome

Raynaud's syndrome is the prototypic symptom complex associated with peripheral vasospasm. “Raynaud's disease” and “Raynaud's phenomenon” are older terms used to describe a primary benign disorder and a secondary more virulent process, respectively. Improvements in immunologic testing have resulted in a decrease in the frequency of the primary classification, and today over 50 percent of patients with severe Raynaud's symptoms have documented autoimmune disease. Use of the term “Raynaud's syndrome” may be more appropriate than the artificial separation of the entity into primary and secondary forms.

Raynaud's syndrome is characterized by episodic cutaneous color changes consisting of sequential pallor, cyanosis, and rubor. It is observed most frequently in the digits of the upper extremities but also may affect the toes. The explanation for the white, blue, and red color changes lies in the pathophysiology of the vasospasm. Initially, cold exposure or emotional stress precipitates intense small-artery vasospasm, with digital blanching and numbness. A cyanotic hue develops as partial arterial perfusion is restored and the cutaneous venules become filled with desaturated blood. Finally, the vasospasm resolves and the digits turn bright red as a result of reactive hyperemia.

Between 70 and 90 percent of patients with Raynaud's syndrome are female, almost all younger than age 40. Raynaud symptoms affect the majority of the general population at one time or another, but only a small percentage have symptoms that are severe enough to cause them to seek treatment. Complications include sclerodactylia (atrophy of skin and loss of elasticity, resembling the changes seen in scleroderma), recurrent paronychia infection, and digital ulceration and gangrene. Amputation of the fingers or toes is occasionally necessary, but fortunately the process almost never progresses to involve structures proximal to the digits.

The treatment of Raynaud's syndrome is initially conservative, with avoidance of tobacco, cold exposure, and drugs that have been reported to exacerbate the symptoms, such as oral contraceptives, beta blockers, and ergotamine. Pharmacologic therapy with vasodilating calcium channel blocking agents such as nifedipine has provided partial resolution of symptoms in many patients and represents the mainstay of treatment of the disorder. Cervical sympathectomy has been used in the treatment of severe Raynaud's syndrome, but results have not been gratifying.

Acrocyanosis

Acrocyanosis is a vasospastic disorder occurring almost exclusively in women. It is characterized by persistent edema, coolness, and cyanosis of the hands, lower legs, and feet. The pathophysiology is that of cutaneous arteriolar vasospasm. The disease is not as dependent on the temperature of the environment as Raynaud's syndrome, and the process never progresses to tissue loss. Vasodilating agents have been beneficial in acrocyanosis, as has avoidance of cold.

Livedo Reticularis

Livedo reticularis is a condition characterized by constant cyanotic mottling of the skin of the lower legs and feet. The upper extremity occasionally is involved. The changes are always present but become more prominent with exposure to cold. Livedo reticularis occurs as a result of the random spasm of cutaneous arterioles in association with the secondary dilatation of venules to produce a reticulated pattern. The disorder occasionally occurs in association with such disorders as systemic lupus erythematosus and periarteritis nodosa. Most patients have no associated diseases and the process is one of cosmetic concern. Avoidance of cold is the only treatment indicated.

Causalgia

Causalgia (“burning pain”), also known as “posttraumatic reflex sympathetic dystrophy,” is a painful disorder that develops after incomplete nerve transection. Vasomotor dysfunction is almost always present. The most frequent causes are penetrating missile injuries, fractures, and crush injury. Patients complain of burning pain in the peripheral portions of the extremity, and the symptoms are not limited to the area supplied by the injured nerve. A characteristic feature of the cutaneous dysesthesia is that its intensity is such that the patient cannot tolerate contact of the affected area with clothing or bed sheets. The pain results in limitation of motion and chronic disability. The vasospasm is associated with cyanosis, edema, hyperhidrosis, and coolness of the extremity. Surgical sympathectomy is the treatment of choice and is successful in relieving pain in the vast majority of patients.

Inflammatory Arteritis

The term “inflammatory arteritis” refers to an arterial inflammatory response arising from a group of diseases of unknown or immunologic cause. Many of the arteritides are associated with inflammatory changes in the veins as well, and the term “vasculitides” may be more appropriate when describing these disorders. The vasculitides can be classified by the size of the vessels involved and by the coexistent clinical features of the disease process. An immunologic mechanism has been defined in almost all the vasculitides, and most are treated with systemic steroids or cytotoxic agents.

Giant Cell Arteritides

Two disorders comprise the giant cell arteritides: temporal arteritis and Takayasu's arteritis. These diseases are identical in histologic appearance and are associated with similar laboratory abnormalities. Anatomically, however, Takayasu's arteritis involves the aorta and its branch vessels near their origin, whereas extracranial lesions occur in only 9 percent of patients with temporal arteritis. Takayasu's arteritis occurs almost exclusively in female patients in their teens and twenties. The female predominance is less in temporal arteritis, averaging 31, and patients are typically over the age of 50 years.

Temporal arteritis classically begins with a prodromal phase of malaise, myalgias, headache, and low-grade fever. These symptoms are followed by a second, quiescent phase. A palpable, tender temporal artery may be found in some patients. Jaw claudication is a frequent complaint, and an abnormal temporal artery biopsy is found in about 50 percent of patients. The association between polymyalgia rheumatica and temporal arteritis is so striking that some have advocated temporal artery biopsies in all patients with polymyalgia rheumatica to rule out occult arteritis. An elevated erythrocyte sedimentation rate is a uniform finding in temporal arteritis, and the diagnosis should be questioned if the sedimentation rate is normal. Ocular complications in the form of unilateral or bilateral visual loss occur as a result of ischemic optic neuritis. Upper-extremity claudication may occur in the rare cases of extracranial involvement. When extracranial manifestations develop, the characteristic arteriographic finding is that of bilateral smooth tapering or occlusion of the axillary and brachial arteries. The ocular and peripheral arterial complications of temporal arteritis do not generally develop until several months after the onset of symptoms, and the disease is self-limited, with cessation of the process after a period of several years.

Steroid therapy should be initiated early to prevent sudden visual loss from ophthalmic artery thrombosis. Steroids frequently result in remarkable resolution of stenotic lesions over a period of several months, and the erythrocyte sedimentation rate should be monitored as an indicator of the efficacy of treatment. Operative revascularization is sometimes necessary for occluded extracranial arterial lesions, but reconstructions tend to thrombose if undertaken during the active phase of the disease and should be delayed until inflammation has been adequately suppressed with steroids.

Takayasu's arteritis, also known as “pulseless disease,” is a rare disorder associated with stenoses and aneurysms of the aortic branch vessels. Like temporal arteritis, acute and chronic phases occur. Systemic symptoms and laboratory abnormalities during the acute phase parallel those of temporal arteritis, except for associated findings of erythema nodosum and arthralgias with synovial changes typical of rheumatoid arthritis in some patients. Diagnostic arteriography should include the entire aorta and its branches. Steroid therapy is instituted initially, and the erythrocyte sedimentation rate is monitored as an index of the response to treatment. Cytotoxic agents have been of some benefit. Operative reconstructive procedures are reserved for lesions unresponsive to medical therapy, but they should be delayed beyond the acute disease phase if possible.

Buerger's Disease

Buerger's disease, also known as thromboangiitis obliterans, is an inflammatory vasculopathy occurring in medium-sized and small arteries of young male smokers. The disease is exceedingly rare in females and is not observed in nonsmokers. The lesions occur in the upper and lower extremities and in superficial veins as well as the arteries. The entity was first described by Winiwarer in 1879 and later by Buerger in 1908. Initially Buerger's disease was thought to occur exclusively in the Jewish population, but subsequent studies have shown this to be false, with other populations having about the same incidence.

The cause of Buerger's disease remains obscure. There is evidence for an autoimmune pathogenesis for the disease, with increases in complement factors and collagen antibody levels. The disease also has been linked to the presence of certain human lymphocyte antigens (HLAs). Smoking is the most important risk factor in the development and progression of the disease process, although the mechanism behind its effects are unknown.

The histopathologic features of Buerger's disease are those of a panangiitis, involving all layers of the vessel wall. Lymphocytes and fibroblasts infiltrate the media and adventitia of the artery in the early stages of the disease. The occluding thrombus is involved with an inflammatory process as well, with multinucleated giant cells and leukocytes giving the appearance of microabscesses within the clot. The late lesion of Buerger's disease is characterized by an occluded, contracted artery with a marked fibrotic reaction in the adventitia, media, and intima. The lesions tend to occur in a localized, segmental fashion, with normal vessel segments interposed between involved segments. The vein and adjacent nerve may be tightly bound to the artery in this dense fibrotic process. The tibial arteries and the vessels of the foot are the predominant sites of involvement in the lower extremity. Approximately 30 percent of patients with Buerger's disease have involvement of the upper extremities, and these lesions occur principally in the vessels of the forearm and hand.

The clinical presentation of patients with Buerger's disease is distinct from that of patients with atherosclerotic disease. Involvement of the smaller arteries may produce symptoms of rest pain and gangrene without antecedent claudication. Necrotic lesions commonly develop at the tips of the fingers and toes. Recurrent superficial thrombophlebitis may develop in the upper or lower extremity. Therapy is directed against the inciting effects of tobacco, with complete arrest of the process once smoking has been abandoned. Vascular reconstructive operations frequently are not feasible, because the involvement of the small vessels of the extremity makes it difficult to locate suitable outflow sites for bypass grafts. Surgical sympathectomy has been used with some success. Digital amputations frequently are necessary, but major amputations usually are avoidable because the larger vessels are not involved.

Periarteritis Nodosa

Periarteritis nodosa is an inflammatory process involving the small and medium-sized arteries of all organs. Occasionally digital artery involvement produces Raynaud's symptoms and may progress to ulceration or gangrene. The disease affects males more frequently than females, in a ratio of 21. Individuals of any age may be affected, but most patients are middle-aged at the time of diagnosis. The pathologic process is that of inflammation progressing to occlusion or aneurysm formation. Renal and gastrointestinal complications occur in the early stages of the disease and include renal failure, intestinal perforation, and intraabdominal hemorrhage. Late mortality occurs as a result of cerebral and cardiovascular events. Steroids have increased the 5-year survival rate to over 50 percent and adjuvant cyclophosphamide therapy has been used with success in severe cases. Operation is reserved for the treatment of hemorrhagic or gangrenous complications.

Hypersensitivity Angiitis

Hypersensitivity angiitis encompasses a diverse group of disorders involving the smaller arteries, with basement membrane thickening, fragmentation of elastic fibers, and swelling of the collagenous structures, terminating in vascular occlusion. With the exception of scleroderma, all the causative mechanisms involve antigen exposure and the formation of antigen-antibody complexes that damage the small vessels. The antigens include hepatitis B virus, tumor antigens, and drugs. The primary clinical manifestation of hypersensitivity angiitis is digital artery occlusion with digital ischemia, Raynaud's symptoms, ulceration, and gangrene. Vasodilators such as calcium channel blockers and guanethidine have been helpful despite the lack of demonstrable vasospasm. The results of surgical sympathectomy have been discouraging.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease with antibodies directed against DNA and other cellular constituents. A prominent component of SLE is an arteritis involving the medium-size vessels of the skin, intestine, kidney, lungs, and heart. Larger arteries and veins are affected with a thrombotic process distinct from the arteritis, secondary to the presence of a circulating substance known as the “lupus anticoagulant.” This substance is not specific to SLE and is also found in other vasculitides. Although an elevated partial thromboplastin time is associated with the lupus anticoagulant, a hemorrhagic propensity does not develop. Thrombosis of the arteries of the upper and lower extremity, the carotid arteries, and the coronary arteries may occur, as may venous thrombosis involving the inferior vena cava, the upper and lower extremity veins, and the retinal veins. Steroid and cytotoxic therapy is directed against the arteritis; long-term anticoagulation therapy with warfarin is directed against the thrombotic diathesis.

Inherited Connective Tissue Disorders

Marfan's syndrome and Ehlers-Danlos syndrome are two relatively rare autosomal dominant inherited diseases of connective tissue. They are not vasculitides, as such. The major clinical features are those of aneurysm formation and dissection of the aorta and its major branches. These complications often produce exsanguinating hemorrhage and rapid death in affected patients in the second through the fifth decade of life.

Marfan's syndrome is characterized by a defect in collagen cross-linking. Mitral valve prolapse, ascending aortic aneurysm, and aortic dissection are the primary cardiovascular manifestations. Therapy is directed at lowering blood pressure with the use of beta blockers and electively resecting aortic aneurysms when the aortic diameter reaches 6 cm or more.

The Ehlers-Danlos syndrome comprises a group of at least ten disease entities identified by defects in the conversion of procollagen to collagen. Hyperelasticity of the skin, spontaneous rupture of large arteries, aortic aneurysm, and aortic dissection are the major clinical manifestations. Arteriography and bypass operations are associated with a substantial risk of hemorrhage, and ligation is the procedure of choice when rupture of a vessel is encountered in Ehlers-Danlos patients.

Antiphospholipid Syndrome

The antiphospholipid syndrome (APS) is a hypercoagulable state characterized by the clinical features of thrombosis, recurrent fetal loss, and thrombocytopenia occurring in association with antiphospholipid antibodies. The two methods currently in use to detect antiphospholipid antibodies are the lupus anticoagulant and anticardiolipin antibody tests, and either or both of these antibodies may be present in patients with APS. Other laboratory abnormalities frequently encountered in patients with APS include thrombocytopenia, elevation of the erythrocyte sedimentation rate, and prolongation of the partial thromboplastin time. The clinical features of APS may be seen in patients with antiphospholipid antibodies and no other concomitant disease process; this is known as primary APS. Alternatively, antiphospholipid antibodies may occur in association with systemic lupus erythematosus or other autoimmune, infectious, malignant, and inflammatory disorders; this is defined as secondary APS. Thrombosis of the venous system is more common than

thrombosis of the arterial system in patients with APS, but the latter is far more devastating. In addition, arterial thrombosis due to primary APS may be difficult to distinguish from atherosclerosis, since circulation to the extremities, brain, and myocardium is frequently affected in both disorders, and the resultant ischemic symptoms are identical. Certain clinical features should raise suspicion of the diagnosis, however. In comparison with the atherosclerotic patient population, patients with arterial manifestations of APS are more often female, are significantly younger, and more frequently have upper-extremity involvement. Bypass of arterial lesions in patients with APS is associated with a very high incidence of early graft thrombosis (75 to 80 percent), although there is some evidence that preoperative and postoperative treatment with steroids, cytotoxic agents, and warfarin may improve the results of vascular reconstruction.

FROSTBITE

Several forms of cold injury have been described, including acute pernio or chilblains, chronic pernio, trench foot, and frostbite. Acute and chronic pernio represent focal, relatively mild injury of the skin and subcutaneous tissues resulting from cold exposure of moderate severity. The lesions tend to heal rapidly and are seldom a problem for the surgeon. Trench foot is principally a military injury produced by prolonged exposure to a cold, damp environment. Trench foot often occurs with temperatures above freezing, but with prolonged immobility. Immersion foot is the seagoing counterpart of trench foot.

Frostbite is the cold injury most frequently encountered in civilian practice. Frostbite occurs with exposure of tissues to subfreezing temperatures for a period of several hours. Shorter-term exposure to subzero temperatures results in a different form of frostbite, commonly occurring in airplanes at high altitudes and characterized by the term “high-altitude” frostbite. It has been demonstrated experimentally that cold-induced injury to mammalian tissues begins when the tissue temperature reaches 10°C. At -5°C cells lose the ability to recover from the freezing process. Observations in the Korean War revealed that frostbite characteristically occurred with exposure to ambient temperatures of -7°C for 7 to 18 h.

Several factors influence the injurious effect of cold exposure, including humidity and wind. Clinical observations have revealed that the most severe cold injuries occur in patients with prolonged contact with moisture or metallic surfaces, both of which function as efficient heat conductors. Wind also accelerates heat loss, presumably through increased evaporation of sweat and disruption of the radiant heat around the body. Coexistent peripheral arterial occlusive disease may contribute to the rapid development of cold-induced tissue injury. Chronic arterial disease should be excluded as a contributing factor whenever severe frostbite is observed in an adult civilian patient.

The pathophysiologic features of frostbite depend on the degree of cold-induced injury. Initially vasoconstriction occurs on exposure to the cold. The histologic findings in mild frostbite consist of a low-grade vasculitis; the process progresses to an intense inflammatory reaction of the intima with severe frostbite. The capillary endothelium becomes permeable, and the resultant extravascular fluid accumulation produces soft-tissue edema. Thrombi form in the terminal arterioles and capillaries, and irreversible tissue necrosis develops. It is not known whether the fundamental cold injury occurs as a result of direct freezing with disruption of cell membranes or from ischemic necrosis secondary to widespread thrombosis of the arterioles and capillaries.

Frostbite may be classified into four degrees of severity, analogous to the classification of burn injury. First-degree injury consists of edema and redness without necrosis; blistering becomes evident in second-degree injury; necrosis of skin constitutes third-degree injury; gangrene develops in fourth-degree injury, necessitating amputation of the affected extremity. A simpler categorization of frostbite divides injuries into superficial and deep classifications. Superficial frostbite involves the skin and superficial subcutaneous tissue; deep frostbite involves the deeper subcutaneous tissue, muscle, and even bone.

Treatment

The treatment of frostbite begins with rapid warming of the injured tissue. The involved body part should be immersed in warm water, with a temperature in the range of 40 to 44°C. Complete rewarming generally requires about 20 min. Once warm, the injured extremity should be elevated to minimize the formation of edema, and antibiotics and antitetanus therapy are instituted. The extent of gangrene is difficult to assess early in the course of frostbite. The degree of irreversible injury is often much less than initially feared, because the skin may be involved to a much greater extent than the subcutaneous tissue. For this reason, amputation should be delayed several weeks, until the precise extent of gangrene can be accurately determined.

Experimental and clinical evidence has demonstrated a beneficial effect from early sympathectomy in the treatment of severe frostbite. Operative sympathectomy should be performed within the first few days of injury if the injury is severe enough to produce tissue necrosis. Sympathectomy is also useful in alleviating the late sequelae of cold injury, including hyperhidrosis, cold sensitivity, and pain. Treatment directed against intravascular thrombosis has theoretical advantages; however, no consistent benefit has been achieved with the use of agents such as heparin or dextran.

The late sequelae of frostbite were well documented in a study by Ervasti of 812 cases with follow-up over 5 to 18 years. Long-term cold sensitivity was present in 82 percent of the patients, color changes of the skin in 73 percent, hyperhidrosis in 59 percent, pain with use of the extremity in 39 percent, and sensory loss in 23 percent. Sympathectomy was associated with improvement in symptomatic residua of frostbite in over 80 percent of the patients in whom it was performed.

ARTERIOVENOUS FISTULAE

An arteriovenous fistula is a direct communication between the arterial and the venous circulation that bypasses the capillary bed. The congenital variety is present at birth and grows or regresses. Although fistulae rarely cause hemodynamic symptoms, they can produce severe local problems that are often refractory to therapy. Fortunately, most congenital fistulae do not require operative therapy. The acquired arteriovenous fistula is most often the result of penetrating trauma; it can produce serious cardiac dysfunction and usually requires repair.

Congenital Fistulae

Classification

Congenital arteriovenous fistulae may be circumscribed or diffuse and are a result of abnormal development of the primitive vascular system. Szilagyi and associates have proposed an embryologic classification that divides these malformations into the hemangiomas and the fistulae. Circumscribed fistulae, called cavernous or simple hemangiomas, make up 19 percent of these lesions. There are two forms of this entity: a nonneoplastic lesion that appears at birth and grows with the child, and a neoplastic lesion that begins as a small lesion just after birth, grows rapidly, and then usually spontaneously involutes. The distinction is important because of the tendency of the latter form to involute.

The diffuse group makes up 81 percent of these lesions and is characterized by anomalous micro or macro arteriovenous communications. These lesions are complex and have hemangiomatous, fistulous, and aneurysmal elements. Although present at birth, they may not become apparent until the second or third decade of life.

Clinical Manifestations

Many of these lesions are disturbing solely because of their cosmetic appearance, which ranges from innocent-looking varicose veins to an ulcerated, bleeding, pulsatile mass. The cutaneous changes may be only a small part of the problem, however. CT and MRI provide the most complete diagnostic information about the extent of the malformation and the need for resection. Arteriography and venography have many limitations as diagnostic procedures because they do not define the extent of muscular and bony involvement and do not allow visualization of the fistulous connections. The principal role of arteriography is in preoperative localization of the afferent arterial supply, but it also may be used to embolize the localized lesion prior to resection.

High-output cardiac failure is rare with the congenital arteriovenous malformation. The congenital malformations cause symptoms ranging from mass effect and thrombosis to bleeding from varicosities. Ulceration of the overlying skin with pain and infection is not uncommon, because of the accompanying venous hypertension. Progressive growth is the rule, because the low resistance on the venous side produces high flows and enlargement of the arterial inflow vessels. Malformations with extensive hemangiomatous changes can be associated with thrombocytopenia and purpura, the Kasabach-Merritt syndrome. One form of congenital fistula is the Klippel-Trenaunay syndrome, characterized by cutaneous hemangiomas with port-wine staining, varicose veins, and hypertrophy of the involved extremity. Patients with this syndrome may not have a deep venous system, and it is an error to excise the abnormal superficial veins without evidence of an intact deep system.

Treatment

The hemangiomas are more circumscribed and can be completely removed when local symptoms dictate. If changes in consistency or appearance are observed, selected biopsies are indicated because the potential for malignant growth exists. Attempts to control the fistulous malformations are more difficult, and surgery should not be considered unless the lesion is life- or limb-threatening. Simple elastic support may suffice in an extremity lesion with low flow.

Intraarterial embolization and staged operative procedures for symptomatic lesions have been largely unsuccessful except as a means of short-term palliation (Fig. 20-41). When operative intervention is required as a last resort, a multidisciplinary team of vascular, orthopaedic, and plastic surgeons offers a better chance for cure. The major vessels entering and leaving the tumor are initially ligated, and the mass is resected with any involved tissue, including muscle, bone, subcutaneous tissue, and skin. Reconstruction is then accomplished by the use of appropriate tissue transfers. Lesions in the chest, abdomen, and pelvis may require circulatory support and deep hypothermia.

Acquired Fistulae

Etiology and Diagnosis

Acquired fistulae are usually a result of penetrating or iatrogenic trauma but can occur spontaneously, such as an aortocaval fistula. Although it was once thought that the fistula would continue to enlarge, it now seems that spontaneous closure occasionally occurs. On examination, there usually are visible veins surrounding the fistula that may have a palpable thrill and a machinery-type murmur throughout the cardiac cycle. The heart rate may slow with compression of the fistula (Branham's sign). The Duplex scanner allows visualization of the increased flow velocities with the lowered resistance, the dilated outflow vessels, and the often-associated false aneurysm. Arteriography is the essential diagnostic tool for identifying the site of the communication and planning the operative approach.

Pathophysiology

When an arteriovenous connection is suddenly created, there is a decrease in blood flow distal to the lesion and an increase in venous pressure (Fig. 20-42). The peripheral vascular resistance is lowered to that of the venous system, and an increase in cardiac output occurs. As the fistula matures, the collateral circulation increases, the distal perfusion approaches normal, and each component dilates. Over the longer term, venous hypertension may develop in the extremity. Growing children may exhibit limb length discrepancies, and cardiac failure may occur.

Treatment

Acquired arteriovenous fistulae should be repaired, because of the risk of life- or limb-threatening complications. Repair is technically easier when done at an early stage of fistula

development. Successful repair requires that all four limbs of the fistula be controlled. An angiographically placed balloon occluding device in the afferent arterial limb can be a helpful adjunct. Once control is obtained, the fistula itself should be exposed and directly divided and sutured. The connection itself may be quite small and can be repaired with several sutures. Larger defects require a patch angioplasty or interposition graft. The long-term prognosis after direct repair is excellent. Early attempts at control by proximal artery ligation were both unsuccessful and dangerous. Ligation of all four vessels without direct exposure of the communication has resulted in a significant incidence of recurrences and distal arterial ischemia. Inaccessible fistulae can be managed angiographically with a variety of coils or plugs of gelatin foam. Recurrences are high with this technique because it requires great skill on the part of the angiographer.

VASCULAR TRAUMA

Major advances have been made in the treatment of arterial injuries on the basis of lessons learned from combat injuries and from the management of atherosclerotic disease. The amputation rate after extremity vascular trauma was 50 percent during World War II and 13 percent during the Korean War; it is now 2 percent for civilian injuries.

General Considerations

Once the airway has been stabilized and volume replacement begun, patients with major vascular injuries are triaged into one of three groups: (1) those whose injuries are life-threatening and require immediate operation; (2) those whose vascular injuries are obvious but whose vital signs permit an arteriogram; and (3) those whose injuries, while not obvious, require evaluation because of their proximity to vascular structures. The signs of arterial injury include a pulsatile or expanding hematoma, pulsatile bleeding, a bruit or thrill, or end-organ ischemia. Suggestive features include unexplained shock, likely location, a stable hematoma, an injury to an adjacent nerve, or a questionable history of arterial bleeding (Table 20-8). Palpable pulses may be present even when there is a significant arterial injury. Arteriography is the gold-standard test for the diagnosis of an arterial injury and should be performed whenever possible.

A major priority of treatment is the control of hemorrhage. Direct digital pressure is the most effective maneuver at the scene of the trauma or in the emergency department. Tourniquets should be used only as a last resort, because they can occlude collateral flow and increase tissue damage. Attempts at blind clamping with hemostats should be avoided, because this may further damage the injured vessel. Neither an embedded weapon nor a hematoma should be removed until proximal control is achieved, because brisk bleeding may ensue.

Since many of these patients are operated on before complete data are available, maximum flexibility is necessary in planning the operative approach. Both legs should be prepared for surgery if there is any chance that a saphenous vein graft might be necessary. The chest should be prepared if there is any chance that the arch vessels have been injured or that control of intraabdominal bleeding cannot be achieved transabdominally. Preparations should be made to administer blood with a rapid-infusion device.

Proximal and distal arterial control should be obtained before the injury is approached. If an intraluminal thrombus is present, it generally can be removed with a balloon catheter. Systemic heparin is not given to patients with multisystem trauma, and the thrombectomized artery can be flushed with heparinized saline. Once the injury is identified, wide debridement of the vessel is performed. This is especially important in high-velocity missile wounds, in which the damage may extend beyond the obvious injury. The debridement should not be compromised in an attempt to simplify the arterial repair.

The type of arterial repair depends on the nature and extent of the injury. Although some sharp, penetrating wounds can be repaired with lateral arteriorrhaphy or a venous patch angioplasty, most arterial wounds require segmental resection. When an end-to-end anastomosis cannot be performed, an interposition graft using size-matched autogenous vein is used. Contralateral saphenous vein is recommended for extremity repairs to preserve the superficial venous drainage in the affected limb. Use of prosthetic grafts is controversial. Rich and associates reported complications when prosthetic material was used in 20 of 26 patients in the Vietnam Vascular Registry, while a conflicting civilian experience was reported by Mattox and associates from Houston. In their experience 10 percent of vascular repairs became infected when autogenous vein or polyester was used, and no infections were noted using *ePTFE*. Completion arteriography is recommended; distal pulses cannot always be felt even when the repair is satisfactory because of arterial spasm.

Extracranial Vascular Trauma

Carotid Artery

Penetrating trauma as well as blunt trauma can injure the carotid artery. In the former, by far more common and easier to diagnose, the artery is partially or completely transected. Blunt injuries are the result of hyperextension or a direct blow and are usually diagnosed when neurologic signs appear, sometimes hours or days after the insult (Fig. 20-43). This lesion is characterized by intimal or medial tears that lead to dissection, stenosis, or thrombosis of the artery. Carotid arteriography is necessary in any hemodynamically stable patient with a suspected blunt injury.

Patients with penetrating carotid artery injuries may present with shock or respiratory distress from an expanding cervical hematoma. Pressure may affect cranial nerves IX, X, XI, or XII. Penetrating carotid injuries are anatomically divided into three zones. Zone I is the area below the top of the sternal notch; zone II extends from the sternal notch to the angle of the mandible; zone III is the region above the angle of the mandible. Arteriography is most helpful in zone I injuries, for planning the proper incision, and in zone III injuries, where the specific site and extent of the injury may influence operative strategy.

Preparation must be made for either a left anterior thoracotomy or a median sternotomy to gain control of the proximal carotid artery, if necessary. An oblique incision anterior to the sternocleidomastoid muscle provides exposure of the artery and can be extended caudally into a median sternotomy or craniad behind the ear. Most penetrating carotid injuries can be managed by lateral suture or end-to-end anastomosis. If an interposition graft is needed, either the external carotid artery or the saphenous vein can be used. External carotid artery injuries can be treated with proximal and distal ligation.

There are two areas of controversy in the management of carotid artery injuries. The first concerns the proper management of the asymptomatic penetrating neck wound. Recommendations vary from obligatory exploration of any wound penetrating the platysma muscle to arteriography and observation. It is reasonable just to observe these patients if they remain asymptomatic and the arteriogram is of sufficient quality to rule out a carotid artery injury. The second controversy concerns the implications of a neurologic deficit. Although it is accepted that carotid artery injuries should be repaired in a neurologically intact patient, opinions vary on the indications for operation when a deficit exists. The best evidence suggests repair for patients with mild deficits and those with a severe deficit who have prograde flow preoperatively. Ligation is recommended for patients with a severe deficit and absence of prograde flow and patients with a distal thrombus that cannot be extracted. Morbidity and mortality rates are lower for all groups of patients, except those in coma, when repair rather than ligation is performed.

Vertebral Arteries

These injuries are usually from penetrating trauma (95 percent). The increased use of arteriography has increased awareness of the problem. Vertebral artery injury rarely causes neurologic symptoms because of the dual blood supply to the basilar artery, but massive hemorrhage can occur. In most angiographically demonstrated occlusions there is complete transection (52 to 81 percent), which, if left alone, develops into arteriovenous fistula or false aneurysm (5 to 30 percent).

Although there are some proponents of radiologically guided occlusion of the injured vertebral artery with detachable balloons, this technique does not control the distal vessel and carries the risk of a guide wire being pushed through a false lumen within the bony foramina of the transverse cervical processes. Operative therapy, which consists of proximal and distal ligation of the injured vessel, remains the procedure of choice.

If the proximal artery appears occluded on the arteriogram and there is no pulsatile hematoma present, the proximal artery can be approached at its origin from the subclavian artery through an oblique skin incision in the neck, with retraction of the carotid sheath medially and the anterior scalene muscle laterally. The distal ligation may require control of the interosseous portion of the vessel. This can be achieved by extending the skin incision to the mastoid process, exposing the prevertebral fascia, and gently removing the bone that forms the anterior border of the interosseous canal. If there is a pulsatile hematoma caused by an injury to the proximal vertebral artery, control should be obtained in the chest. Occasionally, repair of the injured vessel is indicated when a proximal transection can be easily transposed onto the common carotid artery or when the contralateral vertebral artery is diseased or absent.

Proximal Brachiocephalic Injuries

Injuries to the innominate, subclavian, and common carotid arteries require immediate diagnosis and control of hemorrhage. The initial presentation may range from an asymptomatic patient with an innocuous-appearing wound to a patient in hypovolemic shock with a massive hemothorax. The wounds should not be explored digitally. Tube thoracostomy is necessary for pneumothorax or hemothorax. Nasogastric tubes should not be placed. Patients in shock require an immediate operation. Arteriography can be performed in a stable patient with a penetrating wound, but a negative result does not replace exploration, because it does not rule out a major injury (22 percent), and sudden hemodynamic collapse is possible (5 percent). By contrast, arteriography is mandatory in the evaluation of blunt trauma to this region.

In operative treatment, the patient is positioned supine with both arms abducted, and the neck, chest, and shoulders are prepared for surgery. In hemodynamically unstable patients, lesions on the right side can be controlled with a median sternotomy, and lesions on the left side with an anterolateral thoracotomy. The oblique cervical incision sparing the mediastinum provides exposure for most cervical injuries, but extension to remove the medial portion of the clavicle is sometimes necessary. The chest wall musculoskeletal flap, the so-called trap door incision, can be used for proximal left subclavian or common carotid artery injuries. Standard principles of arterial repair follow control of the bleeding. Wound debridement and lateral closure are often possible in these large vessels. Occasionally an autogenous patch is required. Ligation and remote prosthetic bypass is reserved for injuries with contamination.

Extremity Injuries

Associated injuries to bones, muscles, veins, and nerves complicate the management of extremity arterial trauma. Signs of arterial involvement may be masked by these associated injuries, and therefore arteriography becomes the most important diagnostic study for establishing the diagnosis and defining the extent of the lesion.

Upper-Extremity Injuries

Subclavian artery injuries are the most difficult to manage. They often are associated with injuries to the brachial plexus—either direct injuries, or indirect injuries from the pressure of an accompanying hematoma. Proximal exposure may require a thoracotomy for left-sided injuries and a median sternotomy for injuries on the right. Results of arterial repair are good, but long-term disability usually follows the nerve injury.

Injuries to the axillary and brachial arteries are handled by incisions directly over the penetrating wound. End-to-end anastomoses are usually possible. The most common upper-extremity vascular injuries are iatrogenic injuries in coronary arteriography and transluminal angioplasty and injuries obtained in intravenous drug abuse. Early repair of these injuries is indicated. Although only one-third of the patients with brachial artery occlusion will develop arm symptoms, given the rich collateral network around the elbow, delayed

repair will necessitate a more complicated operation.

Lower-Extremity Injuries

Most penetrating injuries of the lower extremity involve the superficial femoral artery; achieving proximal and distal control is similar to performing an elective femoral-popliteal artery bypass. Arteriography should be performed when the diagnosis is in question. Wounds entering the lateral aspect of the thigh and exiting posteriorly do not need further study unless suggestive signs of arterial injury are present. Medial-entry wounds or those in proximity to a major artery should undergo arteriography.

Limb loss rates from arterial injuries associated with fractures and other soft-tissue trauma range as high as 44 percent in civilian practice and higher in military series. Many of the patients with salvaged limbs have decreased function from muscle loss or nerve injury. Long-bone fractures may cause arterial damage by acute angulation, laceration, or longitudinal stretching and subsequent thrombosis (Fig. 20-44). The arteries most often involved in the lower extremity are the distal superficial femoral and popliteal arteries and the proximal tibial arteries around the knee; in the upper extremity, it is the brachial artery just above and below the antecubital fossa. These lesions may cause immediate or delayed arterial occlusion, and arteriography is indicated for high-risk fractures in these regions when any evidence of arterial compromise is present.

Fracture stabilization in the sequence of repair of concomitant bony and arterial injuries is controversial. Initial bone stabilization may correct perfusion abnormalities and protect any subsequent vascular repair from damage due to movement, but it delays restoration of flow unless a temporary shunt is placed, which may impede access to the injured vessel. On the other hand, initial stabilization of the fracture might result in damage to a vascular repair that was performed first. In general it is preferable to stabilize fractures before the vascular repair, but this sequence must be determined in each case according to the degree of distal ischemia and the presence of hemorrhage. Important technical considerations in repair of combined injuries include: (1) early fasciotomy before orthopaedic repair; (2) preferential use of the contralateral saphenous vein; (3) repair of major venous injuries; (4) completion arteriography; and (5) adequate soft-tissue coverage using appropriate muscle flaps.

The liberal use of fasciotomy in the injured extremity is important in reducing postoperative edema and the compartmental hypertension that may lead to myonecrosis and nerve damage. Reperfusion injury of ischemic skeletal muscle is related to damage from oxygen-derived free radicals. These compounds increase vascular permeability, which permits the loss of intravascular fluid from the capillaries into the interstitial space. Mannitol, a free-radical scavenger, therefore should be given before limb revascularization. Objective measurements of compartment pressures can be made by determining the pressure within a closed system that is required to overcome the pressure in the compartment. Pressures higher than 40 mmHg mandate immediate decompression if clinical signs of an elevated compartmental pressure is present. These include sensory loss in the first metatarsal space, inability to dorsiflex the great toe, or foot drop. Patients in whom the pressure is greater than 50 mmHg should have immediate decompression regardless of the clinical findings. Fasciotomy should be performed through limited skin incisions if possible, because the fascia is the limiting tissue.

Progress in microvascular tissue transfers and improvements in skeletal fixation in recent years have increased the number of salvaged extremities. Occasionally early amputation is required because of the magnitude of the injury. Avulsed nerves and extensive soft-tissue and bony destruction may make the limb useless even after successful arterial repair. The term “crush syndrome” was applied to the ischemia-induced syndrome of myonecrosis, myoglobinuria, and renal failure during the London Blitz in World War II. Complications in the postoperative period, such as metabolic abnormalities from injured skeletal muscle, sepsis, or failure of the arterial repair, also may lead to amputation. The principle of life over limb must always be followed when treating these complicated injuries.

Abdominal Vascular Injuries

Most abdominal vascular injuries follow penetrating trauma. Approximately 20 percent of patients with abdominal missile wounds have a major vascular injury. The aorta, the inferior vena cava, and the iliac vessels are most often involved, and the presenting clinical problem is usually exsanguinating hemorrhage. Diagnostic arteriography, although helpful, is rarely indicated. Blunt abdominal trauma is less common and usually involves avulsion of the hepatic veins and visceral arteries. Most of these injuries are associated with trauma to other organ systems, so the surgeon is faced with two problems: control of bleeding, and management of solid organ or hollow viscus wounds that may be contaminated.

Principles of Management

Hemostasis is an essential part of the resuscitative effort, so operation must not be delayed for a detailed diagnostic evaluation. The beneficial tamponading effect of the intact abdominal cavity should not be forgotten. In cases of severe hypotension aortic control can be achieved with the use of a left anterolateral thoracotomy through the sixth or seventh interspace. An autotransfusion device should be available, but the salvaged blood should not be reinfused until an intestinal injury has been ruled out. The chest, abdomen, and groins are prepared for surgery. A midline abdominal incision should be made for rapid and generous exposure. The aorta is clamped at the diaphragm if arterial bleeding is profuse and cannot be controlled with packing. Blood and clot are rapidly removed, the abdomen packed with large pads, and the blood volume restored. Any intraperitoneal soilage is identified and controlled and then specific injuries are sought out.

Aortic injuries have mortality rates from 50 to 90 percent, depending in part on the location of the injury. They are associated with a midline retroperitoneal hematoma and must be approached initially with aortic control at the diaphragm. The hematoma can then be opened and the clamp moved distally. Inferior vena cava and renal artery lesions require mobilization of the right or left colon. Lesions of the suprarenal aorta can be isolated with the use of the medial visceral rotation technique. Occasionally the incision must be extended into the chest for proximal aortic control in the face of uncontrolled hemorrhage. Most patients with aortic injuries who reach the hospital can have the injury repaired with the lateral suture technique. Occasionally a graft is required, and the decision to use one depends on the degree of contamination present. Prosthetic grafts have been used successfully in situations with minimal contamination. Ligation and extraanatomic bypass is preferred, however, in cases where contamination is severe. Iliac artery injuries usually require graft replacement, and the same rules about contamination apply. A femoral-to-femoral artery bypass usually serves as a satisfactory replacement for the injured iliac artery. The celiac axis and its branches can be ligated in most patients without adverse consequences. Injuries to the proximal superior mesenteric artery or vein should be repaired by lateral suture or by saphenous vein bypass. More distal lesions are ligated, and bowel resection may be indicated. These patients require a second-look operation.

Pediatric Injuries

Pediatric arterial injury is uncommon, and standardized approaches are lacking, especially for the group of iatrogenic injuries of infancy that make up virtually all of the injuries in children under the age of 2 years. These injuries present special challenges because of the small vessel size and the different implications of non-limb-threatening ischemia. The manifestations of acute arterial ischemia in a child are similar to those in an adult. Chronic ischemia causes impaired growth in the affected limb rather than claudication or tissue loss. In general pediatric arterial lesions should be repaired promptly. The only exception may be an iatrogenic femoral artery occlusion in an infant, in which case heparin therapy and observation of an extremity whose viability is not in question may yield better long-term results than early operation.

AMPUTATIONS

The indications for amputation of part or all of an extremity include: (1) loss of viability secondary to nonreconstructible ischemia; (2) trauma that is sufficiently extensive to preclude repair; (3) tumor of the bone, soft tissue, muscles, blood vessels, or nerves; and (4) extensive infection that does not respond to conservative measures or contributes to septicemia. More than two-thirds of the amputations in civilians in Western societies are performed for peripheral vascular disease, usually as the result of extensive lower-extremity atherosclerotic occlusion.

The most commonly used procedures are *above-knee (AK)* and *below-knee (BK)* amputations, though a variety of eponyms have been applied to specific levels of amputations and refinements of technique. Transmetatarsal and digital amputations are less frequently indicated in patients with peripheral vascular disease. The Syme amputation, knee disarticulation, hip disarticulation, and hemipelvectomy are usually reserved for malignant and traumatic lesions. At each level, the operative procedure and postoperative management are directed at achieving primary healing, a painless stump that will withstand the pressures of a prosthesis, and relatively unrestricted ambulation.

Selection of Level

Several factors contribute to the decision concerning level of amputation (Fig. 20-45). When amputation is performed for malignant disease, the principal factor is wide excision of grossly apparent tumor. In the case of amputation subsequent to trauma or for peripheral vascular disease, the major factor determining the optimal level is usually the extent of healthy tissue. Other factors include the length of the stump sufficient for function of a prosthesis and the cosmetic effect of a prosthesis.

The longer the amputation stump, the more functional will be the limb, and the better control the patient will have of the prosthesis. For traumatic amputations with irregular damage to the skin, grafting procedures and mobilization of flaps are indicated to maintain as much of the bony length as possible. AK amputees expend about twice as much energy to ambulate as BK amputees.

There are exceptions to the general rule of “the longer, the better.” For the lower extremity, proximal to the Syme amputation, the best level below the knee as far as prosthetic fitting is concerned is at the distal musculotendinous junction of the gastrocnemius muscle. Every effort should be made to preserve the knee joint. A below-knee prosthesis can be fitted to a stump as short as 5 cm, improving the chances of successful ambulation. In the pediatric population, disarticulation is frequently the procedure of choice in order to save the growing epiphysis and minimize the problem of distal bone overgrowth. In the upper extremity, as much length as possible should always be saved, even if there is only a very short below-elbow or humeral stump.

Other factors that contribute to the selection of amputation site are the patient's general condition and, particularly, the feasibility of rehabilitation. AK amputations are indicated for bedridden patients who require nursing care, since these procedures are associated with a higher incidence of primary healing. A BK amputation in a nonambulatory patient will result in a tight flexure contracture and therefore should not be performed. If there is established contracture, it is always preferable to amputate the leg above the level of contracture.

A correlation has been reported between the healing of digital and transmetatarsal amputations and the presence of peripheral pulses. In patients with a palpable popliteal pulse healing at this level occurred twice as effectively as in those in whom only a femoral pulse was demonstrated. The presence of a popliteal pulse has been associated with a 97 percent success rate for BK amputations, as compared to 82 percent of patients with absent popliteal pulses. In another study, 79 percent of BK amputation failed when the femoral pulse was absent, as compared to 29 percent wound breakdown when the femoral pulse was palpable. When the popliteal pulse was present, the failure rate was 10 percent.

The value of Doppler systolic blood pressure and arterial waveform analysis using the segmental plethysmograph in the selection of BK and forefoot amputation sites has been assessed. A calf systolic pressure higher than 70 mmHg was associated with a 97 percent success rate for BK amputations. However, because of a high false-negative rate, a patient should not be denied a BK amputation on the basis of this determination. The ankle systolic pressure has not proved valuable in predicting the healing of forefoot amputations. An assessment of Doppler ultrasonography and digital plethysmography concluded that they are imprecise indices of the healing of amputations for arterial insufficiency.

At all levels, healing ability is a function of nutritional skin blood flow. The status of the limb circulation may be evaluated by assessing the skin circulation. The clearance of radiolabeled xenon, measured at the anterior incision line, has been found to be well correlated with the healing of amputations. Quantification of skin fluorescein delivery by fiberoptic fluorometry also has predicted the healing of an amputation site. Measurement of transcutaneous P_{O_2} has been used to determine amputation levels; high saturation was indicative of good healing potential, but no level could be defined below which healing would not occur. Thermography tended to overestimate the degree of ischemia and to indicate a higher level of amputation than necessary. Despite the availability of these objective tests, most amputation levels are chosen on the basis of clinical findings alone. When in doubt, one should err conservatively, explaining the possibility of subsequent revision to the patient and family.

The two general classes of amputations performed for lower-limb ischemia are the standard or conventional amputation and the provisional or open (guillotine) amputation. The conventional amputation is performed by constructing curved skin and fascial flaps that have their base at the level of amputation. The muscles, major blood vessels, and bone are divided at the level of amputation, and the major nerves are put on slight stretch and transected so that they retract proximally. The muscles may be tapered so that not too much soft tissue remains over the bone end, and the distal inch of periosteum may be removed to avoid leaving a detached segment that can cause bone spur formation. After the amputation has been completed, the deep and superficial fascia are approximated over the bone, and the skin is loosely closed. The wound may be closed with or without drainage with a catheter connected to a closed suction apparatus. Guillotine amputations should be regarded as provisional procedures performed in the case of sepsis, when the infection precludes primary closure of the wound. They are of historical interest as the most commonly employed procedure before the age of modern surgery. The procedure is performed well below the level planned for a subsequent, definitive amputation. A circumferential incision is made and carried down to the bones. The bones are transected and the wound is packed open. Dressings are changed frequently and a definitive amputation is performed when the septic process has resolved.

Postoperatively, a lightly compressive dressing is applied to the stump, usually in the form of a “stump sock.” The wound is not examined for four or five days, unless signs of infection develop. Contractures are prevented by stump exercises and stretching the proximal joint in the hope of achieving full motion of the remaining joints of the amputated extremity. Rehabilitation requires the services of an experienced physiotherapist, an occupational therapist, and a prosthetist. *Immediate postoperative prostheses (IPOP)* are used increasingly in the management of extremity amputees. In this situation, a rigid dressing is applied at the operating table. The stump is covered with a sterilized sock and a plaster cast, and a prosthetic unit that includes socket attachment flaps may be applied immediately after the rigid dressing has dried. The patient is then encouraged to walk between parallel bars 24 h after the operation, and weight bearing is increased daily. The rigid dressing is kept in place for approximately 2 weeks, at which time the sutures are removed and a new socket is applied without delay. Ten days later the second socket is removed, and at that time stump measurements and a cast are made for a permanent prosthesis. Another temporary socket is provided until the permanent prosthesis is available. With both an IPOP and conventional management, shrinkage of the stump occurs in time and may necessitate a new socket for use with a permanent prosthesis.

Morbidity and Mortality

The operative mortality for amputations performed for isolated tumor, trauma, or infection is less than 3 percent. The mortality rate increases by an order of magnitude in patients who exhibit signs of arteriosclerotic disease. Diabetes does not significantly affect the mortality rate. The mortality rates are generally higher for more proximal amputations in the lower extremity. The most frequent causes of morbidity include cardiac (52 percent) and pulmonary (26 percent) complications. Phantom limb pain is a problem in many patients, with incapacitating pain in the distribution of the amputated extremity.

In a series of 130 patients with unilateral amputation, 70 (54 percent) received prostheses, 84 percent of whom subsequently had successful rehabilitation. Of those who received unilateral amputations, only 30 percent of the *AK* group had successful rehabilitation, whereas 66 percent of the *BK* group were able to walk on prostheses. In the patients with bilateral amputations, 30 percent had successful rehabilitation, which required that at least one of the amputation sites be at the BK level. For the *IPOP* group, the time was shorter from amputation to the fitting of a permanent prosthesis, and rehabilitation rate was higher.

Lower-Extremity Amputations

Toe Amputation

Amputation of one or more toes may be performed for gangrene or osteomyelitis. A transphalangeal level may be used if necrosis is distal to the *proximal interphalangeal (PIP)* joint and if there is absence of cellulitis, necrosis, and edema in the skin to be used for the flaps. If a more proximal amputation is required, transmetatarsal resection with removal of the metatarsal head is preferable to disarticulation (Fig. 20-46). The latter is associated with an increased incidence of breakdown, since the stump is bulky, and in the face of infection or poor vascular supply the exposed cartilage resists infection less effectively than does bone. The incidence of healing at both the transphalangeal and transmetatarsal levels has been relatively poor, with reports ranging from 40 to 60 percent. A direct relationship has been demonstrated between healing at these levels and the presence of popliteal and pedal pulses, suggesting that the poor results were related to poor selection of amputation sites.

Transmetatarsal Amputation

The indications for this procedure include necrosis proximal to the *PIP* joint, but distal to the level of the transmetatarsal incision. Necrosis in the interdigital creases constitutes a relatively frequent indication. In one series, primary healing was achieved in 54 percent of patients with absent pedal pulses. The healing of transmetatarsal amputations in patients with peripheral vascular disease is correlated with the potential for revascularization. Healing occurred in only 24 percent of patients with nonreconstructible disease and over 80 percent of patients with reconstructible disease. Prior lumbar sympathectomy did not alter the rate of healing. If infection or gangrene compromises the standard plantar skin flap, open or guillotine amputation at the midtarsal level can achieve a high level of healing and a durable stump. Wound closure can occur by contracture or partial-thickness skin graft.

Skin incisions and subcutaneous flaps are established so that the plantar flap is long, with a very short dorsal flap cut directly over the line of bone transection (Fig. 20-47). This configuration permits placement of the scar on the dorsal, non-weight-bearing surface of the foot. The metatarsals are divided just proximal to the level of the dorsal incision are removed, and the skin and fascia are closed in layers.

Syme Amputation

Terminal arterial disease involving the distal part of the foot constitutes one of the few peripheral vascular disorders for which the Syme amputation is indicated. In one study the Syme amputation following preliminary ray or transmetatarsal amputation for infection in diabetic patients with peripheral vascular disease was successful in about 85 percent of cases when the posterior tibial pulse was palpable. Functionally, this operation represents an acceptable level for amputation, because it maintains the length of the extremity and preserves the heel skin, which provides an excellent weight-bearing stump (Fig. 20-48). The prosthesis, however, is more difficult to fit.

Below-Knee (BK) Amputation

The below-knee level is probably the most common initial choice for patients with a nonviable foot. Major functional advantages of the BK amputation over the *AK* level are the ability to provide a more functional prosthesis for complete rehabilitation, the ability of the patient to move more easily in and out of bed, and a reduction in energy expenditure in ambulation and in the incidence of phantom limb pain. The stumps of BK amputations can be lengthened by distraction osteogenesis to improve prosthesis fit and increase ambulation. The BK amputation constitutes the level of choice for ischemic lesions of the foot that do not extend above the malleoli, but generally it is not applicable if the gangrene extends in continuity above the ankle. Ischemic rigor of the calf muscles is another contraindication. Contracture of the knee or hip is a relative contraindication, because it negates the functional advantages of this level.

The choice between the BK and AK amputations is determined by the patient's general health and potential for rehabilitation and an evaluation of the vascular status at the proposed level of amputation. No essential difference in healing rate is noted in patients with or without palpable popliteal pulses, but the absence of a femoral pulse is associated with a high failure rate for BK amputation. Healing is not influenced by the presence of diabetes. Healing of BK amputations has been reported in 68 to 90 percent of cases in large series, compared with healing rates of 82 to 98 percent for AK amputations. By contrast, a higher percentage of BK amputees regain ambulatory abilities with a prosthesis. Rehabilitation rates for patients with ischemia who had BK amputations range from 50 to 90 percent.
